After the integrity of the urinary catheter and drainage system was checked, 1 L of Plasma-Lyte along with 500 mL of 5% albumin and 10 mg of furosemide were administered intravenously but failed to significantly increase urinary output. Indigo carmine was given intravenously, and the proximal end of a severed left ureter was subsequently identified. A urologist was called and the ureter was reanastomosed.

McMahon BA, Koyner JL. Risk stratification for acute kidney injury: Are
Anesthesia for Patients with Kidney Disease

KEY CONCEPTS

1. The utility of a single serum creatinine measurement as an indicator of glomerular filtration rate (GFR) is limited in critical illness: The rate of creatinine production, and its volume of distribution, may be abnormal in the critically ill patient, and the serum creatinine concentration often does not accurately reflect GFR in the physiological disequilibrium of acute kidney injury (AKI).

2. Creatinine clearance measurement is the most accurate method available for clinically assessing overall kidney function.

3. The accumulation of morphine and meperidine metabolites has been reported to prolong respiratory depression in patients with kidney failure.

4. Succinylcholine can be safely used in patients with kidney failure in the absence of hyperkalemia at the time of induction.

5. Extracellular fluid overload from sodium retention, in association with increased cardiac demand imposed by anemia and hypertension, makes patients with end-stage kidney disease particularly prone to congestive heart failure and pulmonary edema.

6. Delayed gastric emptying secondary to kidney disease–associated autonomic neuropathy may predispose patients to perioperative aspiration.

7. Controlled ventilation should be considered for patients with kidney failure under general anesthesia. Inadequate spontaneous or assisted ventilation with progressive hypercarbia under anesthesia can result in respiratory acidosis that may exacerbate preexisting acidemia, lead to potentially severe circulatory depression, and dangerously increase
Correct anesthetic management of patients with renal insufficiency is as critical as management of those with frank kidney failure, especially during procedures associated with a relatively high incidence of postoperative kidney failure, such as cardiac and aortic reconstructive surgery.

Intravascular volume depletion, sepsis, obstructive jaundice, crush injuries, and renal toxins, such as radiocontrast agents, certain antibiotics, angiotensin-converting enzyme inhibitors, and nonsteroidal antiinflammatory drugs, are major risk factors for acute deterioration in kidney function.

Kidney protection with adequate hydration and maintenance of renal blood flow is especially important for patients at high risk for AKI and kidney failure undergoing cardiac, major aortic reconstructive, and other surgical procedures associated with significant physiological trespass. The use of mannitol, low-dose dopamine infusion, loop diuretics, or fenoldopam for kidney protection is controversial and without proof of efficacy.

Acute kidney injury (AKI) is a common problem, with an incidence of up to 5% in all hospitalized patients and up to 8% in critical illness. Postoperative AKI may occur in 1% or more of general surgery patients, and up to 30% of patients undergoing cardiothoracic and vascular procedures. Perioperative AKI is a markedly underappreciated problem that greatly increases perioperative morbidity, mortality, and costs. It is a systemic disorder that can include fluid and electrolyte derangements, respiratory failure, major cardiovascular events, weakened immunocompetence leading to infection and sepsis, altered mental status, hepatic dysfunction, and gastrointestinal hemorrhage. It is also a major cause of chronic kidney disease. Preoperative risk factors for perioperative AKI include preexisting kidney disease, hypertension, diabetes mellitus, liver disease, sepsis, trauma, hypovolemia, multiple myeloma, and age greater than 55 years. The risk of perioperative AKI is also increased by exposure to nephrotoxic agents such as nonsteroidal antiinflammatory drugs (NSAIDs), radiocontrast agents, and antibiotics (see Table 30–4). The clinician must possess a thorough understanding of the risks of AKI, its differential diagnosis, and its evaluation strategy (Figure 31–1).
Evaluating Kidney Function

Impaired kidney function may be due to glomerular dysfunction, tubular dysfunction, or urinary tract obstruction. Accurate clinical assessment of kidney function is often difficult and relies heavily on laboratory determinations of glomerular filtration rate (GFR), including creatinine clearance, and other evaluations (Tables 31–1 and 31–2). Even small postoperative increases in serum creatinine are associated with increased morbidity and mortality, although many factors may confound its measurement (Figure 31–2). Systems employed in defining and staging the degree of kidney dysfunction include the Acute Dialysis Quality Initiative Risk, Injury, Failure, Loss, End-Stage (RIFLE) criteria and the Acute Kidney Injury Network (AKIN) staging system. These systems were merged into the Kidney Disease Improving Global Outcomes (KDIGO)
classification (Table 31–3). Thus, the traditional diagnosis of AKI, based upon serum creatinine and urine output, has been refined into an increase of serum creatinine of 0.3 mg/dL or more within 48 h or a 1.5-fold or greater increase in baseline within 7 days. Since AKI is a systemic disorder, it is important to recall that the kidney excretory function assessed via serum creatinine and urine output ignores endocrine, metabolic, and immunological kidney functions. A great deal of research is currently evaluating plasma and urine biomarkers associated with AKI, such as cystatin C, neutrophil gelatinase–associated lipocalin, interleukin-18, and kidney injury molecule-1, and several are now commercially available (Figure 31–3). It is likely that biomarkers will play an increasingly prominent role in the near future for diagnosis, staging, and prognostic assessment of AKI.

#### FIGURE 31–2

Factors having an acute effect on creatinine:
- **Acute rise in creatinine:**
  - Dietary creatine intake
  - Nutritional muscle breakdown
  - Decreased glomerular filtration
  - AKI
  - Reduced tubular secretion
  - Trimethoprim and cimetidine

**False elevation of creatinine:**
- False assay interference
  - Hyperglycemia and DKA
  - Delayed contribution
  - Other: hemolysis, high total protein

**Acute fall/blunted rise in creatinine:**
- Reduced creatinine generation
  - Sepsis
  - Increased volume of distribution
  - Edematous states
  - Acute fluid overload

Factors having a chronic effect on creatinine:
- **Chronic “elevation” of creatinine:**
  - Increased creatinine generation
    - Kidney disease
    - Female sex
    - Decreased muscle mass
  - End-stage renal disease
  - Hypothyroidism
  - Enzymatic interference
  - Hyperglycemia, hemolysis

**False reduction of creatinine:**
- False assay interference
- Nonrenal generation of creatinine

**Chronic “reduction” in creatinine:**
- Low dietary protein (cooking meat) intake
- Reduced creatinine generation with lower muscle mass
- Male sex
- Muscle wasting conditions
- Metabolism
- Malnutrition and critical illness

BLOOD UREA NITROGEN

The primary source of urea in the body is the liver. During protein catabolism, ammonia is produced from the deamination of amino acids. Hepatic conversion of ammonia to urea prevents the buildup of toxic ammonia levels:

$$2\text{NH}_3 + \text{CO}_2 \rightarrow \text{H}_2\text{N} - \text{CO} - \text{NH}_2 + \text{H}_2\text{O}$$

Blood urea nitrogen (BUN) is therefore directly related to protein catabolism.
and inversely related to glomerular filtration. As a result, BUN is not a reliable indicator of the GFR unless protein catabolism is normal and constant. Recall that 40% to 50% of the urea filtrate is normally reabsorbed passively by the renal tubules; hypovolemia increases this fraction.

The normal BUN concentration is 10 to 20 mg/dL. Lower values may be seen with starvation or liver disease; elevations usually result from decreases in GFR or increases in protein catabolism. The latter may be due to a high catabolic state (trauma or sepsis), degradation of blood either in the gastrointestinal tract or in a large hematoma, or a high-protein diet. BUN concentrations greater than 50 mg/dL are generally associated with impaired kidney function.

**SERUM CREATININE**

Creatine is a product of muscle metabolism that is nonenzymatically converted to creatinine. Daily creatinine production in most people is relatively constant and related to muscle mass, averaging 20 to 25 mg/kg in men and 15 to 20 mg/kg in women. Creatinine is then filtered (and to a minor extent secreted) but not reabsorbed in the kidneys. Serum creatinine concentration is therefore directly related to body muscle mass and inversely related to glomerular filtration (Figure 31–4). Because body muscle mass is usually relatively constant, serum creatinine measurements are generally reliable indices of GFR in the ambulatory patient. However, the utility of a single serum creatinine measurement as an indicator of GFR is limited in critical illness: The rate of creatinine production, and its volume of distribution, may be abnormal in the critically ill patient, and a single serum creatinine measurement often will not accurately reflect GFR in the physiological disequilibrium of AKI.
The normal serum creatinine concentration is 0.8 to 1.3 mg/dL in men and 0.6 to 1 mg/dL in women. Note from Figure 31–4 that each doubling of the serum creatinine represents a 50% reduction in GFR. As previously noted, many factors may affect serum creatinine measurement.

GFR declines with increasing age in most individuals (5% per decade after age 20), but because muscle mass also declines, the serum creatinine remains relatively normal; creatinine production may decrease to 10 mg/kg. Thus, in elderly patients, small increases in serum creatinine may represent large changes in GFR. Using age and lean body weight (in kilograms), GFR can be estimated by the following formula for men:

$$\text{Creatinine clearance} = \frac{[(140 - \text{Age}) \times \text{Lean body weight}]}{(72 \times \text{Plasma creatinine})}$$

For women, this equation must be multiplied by 0.85 to compensate for a smaller muscle mass.

The serum creatinine concentration requires 48 to 72 h to equilibrate at a new level following acute changes in GFR.

**CREATININE CLEARANCE**

Creatinine clearance measurement is the most accurate method available for
clinically assessing overall kidney function (actually, GFR). Although measurements are usually performed over 24 h, 2-h creatinine clearance determinations are reasonably accurate and easier to perform. Mild impairment of kidney function generally results in creatinine clearances of 40 to 60 mL/min. Clearances between 25 and 40 mL/min produce moderate kidney dysfunction and nearly always cause symptoms. Creatinine clearances less than 25 mL/min are indicative of overt kidney failure.

Later stage kidney disease leads to increased creatinine secretion in the proximal tubule. As a result, with declining kidney function the creatinine clearance progressively overestimates the true GFR. Moreover, relative preservation of GFR despite progressive kidney disease may result from compensatory hyperfiltration in the remaining nephrons and increases in glomerular filtration pressure. It is therefore important to look for other signs of deteriorating kidney function such as hypertension, proteinuria, or abnormalities in urine sediment.

**BLOOD UREA NITROGEN:CREATININE RATIO**

Low renal tubular flow rates enhance urea reabsorption but do not affect creatinine excretion. As a result, the ratio of BUN to serum creatinine increases to more than 10:1. Decreases in tubular flow can be caused by decreased kidney perfusion or obstruction of the urinary tract. **BUN:creatinine ratios greater than 15:1 are therefore seen in volume depletion and in edematous disorders associated with decreased tubular flow (eg, congestive heart failure, cirrhosis, nephrotic syndrome) as well as in obstructive uropathies.** Increases in protein catabolism can also increase this ratio.

**URINALYSIS**

Urinalysis continues to be routinely performed for evaluating kidney function. Although its utility and cost-effectiveness for this purpose are questionable, urinalysis can be helpful in identifying some disorders of renal tubular dysfunction as well as some nonrenal disturbances. A routine urinalysis typically includes pH; specific gravity; detection and quantification of glucose, protein, and bilirubin content; and microscopic examination of the urinary sediment. Urinary pH is helpful only when arterial pH is also known. A urinary pH greater than 7.0 in the presence of systemic acidosis is suggestive of renal tubular acidosis (see Chapter 50). Specific gravity is related to urinary osmolality; 1.010 usually corresponds to 290 mOsm/kg. A specific gravity greater than 1.018 after
an overnight fast is indicative of adequate renal concentrating ability. A lower specific gravity in the presence of hyperosmolality in plasma is consistent with diabetes insipidus.

Glycosuria is the result of either a reduced tubular threshold for glucose (normally 180 mg/dL) or hyperglycemia. Proteinuria detected by routine urinalysis should be evaluated by means of 24-h urine collection. Urinary protein excretions greater than 150 mg/d are significant. Elevated levels of bilirubin in the urine are seen with biliary obstruction.

Microscopic analysis of the urinary sediment detects the presence of red or white blood cells, bacteria, casts, and crystals. Red cells may be indicative of bleeding due to tumor, stones, infection, coagulopathy, or trauma (commonly, urinary catheterization). White cells and bacteria are generally associated with infection. Disease processes at the level of the nephron produce tubular casts. Crystals may be indicative of abnormalities in oxalic acid, uric acid, or cystine metabolism.

**Altered Kidney Function & the Effects of Anesthetic Agents**

Most drugs commonly employed during anesthesia (other than volatile anesthetics) are at least partly dependent on renal excretion for elimination. In the presence of kidney impairment, dosage modifications may be required to prevent accumulation of the drug or its active metabolites. Moreover, the systemic effects of AKI can potentiate the pharmacological actions of many of these agents. This latter observation may be the result of decreased protein binding of the drug, greater brain penetration due to some breach of the blood–brain barrier, or a synergistic effect with the toxins retained in kidney failure.

**INTRA VE NOUS AGENT S**

**Propofol & Etomidate**

The pharmacokinetics of both propofol and etomidate are minimally affected by impaired kidney function. Decreased protein binding of etomidate in patients with hypoalbuminemia may enhance its pharmacological effects.

**Barbiturates**
Patients with kidney disease often exhibit increased sensitivity to barbiturates during induction, even though pharmacokinetic profiles appear to be unchanged. The mechanism appears to be an increase in free circulating barbiturate from decreased protein binding. Acidosis may also favor a more rapid entry of these agents into the brain by increasing the nonionized fraction of the drug (see Chapter 26).

**Ketamine**

Ketamine pharmacokinetics are minimally altered by kidney disease. Some active hepatic metabolites are dependent on renal excretion and can potentially accumulate in kidney failure.

**Benzodiazepines**

Benzodiazepines undergo hepatic metabolism and conjugation prior to elimination in urine. Because they are highly protein bound, increased benzodiazepine sensitivity may be seen in patients with hypoalbuminemia. Diazepam and midazolam should be administered cautiously in the presence of kidney impairment because of a potential for the accumulation of active metabolites.

**Opioids**

Most opioids used in anesthetic practice (morphine, meperidine, fentanyl, sufentanil, and alfentanil) are inactivated by the liver; some of these metabolites are then excreted in urine. Remifentanil pharmacokinetics are unaffected by kidney function due to rapid ester hydrolysis in blood. With the exception of morphine and meperidine, significant accumulation of active metabolites generally does not occur with these agents. Accumulation of morphine (morphine-6-glucuronide) and meperidine (normeperidine) metabolites may prolong respiratory depression in patients with kidney failure, and increased levels of normeperidine are associated with seizures. The pharmacokinetics of the most commonly used opioid agonist–antagonists (butorphanol, nalbuphine, and buprenorphine) are unaffected by kidney failure.

**Anticholinergic Agents**

In doses used for premedication, atropine and glycopyrrolate can generally be
used safely in patients with kidney impairment. Because up to 50% of these drugs and their active metabolites are normally excreted in urine, however, the potential for accumulation exists following repeated doses. Scopolamine is less dependent on renal excretion, but its central nervous system effects can be enhanced by decreased kidney function.

**Phenothiazines, H₂ Blockers, & Related Agents**

Most phenothiazines, such as promethazine, are metabolized to inactive compounds by the liver. Droperidol may be partly dependent on the kidneys for excretion. Although their pharmacokinetic profiles are not appreciably altered by kidney impairment, potentiation of the central depressant effects of phenothiazines by the systemic effects of kidney disease may occur.

All H₂-receptor blockers are dependent on kidney excretion, and their dose must be reduced for patients with kidney disease. Proton pump inhibitor dosage does not need to be reduced for patients with kidney disease. Metoclopramide is partly excreted unchanged in urine and will accumulate in kidney failure. Although up to 50% of dolasetron is excreted in urine, no dosage adjustments are recommended for any of the 5-HT₃ blockers in patients with kidney disease.

**INHALATION AGENTS**

**Volatile Agents**

Volatile anesthetic agents are ideal for patients with kidney disease because of lack of dependence on the kidneys for elimination, ability to control blood pressure, and minimal direct effects on kidney blood flow. Although patients with mild to moderate kidney impairment do not exhibit altered uptake or distribution, accelerated induction and emergence may be seen in severely anemic patients (hemoglobin <5 g/dL) with chronic kidney failure; this observation may be explained by a decrease in the blood:gas partition coefficient or by a decrease in minimum alveolar concentration. Some clinicians avoid sevoflurane (with <2 L/min gas flows) for patients with kidney disease who undergo lengthy procedures (see Chapters 8 and 30).

**Nitrous Oxide**

Some clinicians omit entirely or limit the use of nitrous oxide (or air) to maintain
an Fio₂ of 50% or greater in severely anemic patients with end-stage kidney disease in an attempt to increase arterial oxygen content. This may be justified in patients with hemoglobin less than 7 g/dL, in whom even a small increase in the dissolved oxygen content may represent a significant percentage of the arterial to venous oxygen difference (see Chapter 23).

**MUSCLE RELAXANTS**

**Succinylcholine**

☐ Succinylcholine can be safely used in patients with kidney failure, in the absence of hyperkalemia at the time of induction. When the serum potassium is known to be increased or is in doubt, succinylcholine should be avoided. Although decreased plasma cholinesterase levels have been reported in uremic patients following dialysis, significant prolongation of neuromuscular blockade is rarely seen.

**Cisatracurium & Atracurium**

Cisatracurium and atracurium are degraded by plasma ester hydrolysis and nonenzymatic Hofmann elimination. These agents are often the drugs of choice for muscle relaxation in patients with kidney failure, especially in clinical situations where neuromuscular function monitoring is difficult or impossible.

**Vecuronium & Rocuronium**

The elimination of vecuronium is primarily hepatic, but up to 20% of the drug is eliminated in urine. The effects of large doses of vecuronium (>0.1 mg/kg) are only modestly prolonged in patients with kidney disease. Rocuronium primarily undergoes hepatic elimination, but prolongation in patients with severe kidney disease has been reported. In general, with appropriate neuromuscular monitoring, these two agents can be used with few problems in patients with severe kidney disease.

**Curare (d-Tubocurarine)**

Elimination of d-tubocurarine is dependent on both kidney and biliary excretion; 40% to 60% of a dose of curare is normally excreted in urine. Increasingly prolonged effects are observed following repeated doses in patients with
decreased kidney function. Smaller doses and longer dosing intervals are therefore required for maintenance of optimal muscle relaxation.

**Pancuronium**

Pancuronium is primarily dependent on renal excretion (60–90%). Although pancuronium is metabolized by the liver into less active intermediates, its elimination half-life is still primarily dependent on renal excretion (60–80%). Neuromuscular function should be closely monitored if these agents are used in patients with abnormal renal function.

**Reversal Agents**

Renal excretion is the principal route of elimination for edrophonium, neostigmine, and pyridostigmine. The half-lives of these agents in patients with renal impairment are therefore prolonged at least as much as any of the above relaxants, and problems with inadequate reversal of neuromuscular blockade are usually related to other factors (see Chapter 11). Thus, “recurarization” due to inadequate duration of reversal agent is unlikely. Sugammadex is a steroidal muscle relaxant encapsulator drug that, even after binding vecuronium or rocuronium, is rapidly and entirely eliminated (along with the neuromuscular blocker) in its unmetabolized form by the kidney (see Chapter 11). Early studies suggest that onset of sugammadex muscle relaxant reversal may be delayed and that the sugammadex–muscle relaxant complex may persist for several days in the plasma of patients with decreased kidney function. Because of the potential patient safety implications of prolonged sugammadex–muscle relaxant complex exposure in this situation, the use of sugammadex is not recommended at this time in patients with low creatine clearance (<30 mL/min) or on renal replacement therapy (RRT).

**Anesthesia for Patients with Kidney Failure**

**PREOPERATIVE CONSIDERATIONS**

**Acute Kidney Failure**

This syndrome is a rapid deterioration in kidney function that results in retention of nitrogenous waste products (azotemia). These substances, many of which
behave as toxins, are byproducts of protein and amino acid metabolism. Impaired kidney metabolic activity may contribute to widespread organ dysfunction (see Chapter 30).

Kidney failure can be classified as prerenal, renal, and postrenal, depending on its cause(s), and the initial therapeutic approach varies accordingly (see Figure 31–1 and Table 31–4). Prerenal kidney failure results from an acute decrease in renal perfusion; intrinsic kidney failure is usually due to underlying kidney disease, kidney ischemia, or nephrotoxins; and postrenal failure is the result of urinary collecting system obstruction or disruption. Both prerenal and postrenal forms of kidney failure are readily reversible in their initial stages but with time both progress to intrinsic kidney failure. Most adult patients with kidney failure first develop oliguria. Nonoliguric patients with kidney failure (urinary outputs >400 mL/d) continue to form urine that is qualitatively poor; these patients tend to have greater preservation of GFR. Although glomerular filtration and tubular function are impaired in both cases, abnormalities tend to be less severe in nonoliguric kidney failure.

TABLE 31–4 Management priorities in patients with acute kidney failure.¹

| • Search for and correct prerenal and postrenal causes |
| • Review medications and patient-administered substances and stop any potential nephrotoxins |
| • Administer medications in doses appropriate for their clearance |
| • Optimize cardiac output and renal blood flow |
| • Monitor fluid intake and output; measure body weight daily |
| • Search for and treat acute complications (hyperkalemia, hyponatremia, acidosis, hyperphosphatemia, pulmonary edema) |
| • Search for and aggressively treat infections and sepsis |
| • Provide early nutritional support |
| • Provide expert supportive care (management of catheter and skin care; pressure sore and deep venous thromboembolic prophylaxis; psychological support). |

The course of intrinsic acute kidney failure varies widely, but the oliguria typically lasts for 2 weeks and is followed by a diuretic phase marked by a
progressive increase in urinary output. This diuretic phase often results in very large urinary outputs and is usually absent in nonoliguric kidney failure. Kidney function improves over the course of several weeks but may not return to normal for up to 1 year, and subsequent chronic kidney disease is common. The course of prerenal and postrenal kidney failure is dependent upon promptness in diagnosis and correction of the causal condition. Diagnostic ultrasound, including point-of-care ultrasound, is increasingly used to rapidly and noninvasively evaluate possible obstructive uropathy.

**Chronic Kidney Disease**

The most common causes of chronic kidney disease (CKD) are hypertensive nephrosclerosis, diabetic nephropathy, chronic glomerulonephritis, and polycystic kidney disease. The uncorrected manifestations of this syndrome *(Table 31–5)* are usually seen only after GFR decreases below 25 mL/min. Patients with GFR less than 10 mL/min are dependent upon RRT for survival, in the form of hemodialysis, hemofiltration, or peritoneal dialysis.

The generalized effects of severe CKD can usually be controlled by RRT. The majority of patients with end-stage kidney disease who do not undergo renal transplantation receive RRT three times per week. There are complications directly related to RRT itself (Table 31–6). Hypotension, neutropenia, hypoxemia, and disequilibrium syndrome are generally transient, if they occur, and resolve within hours after RRT. Factors contributing to hypotension during dialysis include the vasodilating effects of acetate dialysate solutions, autonomic neuropathy, and rapid removal of fluid. The interaction of white cells with cellophane-derived dialysis membranes can result in neutropenia and leukocyte-mediated pulmonary dysfunction leading to hypoxemia. *Dialysis disequilibrium syndrome* (DDS) is most frequently seen following aggressive dialysis and is characterized by transient alterations in mental status and focal neurological deficits that are secondary to cerebral edema.

Manifestations of Kidney Failure

A. Metabolic
Multiple metabolic abnormalities, including hyperkalemia, hyperphosphatemia, hypocalcemia, hypermagnesemia, hyperuricemia, and hypoalbuminemia, typically develop in patients with kidney failure. Water and sodium retention can result in worsening hyponatremia and extracellular fluid overload, respectively. Failure to excrete nonvolatile acids produces an increased anion gap metabolic acidosis (see Chapter 50). Hypernatremia and hypokalemia are uncommon complications.

Hyperkalemia is a potentially lethal consequence of kidney failure (see Chapter 49). It usually occurs in patients with creatinine clearances of less than 5 mL/min, but it can also develop rapidly in patients with higher clearances in the setting of large potassium loads (eg, trauma, hemolysis, infections, or potassium administration).

Hypermagnesemia is generally mild unless magnesium intake is increased
(commonly from magnesium-containing antacids). Hypocalcemia is secondary to resistance to parathyroid hormone, decreased intestinal calcium absorption secondary to decreased kidney synthesis of 1,25-dihydroxycholecalciferol, and hyperphosphatemia-associated calcium deposition into bone. Symptoms of hypocalcemia rarely develop unless patients are also alkalotic.

Patients with kidney failure also rapidly lose tissue protein and readily develop hypoalbuminemia. Anorexia, protein restriction, and dialysis are contributory.

B. Hematologic

Anemia is nearly always present when the creatinine clearance is below 30 mL/min. Hemoglobin concentrations are generally 6 to 8 g/dL due to decreased erythropoietin production, red cell production, and red cell survival. Additional factors may include gastrointestinal blood loss, hemodilution, bone marrow suppression from recurrent infections, and blood loss for laboratory testing. Even with transfusions, it is often difficult to maintain hemoglobin concentrations greater than 9 g/dL. Erythropoietin administration may partially correct the anemia. Increased levels of 2,3-diphosphoglycerate (2,3-DPG), which facilitates the unloading of oxygen from hemoglobin (see Chapter 23), develop in response to the decrease in blood oxygen-carrying capacity. The metabolic acidosis associated with CKD also favors a rightward shift in the hemoglobin–oxygen dissociation curve. In the absence of symptomatic heart disease, most CKD patients tolerate anemia well.

Both platelet and white cell function are impaired in patients with kidney failure. Clinically, this is manifested as a prolonged bleeding time and increased susceptibility to infections, respectively. Most patients have decreased platelet factor III activity as well as decreased platelet adhesiveness and aggregation. Patients who have recently undergone hemodialysis may also have residual anticoagulant effects from heparin.

C. Cardiovascular

Cardiac output increases in kidney failure to maintain oxygen delivery due to decreased blood oxygen-carrying capacity. Sodium retention and abnormalities in the renin–angiotensin system result in systemic arterial hypertension. Left ventricular hypertrophy is a common finding in CKD. Extracellular fluid overload from sodium retention, in association with increased cardiac demand imposed by anemia and hypertension, makes CKD patients prone to congestive heart failure and pulmonary edema. Increased permeability of the alveolar–
capillary membrane may also be a predisposing factor for pulmonary edema associated with CKD (see later discussion). Arrhythmias, including conduction blocks, are common, and may be related to metabolic abnormalities and to deposition of calcium in the conduction system. Uremic pericarditis may develop in some patients, who may be asymptomatic, may present with chest pain, or may present with cardiac tamponade. Patients with CKD also characteristically develop accelerated peripheral vascular and coronary artery atherosclerotic disease.

Intravascular volume depletion may occur in high-output acute kidney failure if fluid replacement is inadequate. Hypovolemia may occur secondary to excessive fluid removal during dialysis.

**D. Pulmonary**

Without RRT or bicarbonate therapy, CKD patients may be dependent on increased minute ventilation as compensation for metabolic acidosis (see Chapter 50). Pulmonary extravascular water is often increased in the form of interstitial edema, resulting in a widening of the alveolar to arterial oxygen gradient and predisposing to hypoxemia. Increased permeability of the alveolar–capillary membrane in some patients can result in pulmonary edema even with normal pulmonary capillary pressures.

**E. Endocrine**

Abnormal glucose tolerance is common in CKD, usually resulting from peripheral insulin resistance (type 2 diabetes mellitus is one of the most common causes of CKD). Secondary hyperparathyroidism in patients with chronic kidney failure can produce metabolic bone disease, predisposing to fractures. Abnormalities in lipid metabolism frequently lead to hypertriglyceridemia and contribute to accelerated atherosclerosis. Increased circulating levels of proteins and polypeptides normally degraded by the kidneys are often present, including parathyroid hormone, insulin, glucagon, growth hormone, luteinizing hormone, and prolactin.

**F. Gastrointestinal**

Anorexia, nausea, vomiting, and ileus are commonly associated with uremia. Hypersecretion of gastric acid increases the incidence of peptic ulceration and gastrointestinal hemorrhage, which occurs in 10% to 30% of patients. Delayed gastric emptying secondary to kidney disease–associated autonomic neuropathy may predispose patients to perioperative aspiration. Patients with CKD also have
an increased incidence of hepatitis B and C, often with associated hepatic dysfunction.

G. Neurological
Asterixis, lethargy, confusion, seizures, and coma are manifestations of uremic encephalopathy, and symptoms usually correlate with the degree of azotemia. Autonomic and peripheral neuropathies are common in patients with CKD. Peripheral neuropathies are typically sensory and involve the distal lower extremities.

Preoperative Evaluation
Most perioperative patients with acute kidney failure are critically ill, and their kidney failure is frequently associated with trauma or perioperative medical or surgical complications. They are typically in a state of metabolic catabolism. Optimal perioperative management is dependent upon RRT. Hemodialysis is more effective than peritoneal dialysis and can be readily accomplished via a temporary internal jugular, subclavian, or femoral dialysis catheter. Continuous renal replacement therapy (CRRT) is often used when patients are too hemodynamically unstable to tolerate intermittent hemodialysis. Indications for RRT are listed in Table 31–7.

Patients with chronic kidney failure commonly present to the operating room for creation or revision of an arteriovenous dialysis fistula under local or regional anesthesia. Preoperative dialysis on the day of surgery or on the previous day is typical. However, regardless of the intended procedure or the
anesthetic employed, one must be certain that the patient is in optimal medical condition; potentially reversible manifestations of uremia (see Table 31–5) should be addressed.

The history and physical examination should address both cardiac and respiratory function. Signs of fluid overload or hypovolemia should be sought. Patients are often relatively hypovolemic immediately following dialysis. A comparison of the patient’s current weight with previous predialysis and postdialysis weights may be helpful. Hemodynamic data and a chest radiograph, if available, are useful in confirming clinical suspicion of volume overload. Arterial blood gas analysis is useful in evaluating oxygenation, ventilation, hemoglobin level, and acid–base status in patients with dyspnea or tachypnea. The electrocardiogram should be examined for signs of hyperkalemia or hypocalcemia (see Chapter 49) as well as ischemia, conduction block, and ventricular hypertrophy. Echocardiography can assess cardiac function, ventricular hypertrophy, wall motion abnormalities, and pericardial fluid. A friction rub may not be audible on auscultation of patients with a pericardial effusion.

Preoperative red blood cell transfusions are usually administered only for severe anemia as guided by the patient’s clinical status. Bleeding time and coagulation studies (or perhaps a thromboelastogram) may be advisable, particularly if neuraxial anesthesia is being considered. Serum electrolyte, BUN, and creatinine measurements can assess the adequacy of dialysis. Glucose measurements guide the potential need for perioperative insulin therapy.

Drugs with significant renal elimination should be avoided if possible (Table 31–8). Dosage adjustments and measurements of blood levels (when available) are necessary to minimize the risk of drug toxicity.

Premedication

Alert patients who are stable can be given reduced doses of a benzodiazepine, if needed. Chemoprophylaxis for patients at risk for aspiration is reviewed in Chapter 17. Preoperative medications—particularly antihypertensive agents—should be continued until the time of surgery (see Chapter 21). The management of diabetic patients is discussed in Chapter 35.

INTRAOPERATIVE CONSIDERATIONS

Monitoring

Patients with kidney disease and failure are at increased risk for perioperative complications, and their general medical condition and the planned operative procedure dictate monitoring requirements. Because of the risk of thrombosis, blood pressure should not be measured by a cuff on an arm with an arteriovenous fistula. Continuous invasive or noninvasive blood pressure monitoring may be indicated in patients with poorly controlled hypertension.

Induction

Patients with nausea, vomiting, or gastrointestinal bleeding should undergo rapid-sequence induction. The dose of the induction agent should be reduced for debilitated or critically ill patients, or for patients who have recently undergone hemodialysis and who remain relative hypovolemic. Propofol, 1 to 2 mg/kg, or
etomidate, 0.2 to 0.4 mg/kg, is often used. An opioid, β-blocker (esmolol), or lidocaine may be used to blunt the hypertensive response to airway instrumentation and intubation. Succinylcholine, 1.5 mg/kg, can be used to facilitate endotracheal intubation in the absence of hyperkalemia. Rocuronium (1 mg/kg), vecuronium (0.1 mg/kg), cisatracurium (0.15 mg/kg), or propofol–lidocaine induction without a relaxant may be considered for intubation in patients with hyperkalemia.

**Anesthesia Maintenance**

The ideal anesthetic maintenance technique should control hypertension with minimal deleterious effect on cardiac output, because increased cardiac output is the principal compensatory mechanism for tissue oxygen delivery in anemia. Volatile anesthetics, propofol, fentanyl, sufentanil, alfentanil, and remifentanil are satisfactory maintenance agents. Meperidine should be avoided because of accumulation of its metabolite normeperidine. Morphine may be used, but prolongation of its effects may occur.

Controlled ventilation should be considered for patients with kidney failure under general anesthesia. Inadequate spontaneous ventilation with progressive hypercarbia under anesthesia can result in respiratory acidosis that may exacerbate preexisting acidemia, lead to potentially severe circulatory depression, and dangerously increase serum potassium concentration (see Chapter 50). On the other hand, respiratory alkalosis may also be detrimental because it shifts the hemoglobin dissociation curve to the left, can exacerbate preexisting hypocalcemia, and may reduce cerebral blood flow.

**Fluid Therapy**

Superficial procedures involving minimal physiological trespass require replacement of insensible fluid losses only. In situations requiring significant fluid volume for maintenance or resuscitation, isotonic crystalloids, colloids, or both may be used (see Chapter 51). Current evidence suggests balanced crystalloids such as Plasma-Lyte or lactated Ringer’s solution are preferable in such circumstances to chloride-rich crystalloids such as 0.9% saline because of the deleterious effects of hyperchloremia on kidney function. However, 0.9% saline is preferable to balanced crystalloids in patients with alkalosis and hypochloremia. Lactated Ringer’s solution should be avoided in hyperkalemic patients when large fluid volumes are required, because it contains potassium 4 mEq/L. Glucose-free solutions should generally be used because of the glucose
intolerance associated with uremia. Blood that is lost should generally be replaced with colloid or packed red blood cells as clinically indicated. Allogeneic blood transfusion may decrease the likelihood of kidney rejection following transplantation because of associated immunosuppression. Hydroxyethyl starch has been associated with increased risk of AKI and death when administered to critically ill patients or those with preexisting impaired kidney function, or when used for volume resuscitation. Its use in other circumstances is controversial at this time and the subject of many investigations. Intraoperative fluid therapy can be guided by noninvasive measurements of stroke volume and cardiac output.

Anesthesia for Patients with Mild to Moderate Kidney Impairment

PREOPERATIVE CONSIDERATIONS

The kidney normally possesses large functional reserve. GFR, as determined by creatinine clearance, can decrease from 120 to 60 mL/min without clinical signs or symptoms of diminished kidney function. Even patients with creatinine clearances of 40 to 60 mL/min usually are asymptomatic. These patients have only mild kidney impairment but should still be thought of as having decreased kidney reserve. Preservation of remaining kidney function is paramount, and best accomplished by maintaining normovolemia and normal kidney perfusion.

When creatinine clearance decreases to 25 to 40 mL/min, kidney impairment is moderate, and patients are said to have renal insufficiency. Azotemia is always present, and hypertension and anemia are common. Correct anesthetic management of this group of patients is as critical as management of those with frank kidney failure, especially during procedures associated with a relatively high incidence of postoperative kidney failure, such as cardiac and aortic reconstructive surgery. Intravascular volume depletion, sepsis, obstructive jaundice, crush injuries, and renal toxins such as radiocontrast agents, certain antibiotics, angiotensin-converting enzyme inhibitors, and NSAIDs (see Table 30–4) are additional major risk factors for acute deterioration in kidney function. Hypovolemia and decreased kidney perfusion are particularly important causative factors in the development of acute postoperative kidney failure. The emphasis in management of these patients is on prevention, because the mortality rate of postoperative kidney failure may surpass 50%.
combination of diabetes and preexisting kidney disease markedly increases perioperative risk of kidney function deterioration and of kidney failure.

Kidney protection with adequate hydration and maintenance of renal blood flow is indicated for patients at high risk for kidney injury and kidney failure. The use of mannitol, low-dose dopamine or fenoldopam infusion, loop diuretics, or bicarbonate infusion for kidney protection is controversial and without proof of efficacy (see earlier discussion). *N*-acetylcysteine, when given prior to the administration of radiocontrast agents, reduces the risk of radiocontrast agent–induced AKI (see Chapter 30).

### INTRAOPERATIVE CONSIDERATIONS

#### Monitoring

The American Society of Anesthesiologists’ basic monitoring standards are used for procedures involving minimal fluid losses. For procedures associated with significant blood or fluid loss, close monitoring of hemodynamic performance and urinary output is important (see Chapter 51). Although maintenance of urinary output does not ensure preservation of kidney function, urinary outputs greater than 0.5 mL/kg/h are preferable. Continuous invasive blood pressure monitoring is also important if rapid changes in blood pressure are anticipated, such as in patients with poorly controlled hypertension and in those undergoing procedures associated with abrupt changes in sympathetic stimulation or in cardiac preload or afterload.

#### Induction

Selection of an induction agent is not as important as ensuring an adequate intravascular volume prior to induction; induction of anesthesia in hypovolemic patients with impaired kidney function frequently results in hypotension. Unless a vasopressor is administered, such hypotension typically resolves only following intubation or surgical stimulation. Kidney perfusion, which may already be compromised by preexisting hypovolemia, may then deteriorate further, first as a result of hypotension, and subsequently from sympathetically or pharmacologically mediated renal vasoconstriction. If sustained, the decrease in renal perfusion may contribute to postoperative kidney impairment or failure. Preoperative hydration usually prevents this sequence of events.
Maintenance of Anesthesia

All anesthetic maintenance agents are acceptable, with the possible exception of sevoflurane administered with low gas flows over a prolonged time period (see Chapter 30). Intraoperative deterioration in kidney function may result from adverse effects of the operative procedure (hemorrhage, vascular occlusion, abdominal compartment syndrome, arterial emboli) or anesthetic (hypotension secondary to myocardial depression or vasodilation), from indirect hormonal effects (sympathoadrenal activation or antidiuretic hormone secretion), or from impeded venous return secondary to positive-pressure ventilation. Many of these effects are avoidable or reversible when adequate intravenous fluids are given to maintain a normal or slightly expanded intravascular volume. The administration of large doses of predominantly α-adrenergic vasopressors (phenylephrine and norepinephrine) may also be detrimental to preservation of kidney function. Small, intermittent doses, or brief infusions, of vasoconstrictors may be useful in maintaining renal blood flow until other measures (eg, transfusion) are undertaken to correct hypotension.

Fluid Therapy

As reviewed earlier, appropriate fluid administration is important in managing patients with preexisting AKI or kidney failure or who are at risk for AKI. We find guidance from noninvasive monitors of stroke volume and cardiac output useful. Concern over fluid overload is justified, but acute problems are rarely encountered in such patients with normal urinary outputs if rational fluid administration guidelines and appropriate monitoring are employed (see Chapter 51). Moreover, the adverse consequences of excessive fluid overload are far easier to treat than those of AKI and kidney failure.

CASE DISCUSSION

A Patient with Uncontrolled Hypertension

A 59-year-old man with a recent onset of hypertension is scheduled for stenting of a stenotic left renal artery. His preoperative blood pressure is 180/110 mm Hg.

What is the likely cause of this patient’s hypertension?
Renovascular hypertension is one of the few forms of hypertension that can be corrected with surgery or mechanical intervention. Others include coarctation of the aorta, pheochromocytoma, Cushing disease, and primary hyperaldosteronism.

Most studies suggest that renovascular hypertension accounts for 2% to 5% of all cases of hypertension. Characteristically it manifests as a relatively sudden onset of hypertension in a person younger than 35 or older than 55 years of age. Renal artery stenosis can also be responsible for the development of accelerated or malignant hypertension in previously hypertensive persons of any age.

**What is the pathophysiology of the hypertension?**

Unilateral or bilateral stenosis of the renal artery decreases the perfusion pressure to the kidney(s) distal to the obstruction. Activation of the juxtaglomerular apparatus and release of renin increase circulating levels of angiotensin II and aldosterone, resulting in peripheral vascular constriction and sodium retention, respectively. The resulting systemic arterial hypertension is often severe.

In nearly two thirds of patients, the stenosis results from an atheromatous plaque in the proximal renal artery. These patients are typically men over the age of 55 years. In the remaining one third of patients, the stenosis is more distal and is due to malformations of the arterial wall, commonly referred to as fibromuscular hyperplasia (or, dysplasia). This latter lesion most commonly presents in women younger than 35 years. Bilateral renal artery stenosis is present in 30% to 50% of patients with renovascular hypertension. Less common causes of stenosis include dissecting aneurysms, emboli, polyarteritis nodosa, radiation, trauma, extrinsic compression from retroperitoneal fibrosis or tumors, and hypoplasia of the renal arteries.

**What clinical manifestations other than hypertension may be present?**

Signs of secondary hyperaldosteronism can be prominent. These include sodium retention in the form of edema, metabolic alkalosis, and hypokalemia. The latter can cause muscle weakness, polyuria, and even tetany.

**How is the diagnosis made?**
The diagnosis is suggested by the clinical presentation previously described. A midabdominal bruit may also be present, but the diagnosis requires laboratory and radiographic confirmation. A definitive diagnosis is made by renal arteriography, and percutaneous balloon angioplasty with stenting may be performed at the same time. The functional significance of the restrictive lesion(s) may be evaluated by selective catheterization of both renal veins and subsequent measurement of plasma renin activity in blood from each kidney. Restenosis rates following angioplasty are estimated to be less than 15% after 1 year. Patients who are not candidates for angioplasty and stenting are referred for surgery.

**Should this patient undergo intervention or surgical correction given his present blood pressure?**

Optimal medical therapy is important in preparing these patients for operation. Relative to patients with well-controlled hypertension, those with poorly controlled hypertension have an increased incidence of intraoperative problems, including marked hypertension, hypotension, myocardial ischemia, and arrhythmias. Ideally, arterial blood pressure should be well controlled prior to surgery. Patients should be evaluated for preexisting kidney dysfunction, and metabolic disturbances such as hypokalemia should be corrected. Patients should also be evaluated as indicated for the presence and severity of coexisting atherosclerotic disease, according to current American College of Cardiology/American Heart Association (ACC/AHA) guidelines (see Chapter 21).

**What antihypertensive agents are most useful for controlling blood pressure perioperatively in these patients?**

β-Adrenergic blocking drugs are frequently utilized for blood pressure control in the perioperative period. They are particularly effective because secretion of renin is partly mediated by β₁-adrenergic receptors. Although parenteral selective β₁-blocking agents such as metoprolol and esmolol would be expected to be most effective, nonselective agents appear equally effective. Esmolol may be the intraoperative β₁-blocking agent of choice because of its short half-life and titratability. Direct vasodilators and nicardipine are also useful in controlling intraoperative hypertension (see Chapter 15).

ACE inhibitors and angiotensin-converting enzyme receptor blockers are
contraindicated in bilateral renal artery stenosis or in unilateral renal artery stenosis where there is only one functioning kidney because they can precipitate kidney failure.

**What intraoperative considerations are important for the anesthesia provider?**

Open surgical revascularization of a kidney is a major procedure, with the potential for major blood loss, fluid shifts, and hemodynamic changes. One of several procedures may be performed, including transaortic renal endarterectomy, aortorenal bypass (using a saphenous vein, synthetic graft, or segment of the hypogastric artery), a splenic to (left) renal artery bypass, a hepatic or gastroduodenal to (right) renal artery bypass, or excision of the stenotic segment with reanastomosis of the renal artery to the aorta. Rarely, nephrectomy may be performed. Isolated stenosis of a renal artery may be corrected with stenting performed with local anesthesia and sedation.

With all “open” procedures, an extensive retroperitoneal dissection often necessitates relatively large volumes of intravenous fluid replacement. Large-bore intravenous access is mandatory because of the potential for extensive blood loss. Heparinization contributes to increased blood loss. Depending on the surgical technique, aortic cross-clamping, with its associated hemodynamic consequences, often complicates anesthetic management (see Chapter 22). Continuous intraarterial blood pressure monitoring will nearly always be used, and central venous pressure monitoring is often helpful. Goal-directed hemodynamic and fluid therapy utilizing arterial pulse contour analysis, esophageal Doppler, or transesophageal echocardiography should be considered for patients with poor ventricular function and may be advisable in most patients to guide fluid management (see Chapter 51). The choice of anesthetic technique is generally determined by the patient’s cardiovascular function.

Generous hydration and maintenance of adequate cardiac output and blood pressure are important to protect both the affected and the normal kidney against acute ischemic injury. Topical cooling of the affected kidney during the anastomosis may also be employed.

**What postoperative considerations are important?**

Although in most patients hypertension is ultimately cured or significantly improved, arterial blood pressure is often quite labile in the early postoperative period. Close hemodynamic monitoring should be
continued well into the postoperative period. Reported operative mortality rates range from 1% to 6%, and most deaths are associated with myocardial infarction. The latter probably reflects the relatively high prevalence of coronary artery disease in older patients with renovascular hypertension.

Anesthesia for Genitourinary Surgery

KEY CONCEPTS

1. Next to the supine position, the lithotomy position is the most commonly used position for patients undergoing urological and gynecological procedures. Failure to properly position and pad the patient can result in pressure sores, nerve injuries, or compartment syndromes.

2. The lithotomy position is associated with major physiological alterations. Functional residual capacity decreases, predisposing patients to atelectasis and hypoxia. Elevation of the legs drains blood into the central circulation acutely. Mean blood pressure often increases, but cardiac output does not change significantly. Conversely, rapid lowering of the legs from the lithotomy or Trendelenburg position acutely decreases venous return and can result in hypotension. Blood pressure measurement should be taken immediately after the legs are lowered.

3. Because of the short duration (15–20 min) and outpatient setting of most cystoscopies, general anesthesia is often chosen, commonly employing a laryngeal mask airway.

4. Both epidural and spinal blockade with a T10 sensory level provide excellent anesthesia for cystoscopy.

5. Manifestations of TURP (transurethral resection of the prostate) syndrome are primarily those of circulatory fluid overload, water intoxication, and, occasionally, toxicity from the solute in the irrigating fluid.

6. Absorption of TURP irrigation fluid is dependent on the duration of the resection and the pressure of the irrigation fluid.

7. When compared with general anesthesia, regional anesthesia for TURP may reduce the incidence of postoperative venous thrombosis. It is also
less likely to mask symptoms and signs of TURP syndrome or bladder perforation.

8 Patients with a history of cardiac arrhythmias and those with a pacemaker or implantable cardioverter defibrillator (ICD) may be at risk for developing arrhythmias induced by shock waves during extracorporeal shock wave lithotripsy (ESWL). Shock waves can damage the internal components of pacemaker and ICD devices.

9 Patients who are undergoing retroperitoneal lymph node dissection and who have received bleomycin preoperatively are at increased risk for developing postoperative pulmonary insufficiency. These patients may be particularly at risk for oxygen toxicity and fluid overload, and for developing acute respiratory distress syndrome postoperatively.

10 For patients undergoing kidney transplantation, the preoperative serum potassium concentration should be below 5.5 mEq/L and existing coagulopathies should be corrected. Hyperkalemia has been reported after release of the vascular clamp following completion of the arterial anastomosis, particularly in pediatric and other small patients. Release of potassium contained in the preservative solution has been implicated as the cause of this phenomenon.

Urological procedures range in impact from simple outpatient cystoscopy to surgical procedures with increased risk of perioperative complications, such as radical cystectomy and nephrectomy for renal cell carcinoma with venacaval thrombosis. Patients undergoing genitourinary procedures may be of any age, but many are elderly with coexisting medical illnesses, including kidney dysfunction. The impact of anesthesia on kidney function is discussed in Chapter 31. This chapter reviews the anesthetic management of common urological procedures. Use of lithotomy and steep head-down (Trendelenburg) positions complicates many of these procedures. Moreover, advances in preoperative patient optimization, perioperative management, and postoperative rehabilitation allow more patients with coexisting disease to be considered acceptable candidates for kidney transplantation, extensive tumor debulking operations, and reconstructive genitourinary procedures.

**CYSTOSCOPY**

**Preoperative Considerations**
Cystoscopy is a very commonly performed urological procedure, and indications for this investigative or therapeutic operation include hematuria, recurrent urinary infections, renal calculi, and urinary obstruction. Bladder biopsies, retrograde pyelograms, transurethral resection of bladder tumors, extraction or laser lithotripsy of kidney stones, and placement or manipulation of ureteral catheters (stents) are also commonly performed through the cystoscope.

Anesthetic management varies with the age and gender of the patient and the purpose of the procedure. General anesthesia is usually necessary for children. Viscous lidocaine topical anesthesia with or without sedation provides satisfactory anesthesia for diagnostic cystoscopy in most women because of the short urethra. Men generally require regional or general anesthesia for diagnostic cystoscopy. Operative cystoscopies involving biopsies, cauterization, or manipulation of ureteral catheters require regional or general anesthesia, regardless of patient gender.

**Intraoperative Considerations**

**A. Lithotomy Position**

Next to the supine position, the lithotomy position is the most commonly used position for patients undergoing urological and gynecological procedures. Failure to properly position and pad the patient can result in pressure sores, nerve injuries, or compartment syndromes. Ideally, two people will move the patient’s legs simultaneously up into, or down from, the lithotomy position. Straps around the ankles or special holders support the legs in lithotomy position (Figure 32–1). The leg supports should be padded wherever there is leg or foot contact, and straps must not impede circulation. When the patient’s arms are tucked to the side, caution must be exercised to prevent the fingers from being caught between the mid and lower sections of the operating room table when the lower section is lowered and raised. Many clinicians will completely enclose the patient’s hands and fingers with protective padding to minimize this risk. Injury to the tibial (common peroneal) nerve, resulting in loss of dorsiflexion of the foot, may result if the lateral knee rests against the strap support. If the legs are allowed to rest on medially placed strap supports, compression of the saphenous nerve can result in numbness along the medial calf. Excessive flexion of the thigh against the groin can injure the obturator and, less commonly, the femoral nerves. Extreme flexion at the thigh can also stretch the sciatic nerve. The most common nerve injuries directly associated with the lithotomy position involve the lumbosacral plexus. Brachial plexus injuries can likewise occur if the upper
extremities are inappropriately positioned (eg, hyperextension at the axilla). Compartment syndrome of the lower extremities with rhabdomyolysis has been reported with prolonged time in the lithotomy position, after which lower extremity nerve damage is also more likely.

The lithotomy position is associated with major physiological alterations. Functional residual capacity decreases, predisposing patients to atelectasis and hypoxia. This effect is amplified by steep Trendelenburg positioning (30–45°), which is commonly utilized in combination with the lithotomy position. Elevation of the legs drains blood into the central circulation acutely. Mean blood pressure and cardiac output may increase. Conversely, rapid lowering of the legs from the lithotomy or Trendelenburg position acutely decreases venous return and cardiac output and can result in hypotension. Vasodilation from either general or regional anesthesia potentiates the hypotension in this situation, and
for this reason, blood pressure measurement should be taken immediately after the legs are lowered.

B. Choice of Anesthesia

1. General anesthesia—Any anesthetic technique suitable for outpatients may be utilized. Because of the short duration (15–20 min) and outpatient setting of most cystoscopies, general anesthesia is often chosen, commonly employing a laryngeal mask airway. Oxygen saturation should be closely monitored when obese or elderly patients, or those with marginal pulmonary reserve, are placed in the lithotomy or Trendelenburg position.

2. Regional anesthesia—Both epidural and spinal blockade provide satisfactory anesthesia for cystoscopy. However, when neuraxial regional anesthesia is chosen most anesthesiologists prefer spinal anesthesia because onset of satisfactory sensory blockade may require 15 to 20 min for epidural anesthesia compared with 5 min or less for spinal anesthesia. Studies fail to demonstrate that immediate elevation of the legs into lithotomy position following administration of hyperbaric spinal anesthesia either increases the dermatomal extent of anesthesia to a clinically significant degree or increases the likelihood of severe hypotension. A T10 sensory level block provides excellent anesthesia for all cystoscopic procedures.

TRANSURETHRAL RESECTION OF THE PROSTATE

Preoperative Considerations

Benign prostatic hyperplasia (BPH) frequently leads to bladder outlet obstruction in men older than 60 years. Although most patients are treated medically, some require surgical intervention. Transurethral resection of the prostate (TURP) may be performed for bladder outlet obstruction due to BPH. Indications for TURP include obstructive uropathy, bladder calculi, and recurrent episodes of urinary retention, urinary tract infections, and hematuria. Patients with prostate cancer who are not candidates for radical prostatectomy may also benefit from TURP to relieve urinary obstruction.

TURP requires regional or general anesthesia. Despite advanced age and prevalence of significant comorbidity, perioperative mortality and medical morbidity (most frequently myocardial infarction, pulmonary edema, and kidney failure) for this procedure are both less than 1%.
The most common surgical complications of TURP are clot retention, failure to void, uncontrolled hematuria requiring surgical revision, urinary tract infection, and chronic hematuria, although other complications may include TURP syndrome, bladder perforation, sepsis, hypothermia, and disseminated intravascular coagulation (DIC). A blood type and screen (see Chapter 51) is adequate for most patients, although crossmatched blood should be available for anemic patients and for patients with a large prostate in which extensive resection is contemplated. Prostatic bleeding can be difficult to control through the cystoscope.

Intraoperative Considerations

TURP is conventionally performed by passing a monopolar electrical loop through a special cystoscope (resectoscope). Using continuous irrigation and direct visualization, prostatic tissue is resected by applying a cutting current to the loop. Because of the characteristics of the prostate and the large amounts of irrigation fluid often used, TURP can be associated with serious complications (Table 32–1).

A. TURP Syndrome
Transurethral prostatic resection, now a relatively uncommon procedure, often opens the extensive network of venous sinuses in the prostate, potentially allowing systemic absorption of the irrigating fluid. The absorption of large amounts of fluid (2 L or more) results in a constellation of symptoms and signs commonly referred to as *TURP syndrome* (Table 32–2). The manifestations are primarily those of circulatory fluid overload, water intoxication, and, occasionally, toxicity from the solute in the irrigating fluid. The incidence of TURP syndrome is less than 1%. This syndrome presents intraoperatively or postoperatively as headache, restlessness, confusion, cyanosis, dyspnea, arrhythmias, hypotension, seizures, or a combination of these, and it can be rapidly fatal. TURP syndrome is most commonly associated with large-volume prostate resection and use of large volumes of irrigation fluid, and has also been much less commonly reported with cystoscopy, arthroscopy, transurethral resection of bladder tumors, and transcervical resection of the endometrium.

1 TURP, transurethral resection of the prostate.

Electrolyte solutions cannot be used for irrigation during monopolar TURP because they disperse the electrocautery current. Water provides excellent visibility because its hypotonicity lyses red blood cells, but significant water absorption can readily result in acute water intoxication. Water irrigation is generally restricted to transurethral resection of bladder tumors only. For monopolar TURP, slightly hypotonic nonelectrolyte irrigating solutions such as
glycine 1.5% (230 mOsm/L) or a mixture of sorbitol 2.7% and mannitol 0.54% (195 mOsm/L) are most commonly used. Less commonly used solutions include sorbitol 3.3%, mannitol 3%, dextrose 2.5% to 4%, and urea 1%. Because all these fluids are still hypotonic, significant absorption of water can occur. Fluid absorption rate is also influenced by irrigation fluid pressure, and high pressures (high bottle or bag height) increases the rate of fluid absorption.

Absorption of TURP irrigation fluid is dependent on the duration of the resection and the pressure of the irrigation fluid. Pulmonary edema can readily result from the absorption of large amounts of irrigation fluid, particularly in patients with limited cardiac reserve. The hypotonicity of these fluids also results in acute hyponatremia and hypoosmolality, which can lead to serious neurological manifestations. Symptoms of hyponatremia usually do not develop until the serum sodium concentration decreases below 120 mEq/L. Marked hypotonicity in plasma ([Na⁺] <100 mEq/L) may also result in acute intravascular hemolysis.

Toxicity may also arise from absorption of the solutes in these fluids. Marked hyperglycinemia has been reported with glycine solutions and may contribute to circulatory depression and central nervous system toxicity. Glycine has been implicated in rare instances of transient blindness following TURP. Hyperammonemia, presumably from the degradation of glycine, has also been documented in a few patients with marked central nervous system toxicity following TURP.

Treatment of TURP syndrome depends on early recognition and should be based on the severity of the symptoms. The absorbed water must be eliminated, and hypoxemia and hypoperfusion treated. Most patients can be managed with fluid restriction and intravenous administration of furosemide. Symptomatic hyponatremia resulting in seizures or coma should be treated with hypertonic saline (see Chapter 49). Seizure activity can be terminated with small doses of midazolam (2–4 mg). Endotracheal intubation may be considered to prevent aspiration until the patient’s mental status normalizes. The amount and rate of hypertonic saline solution (3% or 5%) needed to correct the hyponatremia to a safe level should be based on the patient’s serum sodium concentration (see Chapter 49).

Recently, additional procedural methods for treatment of BPH have included bipolar TURP, laser and radiofrequency ablation, photodynamic and thermal therapy, and cryotherapy. Low-voltage bipolar TURP allows use of isotonic saline irrigation fluid, thus avoiding TURP syndrome with the exception of the persisting risk of fluid overload, and because the procedure simultaneously
cauterizes as it resects, it decreases the risk of clot retention.

**B. Hypothermia**
Large volumes of irrigating fluids at room temperature can be a major source of heat loss in patients. Irrigating solutions should be warmed to body temperature prior to use to prevent hypothermia. Postoperative shivering associated with hypothermia may dislodge clots and promote postoperative bleeding.

**C. Bladder Perforation**
The incidence of **bladder perforation** during TURP is less than 1% and may result from either the resectoscope going through the bladder wall or from overdistention of the bladder with irrigation fluid. Most bladder perforations are extraperitoneal and are signaled by poor return of the irrigating fluid. Awake patients will typically complain of nausea, diaphoresis, and retropubic or lower abdominal pain. Large extraperitoneal, and most intraperitoneal, perforations are usually even more obvious, presenting as sudden unexplained hypotension or hypertension, and with generalized abdominal pain in awake patients. Regardless of the anesthetic technique employed, perforation should be suspected in settings of sudden hypotension or hypertension, particularly with acute, vagal-mediated bradycardia.

**D. Coagulopathy**
DIC following TURP may result from the release of thromboplastins from prostate tissue during the procedure. Rarely, patients with metastatic carcinoma of the prostate develop a coagulopathy from primary fibrinolysis due to secretion of a fibrinolytic enzyme. Coagulopathy may be suspected from diffuse, uncontrollable bleeding, but must be defined with laboratory tests. Primary fibrinolysis should be treated with ε-aminocaproic acid (Amicar) or tranexamic acid. Treatment of DIC in this setting may require heparin in addition to replacement of clotting factors and platelets, and consultation with a hematologist should be considered.

**E. Septicemia**
The prostate is often colonized with bacteria and may harbor chronic infection. Extensive surgical resection with the opening of venous sinuses can allow entry of organisms into the bloodstream. Bacteremia following transurethral surgery is common. Prophylactic antibiotic therapy (most commonly gentamicin, levofloxacin, or cefazolin) prior to TURP is often administered.
F. Choice of Anesthesia

Either spinal or epidural anesthesia with a T10 sensory level, or general anesthesia, provides excellent anesthesia and good operating conditions for TURP. When compared with general anesthesia, regional anesthesia may reduce the incidence of postoperative venous thrombosis. It is also less likely to mask symptoms and signs of TURP syndrome or bladder perforation. Clinical studies have failed to show any differences in blood loss, postoperative cognitive function, and mortality between regional and general anesthesia. Acute hyponatremia from TURP syndrome may delay or prevent emergence from general anesthesia.

G. Monitoring

Evaluation of mental status in the awake or moderately sedated patient is the best monitor for detection of early signs of TURP syndrome and bladder perforation. Blood loss is particularly difficult to assess during TURP because of the use of irrigating solutions, so it is necessary to rely on clinical signs of hypovolemia (see Chapter 51). Blood loss averages approximately 3 to 5 mL/min of resection (usually 200–300 mL total) but is rarely life-threatening. Transient, postoperative decreases in hematocrit may simply reflect hemodilution from absorption of irrigation fluid. Very few patients will require intraoperative blood transfusion.

LITHOTRIPSY

The treatment of kidney stones has evolved from primarily open surgical procedures to less invasive or entirely noninvasive techniques. Cystoscopic procedures, including flexible ureteroscopy with stone extraction, stent placement, and intracorporeal lithotripsy (laser or electrohydraulic), along with medical expulsive therapy (MET), have become first-line therapy. Extracorporeal shock wave lithotripsy (ESWL) is also utilized, primarily for 4-mm to 2-cm intrarenal stones, and percutaneous and laparoscopic nephrolithotomy for larger or impacted stones. MET has become the treatment of choice among many clinicians for acute episodes of urolithiasis: for stones up to 10 mm in diameter, administration of the α-blockers tamsulosin (Flomax), doxazosin (Cardura), or terazosin (Hytrin) or the calcium channel blocker nifedipine (Procardia, Adalat) increases the likelihood of stone expulsion.

During ESWL, repetitive high-energy shocks (sound waves) are generated and focused on the stone, causing it to fragment. Water or (more commonly) a
conducting gel couples the generator to the patient. The change in acoustic impedance at the tissue–stone interface creates shear and tear forces on the stone, fragmenting it sufficiently to allow its passage in small pieces down the urinary tract. Ureteral stents are often placed prior to the procedure. Contraindications to the procedure include the inability to position the patient so that lung and intestine are away from the sound wave focus, urinary obstruction below the stone, untreated infection, a bleeding diathesis, and pregnancy. The presence of a nearby aortic aneurysm or an orthopedic prosthetic device is a relative contraindication.

Electrohydraulic, electromagnetic, or piezoelectric shock wave generators may be used for ESWL. With older electrohydraulic units, the patient is placed in a hydraulic chair and immersed in a heated water bath, which conducts the shock waves to the patient. Modern lithotriptors generate shock waves either electromagnetically or from piezoelectric crystals. The generator is enclosed in a water-filled casing and comes in contact with the patient via a conducting gel on a plastic membrane (Figure 32–2). In the case of electromagnetic machines, the vibration of a metallic plate in front of an electromagnet produces the shock waves. With piezoelectric models, the waves are the result of changes in the external dimensions of ceramic crystals when electric current is applied.
Preoperative Considerations

Patients with a history of cardiac arrhythmias and those with a pacemaker or implantable cardioverter defibrillator (ICD) may be at greater risk for arrhythmias during ESWL. Synchronization of the shock waves with the electrocardiogram (ECG) R wave decreases the incidence of arrhythmias during ESWL. The shock waves are usually timed to be 20 ms after the R wave to correspond with the ventricular refractory period, although studies suggest that asynchronous delivery of shocks may be safe in patients without heart disease. Shock waves can damage the internal components of implanted cardiac devices. The manufacturer should be contacted as to the best method for managing the device (eg, reprogramming or applying a magnet).

Intraoperative Considerations
Anesthetic considerations for ureteroscopy, stone manipulation, and laser lithotripsy are similar to those for cystoscopic procedures. ESWL requires special considerations, particularly when older lithotriptors requiring the patient to be immersed in water are used.

A. Effects of Immersion During ESWL
Immersion into a heated water bath (36–37°C) initially results in vasodilation that can transiently lead to hypotension. Arterial blood pressure, however, subsequently rises as venous blood is redistributed centrally due to the hydrostatic pressure of water on the legs and abdomen. Systemic vascular resistance (SVR) rises and cardiac output may decrease. Moreover, the increase in intrathoracic blood volume reduces functional residual capacity and may predispose some patients to hypoxemia.

B. Choice of Anesthesia
Pain during lithotripsy is from dissipation of a small amount of energy as shock waves enter the body through the skin. The pain is therefore localized to the skin and is proportionate to the shock wave intensity. Older water bath lithotripsy units require 1000 to 2400 relatively high-intensity shock waves, which most patients cannot tolerate without either regional or general anesthesia. In contrast, newer lithotripsy units that are coupled directly to the skin utilize 2000 to 3000 lower-intensity shock waves that usually require only light sedation.

C. Regional Anesthesia
Continuous epidural anesthesia is commonly employed when ESWL utilizes older water bath lithotriptors. A T6 sensory level ensures adequate anesthesia, as renal innervation is derived from T10 to L2. When using the loss of resistance technique for placement of the epidural catheter, saline should be used instead of air during epidural catheter insertion as air in the epidural space can dissipate shock waves and may promote injury to neural tissue. Foam tape should not be used to secure the epidural catheter as this type of tape has been shown to dissipate the energy of the shock waves when it is in their path. Spinal anesthesia can also be used satisfactorily but offers less control over the sensory level and an uncertain duration of surgery; for this reason, epidural anesthesia is usually preferred.

Disadvantages of regional anesthesia or sedation include the inability to control diaphragmatic movement (excessive diaphragmatic excursion can move the stone out of the wave focus and may prolong the procedure) and bradycardia.
(this will prolong the procedure when shock waves are coupled to the ECG). Glycopyrrolate may be administered to accelerate the ESWL procedure.

D. General Anesthesia
General endotracheal anesthesia allows control of diaphragmatic excursion during lithotripsy using older water bath lithotriptors. The procedure is complicated by the inherent risks associated with placing a supine anesthetized patient in a chair, elevating and then lowering the chair into a water bath to shoulder depth, and then reversing the sequence at the end. A light general anesthetic technique in conjunction with a muscle relaxant is preferable. The muscle relaxant ensures patient immobility and control of diaphragmatic movement.

E. Monitored Anesthesia Care
Monitored anesthesia care with intravenous midazolam and fentanyl is usually adequate for modern low-energy lithotripsy. Deeper sedation may also be used.

F. Monitoring
Standard anesthesia monitoring must be used for conscious or deep sedation, or for general anesthesia. Supraventricular arrhythmias may occur even with R wave synchronized shocks. With immersion lithotripsy, ECG pads should be attached securely with waterproof dressing. The temperature of the bath and the patient should be monitored to prevent hypothermia or hyperthermia.

G. Fluid Management
Intravenous fluid therapy is typically generous. Following an initial intravenous crystalloid fluid bolus, an additional 1000 to 2000 mL is often given with a small dose of furosemide to maintain brisk urinary flow and flush stone debris and blood clots. Patients with impaired cardiac reserve require more conservative fluid therapy.

NONCANCER SURGERY OF THE UPPER URETER & KIDNEY
Laparoscopic urological procedures, including partial and total nephrectomy, live donor nephrectomy, nephrolithectomy, and pyeloplasty are increasingly utilized because of advantages that include less perioperative pain, shorter
hospital length of stay, and relatively rapid convalescence and return to function. Both transperitoneal and retroperitoneal approaches have been developed. A hand-assisted technique employs an additional larger incision that allows the surgeon to insert one hand for tactile sensation and facilitation of dissection. Anesthetic management is similar to that for any laparoscopic procedure.

Open procedures for kidney stones in the upper ureter and renal pelvis, and nephrectomies for nonmalignant disease, are often carried out in the “kidney rest” or lateral flexed position. With the patient in a full lateral position, the dependent leg is flexed and the other leg is extended. An axillary roll is placed beneath the dependent upper chest to minimize the risk of brachial plexus injury. The operating table is then extended to achieve maximal separation between the iliac crest and the costal margin on the operative side, and the kidney rest (a bar in the groove where the table bends) is elevated to raise the nondependent iliac crest higher and improve surgical exposure.

The lateral flexed position is associated with adverse respiratory and circulatory effects. Functional residual capacity is reduced in the dependent lung but may increase in the nondependent lung. In the anesthetized patient receiving controlled ventilation, ventilation/perfusion mismatching occurs because the dependent lung receives greater blood flow than the nondependent lung, whereas the nondependent lung receives greater ventilation, predisposing the patient to atelectasis in the dependent lung and to shunt-induced hypoxemia. The arterial to end-tidal gradient for carbon dioxide progressively increases during general anesthesia in this position, indicating that dead space ventilation also increases in the nondependent lung. Moreover, elevation of the kidney rest can significantly decrease cardiac output in some patients by compressing the inferior vena cava. Venous pooling in the legs potentiates anesthesia-induced vasodilation.

Because of the potential for large blood loss and limited access to major vascular structures in the lateral flexed position, initial placement of at least one large-bore intravenous catheter is advisable. Arterial catheters are often utilized. Endotracheal tube placement may be altered during positioning; thus proper endotracheal tube placement must again be verified following final patient positioning prior to skin preparation and surgical draping. Intraoperative pneumothorax may occur as a result of surgical entry into the pleural space.

**SURGERY FOR UROLOGICAL MALIGNANCIES**

Improved survival rates for patients with urological cancer following radical surgical resections have resulted in an increase in the number of procedures
performed for prostatic, bladder, testicular, and renal cancer. The desire for accelerated, less-complicated recovery with smaller, less painful incisions has prompted development of laparoscopic pelvic and abdominal operations, including radical prostatectomy, cystectomy, pelvic lymph node dissection, nephrectomy, and adrenalectomy. Robotic-assisted technology has increasingly been applied to these procedures over the past decade.

Many urological procedures are carried out with the patient in a hyperextended supine position to facilitate exposure of the pelvis during pelvic lymph node dissection, retropubic prostatectomy, or cystectomy (Figure 32–3). The patient is positioned supine with the iliac crest over the break in the operating table, and the table is extended such that the distance between the iliac crest and the costal margin increases maximally. Care must be taken to avoid putting excessive strain on the patient’s back. The operating room table is also tilted head-down to make the operative field horizontal. In the frog-leg position, a variation of the hyperextended supine position, the knees are also flexed and the hips are abducted and externally rotated.

### 1. Prostate Cancer

**Preoperative Considerations**

Adenocarcinoma of the prostate is the most common nonskin cancer in men and is second only to lung cancer as the most common cause of cancer deaths in men older than 55 years. Approximately one in six men will be diagnosed with prostate cancer in their lifetime. Management varies from surveillance to radical surgery. Important variables include the grade and stage of the malignancy, the patient’s age, the concentration of prostate-specific antigen (PSA), and the presence of medical comorbidity. Transrectal ultrasound is used to guide transrectal biopsies. Clinical staging is based on the Gleason score of the biopsy specimens, magnetic resonance imaging (MRI) to determine whether there is
tumor migration to regional lymph nodes, and bone scan.

**Intraoperative Considerations**

Patients with prostate cancer may present to the operating room for open radical retropubic prostatectomy with lymph node dissection, robot-assisted laparoscopic prostatectomy with pelvic lymph node dissection, salvage prostatectomy (following failure of radiation therapy), cryoablation, or bilateral orchietomy for hormonal therapy.

**A. Radical Retropubic Prostatectomy**

Radical retropubic prostatectomy is usually performed with pelvic lymph node dissection through a lower midline abdominal incision. It may be curative for localized prostate cancer or occasionally used as a salvage procedure after failure of radiation. The prostate is removed en bloc with the seminal vesicles, ejaculatory ducts, and part of the bladder neck. A “nerve-sparing” technique may be used to help preserve sexual function. Following prostatectomy, the remaining bladder neck is anastomosed directly to the urethra over an indwelling urinary catheter. The surgeon may ask for intravenous administration of indigo carmine for visualization of the ureters, and this dye can be associated with hypertension or hypotension.

Radical retropubic (open) prostatectomy may be accompanied by significant operative blood loss. Most centers use direct arterial blood pressure monitoring, and central venous pressure monitoring may also be employed. Other centers routinely utilize noninvasive cardiac output monitoring (eg, LiDCOrapid or FloTrac/Vigileo). Operative blood loss varies considerably from center to center, with mean values less than 500 mL common. Factors influencing blood loss include prostate size, duration of operation, and the skill and experience of the surgeon. Blood loss and operative morbidity and mortality are similar in patients receiving general anesthesia and those receiving regional anesthesia. Neuraxial anesthesia requires a T6 sensory level, but these patients typically do not tolerate regional anesthesia without deep sedation because of the hyperextended supine position. The combination of a prolonged Trendelenburg position together with administration of large amounts of intravenous fluids may rarely produce edema of the upper airway. The risk of hypothermia should be minimized by utilizing a forced-air warming blanket and an intravenous fluid warmer.

Postoperative complications include hemorrhage, deep venous thrombosis (perhaps with pulmonary embolus), injuries to the obturator nerve, ureter, and
rectum, and urinary incontinence and impotence. Extensive surgical dissection around the pelvic veins increases the risk of intraoperative venous air embolism and postoperative thromboembolic complications. An enhanced recovery approach to perioperative care should be standard. Although epidural anesthesia may reduce the incidence of postoperative deep venous thrombosis following open prostatectomy, this beneficial effect may be negated by the routine use of warfarin or fractionated heparin prophylaxis postoperatively, and in the era of enhanced recovery is less often used. Ketorolac and acetaminophen can be used as analgesic adjuvants and have been reported to decrease opioid requirements, improve analgesia, and promote earlier return of bowel function.

B. Robot-Assisted Laparoscopic Radical Prostatectomy

Robot-assisted laparoscopic radical prostatectomy with pelvic lymph node dissection differs from most other laparoscopic procedures by the frequent use of steep (>30°) Trendelenburg position for surgical exposure. Patient positioning, duration of procedure, need for abdominal distention, and desirability of increasing minute ventilation require use of general endotracheal anesthesia. Nitrous oxide is usually avoided to prevent bowel distention. Most laparoscopic prostatectomies are performed with robotic assistance, and the majority of radical prostatectomies in the United States are now performed via robot-assisted laparoscopy. When compared with open retropubic prostatectomy, laparoscopic robot-assisted prostatectomy is associated with a longer procedure time but with less blood loss and fewer blood transfusions, lower postoperative pain scores and lower opioid requirements, less postoperative nausea and vomiting, and shorter hospital length of stay. The steep Trendelenburg position can lead to head and neck tissue edema and to increased intraocular pressure. Complications reported to be associated with such positioning include upper airway edema and postextubation respiratory distress, postoperative visual loss involving ischemic optic neuropathy or retinal detachment, and brachial plexus injury. The surgeon should be routinely advised as to the length of time during which steep Trendelenburg positioning is maintained, and some centers have abandoned the routine use of this positioning entirely.

Most clinicians use a single large-bore intravenous catheter. The risk of hypothermia should be minimized by utilizing a forced-air warming blanket and an intravenous fluid warmer. Adequate postoperative analgesia is provided by ketorolac or acetaminophen, or both, and supplemented as needed with opioids. Postoperative epidural analgesia is not warranted because of relatively low postoperative pain scores and because patients may be discharged 24 h after
surgery.

C. Bilateral Orchiectomy
Bilateral orchiectomy may be performed for hormonal control of metastatic prostate cancer. The procedure is relatively short (20–45 min) and is performed through a single midline scrotal incision. Although bilateral orchiectomy can be performed with local or regional anesthesia, most patients and many clinicians prefer general anesthesia, usually administered via a laryngeal mask airway, or spinal anesthesia.

2. Bladder Cancer
Preoperative Considerations
Bladder cancer occurs at an average patient age of 65 years with a 3:1 male to female ratio. Transitional cell carcinoma of the bladder is second to prostate adenocarcinoma as the most common malignancy of the male genitourinary tract. The association of cigarette smoking with bladder carcinoma results in coexistent coronary artery and chronic obstructive pulmonary disease in many of these patients. Underlying kidney impairment, when present, may be age related or secondary to urinary tract obstruction. Staging includes cystoscopy and computed tomography (CT) or MRI scans. Intravesical chemotherapy is used for superficial tumors, and transurethral resection of bladder tumors (TURBT) is carried out via cystoscopy for low-grade, noninvasive bladder tumors. Some patients may receive preoperative radiation to shrink the tumor before radical cystectomy. Urinary diversion is usually performed immediately following cystectomy.

Intraoperative Considerations
A. Transurethral Bladder Resection
Bladder tumors may occur at various sites within the bladder, and laterally located tumors may lie in proximity to the obturator nerve. In such cases, if spinal anesthesia is administered or if general anesthesia is administered without use of a muscle relaxant, use of the cauter y resectoscope may result in stimulation of the obturator nerve and adduction of the legs. Urologists rarely derive amusement from having their ear struck by the patient’s knee; thus, in contrast to TURP, TURBT procedures are more commonly performed with
general anesthesia and neuromuscular blockade. TURBT, unlike TURP, is rarely associated with absorption of significant amounts of irrigating solution.

**B. Radical Cystectomy**

With radical cystectomy, all anterior pelvic organs—including the bladder, prostate, and seminal vesicles—are removed in men; the bladder, uterus, cervix, ovaries, and part of the anterior vaginal vault may be removed in women. Pelvic node dissection and urinary diversion are also carried out. Radical cystectomy is associated with the greatest risk of perioperative morbidity and mortality of all major urological procedures, especially in the elderly patient population. However, continuous improvements in neoadjuvant chemotherapy and enhanced recovery after surgery programs have been associated with progressively lower rates of perioperative morbidity and mortality as well as higher rates of 1- and 5-year survival. When compared with open radical cystectomy, robot-assisted radical cystectomy is associated with reduced perioperative complications, less blood loss and transfusion, and shorter hospital length of stay.

Duration of radical cystectomy is typically 4 to 6 h and blood transfusion is frequently utilized. General endotracheal anesthesia with a muscle relaxant provides optimal operating conditions. Controlled hypotensive anesthesia may reduce intraoperative blood loss and transfusion requirements in open cystectomy, and some surgeons also believe it improves surgical visualization. However, maintenance of mean arterial pressure below 55 to 65 mm Hg may be associated with increased risk of acute kidney injury and stroke. Continuous epidural anesthesia can facilitate the induced hypotension, decrease general anesthetic requirements, and facilitate postoperative analgesia. Optimized intraoperative fluid administration (using noninvasive cardiac output monitoring) may decrease blood transfusion requirements, postoperative complications, and hospital length-of-stay. Continuous epidural infusion or transversus abdominis plane (TAP) block is frequently used for postoperative analgesia.

Many clinicians will place an arterial catheter along with two large-bore intravenous lines. Urinary output is correlated with the progress of the operation, as the urinary collection path is interrupted at an early point during most of these procedures. As with all lengthy operative procedures, the risk of hypothermia is minimized by use of a forced-air warming blanket and intravenous fluid warming.

**C. Urinary Diversion**
Urinary diversion (ie, implanting the ureters into a segment of bowel) is usually performed immediately following radical cystectomy. The selected bowel segment is either left in situ, such as in ureterosigmoidostomy, or divided with its mesenteric blood supply intact and attached to a cutaneous stoma or urethra. Moreover, the isolated bowel can either function as a conduit (eg, ileal conduit) or be reconstructed to form a continent reservoir (neobladder). Conduits may be formed from ileum, jejunum, or colon.

Major anesthetic goals for urinary diversion procedures include keeping the patient well hydrated and maintaining a brisk urinary output once the ureters are opened. Neuraxial anesthesia often produces unopposed parasympathetic activity due to sympathetic blockade, which results in a contracted, hyperactive bowel that makes construction of a continent ileal reservoir technically difficult. Papaverine (100–150 mg as a slow intravenous infusion over 2–3 h), glycopyrrolate (1 mg), or glucagon (1 mg) may alleviate this problem.

Prolonged contact of urine with bowel mucosa (slow urine flow) may produce significant metabolic disturbances. Hyponatremia, hypochloremia, hyperkalemia, and metabolic acidosis can occur following construction of jejunal conduits. In contrast, colonic and ileal conduits may be associated with hyperchloremic metabolic acidosis. The use of temporary ureteral stents and maintenance of high urinary flow help alleviate this problem in the early postoperative period.

3. **Testicular Cancer**

**Preoperative Considerations**

Testicular tumors are classified as either seminomas or nonseminomas. The initial treatment for all tumors is radical (inguinal) orchiectomy, and subsequent management depends on tumor histology. Retroperitoneal lymph node dissection (RPLND) plays a major role in the staging and management of patients with nonseminomatous germ cell tumors. Low-stage disease is managed with RPLND or in some instances by surveillance. High-stage disease is usually treated with chemotherapy followed by RPLND.

In contrast to other tissue types, seminomas are very radiosensitive tumors that are primarily treated with retroperitoneal radiotherapy. Chemotherapy is used for patients who relapse after radiation. Patients with large bulky seminomas or those with increased α-fetoprotein levels (usually associated with nonseminomas) are treated primarily with chemotherapy. Chemotherapeutic
agents commonly include cisplatin, vincristine, vinblastine, cyclophosphamide, dactinomycin, bleomycin, and etoposide. RPLND is usually undertaken for patients with residual tumor after chemotherapy.

Patients undergoing RPLND for testicular cancer are typically young (15–35 years old) but are at increased risk for morbidity from the residual effects of preoperative chemotherapy and radiation therapy. In addition to bone marrow suppression, specific organ toxicity may be encountered, such as impaired kidney function following cisplatin, pulmonary fibrosis following bleomycin, and neuropathy following vincristine.

**Intraoperative Considerations**

**A. Radical Orchiectomy**

Inguinal orchiectomy can be carried out with regional or general anesthesia. Anesthetic management may be complicated by reflex bradycardia from traction on the spermatic cord.

**B. Retroperitoneal Lymph Node Dissection**

The retroperitoneum is usually accessed through a midline incision, but regardless of the surgical approach, all lymphatic tissue between the ureters from the renal vessels to the iliac bifurcation is removed. With the standard RPLND, all sympathetic fibers are disrupted, resulting in loss of normal ejaculation and infertility. A modified technique that may help preserve fertility limits the dissection below the inferior mesenteric artery to include lymphatic tissue only on the ipsilateral side of the testicular tumor.

Patients receiving bleomycin preoperatively may be particularly at risk for oxygen toxicity and fluid overload. Excessive intravenous fluid administration may promote pulmonary insufficiency or acute respiratory distress syndrome postoperatively and should be avoided. Anesthetic management should include use of the lowest inspired concentration of oxygen compatible with oxygen saturation above 90%. Positive end-expiratory pressure (5–10 cm H₂O) may help optimize oxygenation.

Evaporative and redistributive fluid losses with open RPLND can be considerable as a result of the large wound and the extensive surgical dissection. Retraction of the inferior vena cava during surgery often results in transient arterial hypotension.

Postoperative pain associated with open RPLND incisions is severe, and
continuous epidural analgesia, intrathecal morphine or hydromorphone, or TAP block should be considered. Because ligation of intercostal arteries during left-sided dissections has rarely resulted in paraplegia, it may be prudent to document normal motor function postoperatively prior to institution of epidural analgesia. The arteria radicularis magna (artery of Adamkiewicz), which is supplied by these vessels and is responsible for most of the arterial blood to the lower half of the spinal cord, arises on the left side in most individuals. It should be noted that unilateral sympathectomy following modified RPLND usually results in the ipsilateral leg being warmer than the contralateral one. Patients who have undergone RPLND frequently complain of severe bladder spasm pain in the postanesthesia care unit.

4. Kidney Cancer

Preoperative Considerations

Renal cell carcinoma is the cause of approximately 3% of all adult cancers and 95% of all kidney cancers. It has a peak incidence between the fifth and sixth decades of life, with 2:1 male to female ratio. It is commonly discovered as an incidental finding in the course of evaluating a supposedly unrelated medical problem, such as in an MRI performed for evaluation of low back pain. The classic triad of hematuria, flank pain, and palpable mass occurs in only 10% of patients, and the tumor often causes symptoms only after it has grown considerably in size. Renal cell carcinoma is frequently associated with paraneoplastic syndromes, such as erythrocytosis, hypercalcemia, hypertension, and nonmetastatic hepatic dysfunction. Tumors confined to the kidney may be treated by open or laparoscopic partial or total nephrectomy, or by percutaneous cryoablation or radiofrequency ablation. Palliative surgical treatment may involve more extensive tumor debulking. In approximately 5% to 10% of patients, the tumor extends into the renal vein and inferior vena cava as a thrombus (Figure 32–4), and in some cases approaches or enters the right atrium. Staging includes CT or MRI scans and an arteriogram. Preoperative arterial embolization may shrink the tumor mass and reduce operative blood loss.
FIGURE 32–4 Mayo classification of venous thrombus invasion in renal cell
Preoperative evaluation of the patient with renal carcinoma should focus on tumor staging, kidney function, the presence of coexisting systemic diseases, and anesthetic management needs dictated by the scope of anticipated surgical resection. Preexisting kidney function impairment depends upon tumor size in the affected kidney as well as coexisting systemic disorders such as hypertension, diabetes, and coronary artery disease. Smoking is a well-established risk factor for renal cell carcinoma, and these patients have a high incidence of underlying coronary artery and chronic obstructive lung disease. Although some patients present with erythrocytosis, the majority are anemic.

**Intraoperative Considerations**

**A. Percutaneous Cryoablation or Radiofrequency Ablation**

Relatively small kidney tumors without metastasis are commonly ablated by interventional radiologists using percutaneous cryoprobes or radiofrequency probes with ultrasonography or CT guidance. This may be performed on an outpatient or 23-h stay basis. Routine American Society of Anesthesiologists (ASA) monitors are used, and general endotracheal anesthesia with muscle relaxation is usually employed to minimize the risk of patient movement during the procedure. An indwelling urinary catheter is typically used if the procedure duration is anticipated to be more than approximately 2 to 3 h. Precautions must be taken for patients with pacemakers or ICDs who are undergoing radiofrequency ablation (see Chapter 21). The patient is typically placed in the lateral decubitus or prone position. The patient may experience significant postoperative pain of limited duration requiring intravenous analgesia.

**B. Radical Nephrectomy**

The operation may be carried out via an anterior subcostal, flank, or (rarely)
midline incision. Hand-assisted laparoscopic technique is often utilized for partial or total nephrectomy associated with a smaller tumor mass. Many centers prefer a thoracoabdominal approach for large tumors, particularly when a tumor thrombus is present. The kidney, adrenal gland, and perinephric fat are removed en bloc with the surrounding (Gerota) fascia. General endotracheal anesthesia is used, often in combination with epidural anesthesia.

This operation has the potential for extensive blood loss because these tumors are very vascular and often very large. Two large-bore intravenous lines with an indwelling peripheral arterial catheter are typically used. Transesophageal echocardiography (TEE), esophageal Doppler, or peripheral pulse wave analysis (Lidco or Vigileo) are often used for hemodynamic monitoring. TEE should be used for all patients with vena cava thrombus. Retraction of the inferior vena cava may be associated with transient arterial hypotension. Only brief periods of controlled hypotension should be used to reduce blood loss because of the potential for acute kidney injury in the contralateral kidney. Reflex vasoconstriction in the unaffected kidney can also result in postoperative kidney dysfunction.

If combined general–epidural anesthesia is employed, administration of epidural local anesthetic may be postponed until the risk of significant operative blood loss has passed. As with all lengthy operative procedures, the risk of hypothermia should be minimized by utilizing core temperature monitoring, a forced-air warming blanket and intravenous fluid warming. The postoperative course of subcostal, flank, or midline incision for open nephrectomy is extremely painful, and epidural analgesia is very useful in minimizing discomfort and accelerating convalescence.

C. Radical Nephrectomy with Excision of Tumor Thrombus
Because of the degree of physiological trespass and potential for major blood loss associated with this operation, the anesthetic management can be challenging. A thoracoabdominal approach allows the use of cardiopulmonary bypass when necessary.

Surgery can significantly prolong and improve quality of life, and in some patients, metastases may regress after resection of the primary tumor. A preoperative ventilation-perfusion scan may detect preexisting pulmonary embolization of the thrombus. Intraoperative TEE is helpful in determining whether the uppermost margin of the tumor thrombus extends to the diaphragm, above the diaphragm, into the right atrium, or even across the tricuspid valve. TEE can also be used to confirm the absence of tumor in the vena cava, right
atrium, and right ventricle after successful surgery.

The presence of a large thrombus (level II, III, or IV) complicates anesthetic management. Problems associated with massive blood transfusion should be anticipated (see Chapter 51). Central venous catheterization should be performed cautiously to prevent dislodgement and embolization of tumor thrombus extending into the right atrium. An increased central venous pressure is typical with significant caval thrombus and reflects the degree of venous obstruction. Pulmonary artery catheters risk dislodgement of right atrial tumor thrombus, and provide no useful information that cannot be obtained from TEE.

Complete obstruction of the inferior vena cava markedly increases operative blood loss because of dilated venous collaterals. Patients are also at significant risk for potentially catastrophic intraoperative pulmonary embolization of the tumor. Tumor embolization may be heralded by sudden supraventricular arrhythmias, arterial desaturation, and profound systemic hypotension. TEE is critical in this situation. Cardiopulmonary bypass may be used when the tumor cannot be pulled back from the right atrium into the cava. Heparinization and hypothermia greatly increase surgical blood loss.

KIDNEY TRANSPLANTATION

The success of renal transplantation, which is largely due to advances in immunosuppressive therapy, has greatly improved the quality of life for patients with end-stage kidney disease. With modern immunosuppressive regimens, cadaveric transplants have achieved almost the same 80% to 90% 3-year graft survival rate as living-related donor grafts.

Preoperative Considerations

Current organ preservation techniques allow ample time (24–48 h) for preoperative dialysis of cadaveric kidney recipients. Living-related transplants are performed electively with simultaneous donor and recipient operations. The recipient’s serum potassium concentration should be below 5.5 mEq/L, and existing coagulopathies should be corrected.

Intraoperative Considerations

Kidney transplantation is carried out by placing the donor kidney retroperitoneally in the iliac fossa and anastomosing the renal vessels to the iliac vessels and the ureter to the bladder. Heparin is administered prior to temporary
clamping of the iliac vessels. Intravenous mannitol administered to the recipient helps establish an osmotic diuresis following reperfusion. Immunosuppression is initiated on the day of surgery with a combination of medications that may include corticosteroids, cyclosporine or tacrolimus, azathioprine or mycophenolate mofetil, antithymocyte globulin, monoclonal antibodies directed against specific subsets of T lymphocytes (OKT3), and interleukin-2 receptor antibodies (daclizumab or basiliximab). The anesthesia provider should discuss in advance with the surgery team the timing and dosage of any immunosuppressive agents that will need to be given perioperatively. Recipient nephrectomy for a failed transplant may be performed for intractable hypertension or chronic infection.

A. Choice of Anesthesia
Most kidney transplants are performed with general anesthesia, although spinal and epidural anesthesia are also utilized. All general anesthetic agents have been employed without any apparent detrimental effect on graft function. Cisatracurium may be the muscle relaxant of choice, as it is not dependent upon renal excretion for elimination. With careful neuromuscular monitoring other relaxants can be used safely.

B. Monitoring
A urinary catheter is placed preoperatively in addition to routine monitors, and brisk urine flow following the arterial anastomosis generally indicates good graft function. If the graft ischemic time was prolonged, an oliguric phase may precede the diuretic phase, in which case intravenous fluid therapy must be appropriately adjusted. Administration of furosemide or additional mannitol may be indicated in such cases. Hyperkalemia has been reported after release of the vascular clamp following completion of the arterial anastomosis, particularly in pediatric and other small patients, and release of potassium contained in the preservative solution has been implicated as the cause of this phenomenon. Donor kidney washout of the preservative solution with ice-cold lactated Ringer’s solution just prior to the vascular anastomosis may help avoid this problem. Serum electrolyte concentrations (particularly potassium) should be monitored closely after completion of the anastomosis. Hyperkalemia may be suspected from peaking of the T wave on the ECG.
Hypotension in the Recovery Room

A 79-year-old man with a history of an inferior myocardial infarction was admitted to the recovery room following TURP under general anesthesia. The procedure took 90 min and was reported to be uncomplicated. On admission, the patient is extubated but still unresponsive, and vital signs are stable. Twenty minutes later, he is noted to be awake but restless. He begins to shiver intensely, his blood pressure decreases to 80/35 mm Hg, and his respirations increase to 40 breaths/min. The bedside monitor shows a sinus tachycardia of 140 beats/min and an oxygen saturation of 92%.

What is the differential diagnosis?

The differential diagnosis of hypotension following TURP should always include (1) hemorrhage, (2) TURP syndrome, (3) bladder perforation, (4) myocardial infarction or ischemia, (5) septicemia, and (6) disseminated intravascular coagulation (DIC).

Other possibilities (see Chapter 56) are less likely in this setting but should always be considered, particularly when the patient fails to respond to appropriate measures (see below).

Based on the history, what is the most likely diagnosis?

A diagnosis cannot be made with reasonable certainty at this point, and the patient requires further evaluation. Nonetheless, the hypotension and shivering must be treated rapidly because of the history of coronary artery disease. The hypotension seriously compromises coronary perfusion, and the shivering markedly increases myocardial oxygen demand (see Chapter 21).

What diagnostic aids would be helpful?

A quick examination of the patient is extremely useful in narrowing down the possibilities. Hemorrhage from the prostate should be apparent from effluent of the continuous bladder irrigation system placed after the procedure. Relatively little blood in the urine makes it look pink or red; brisk hemorrhage is often apparent as grossly bloody drainage. Occasionally, the drainage may be scant because of clots blocking the drainage catheter; irrigation of the catheter is indicated in such cases.
Clinical signs of peripheral perfusion are invaluable. Hypovolemic patients have decreased peripheral pulses, and their extremities are usually cool and may be cyanotic. Poor perfusion is consistent with hemorrhage, bladder perforation, DIC, and severe myocardial ischemia or infarction. A full, bounding peripheral pulse with warm extremities is suggestive of, but not always present in, septicemia. Signs of fluid overload should be searched for, such as jugular venous distention, pulmonary crackles, and an \$S_3\$ gallop. Fluid overload is more consistent with TURP syndrome, but may also be seen in myocardial infarction or ischemia.

The abdomen should be examined for signs of perforation. A rigid and tender or distended abdomen is very suggestive of perforation and should prompt immediate surgical evaluation. When the abdomen is soft and nontender, perforation can reasonably be excluded.

Further evaluation requires laboratory measurements, an ECG, a chest radiograph, and possibly a transthoracic echocardiogram. Blood should be immediately obtained for arterial blood gas analysis and measurements of hematocrit, hemoglobin, electrolytes, glucose, platelet count, and prothrombin and partial thromboplastin tests. If DIC is suggested by diffuse oozing, fibrinogen and fibrin split product measurements will confirm the diagnosis. A 12-lead ECG should be evaluated for evidence of ischemia or evolving myocardial infarction. A chest radiograph should be obtained to search for evidence of pulmonary congestion, aspiration, pneumothorax, or cardiomegaly. An echocardiogram helps determine end-diastolic volume and systolic function (particularly the presence or absence of regional wall motion abnormalities), and can detect valvular abnormalities; comparison to prior studies would be invaluable. Sonography of the abdomen can be used to detect extravasation.

**While laboratory measurements are being performed, what therapeutic and diagnostic measures should be undertaken?**

Immediate measures aimed at avoiding hypoxemia and hypoperfusion should be instituted. Supplemental oxygen should be administered, and endotracheal intubation is indicated if significant hypoventilation or respiratory distress is present. Frequent blood pressure measurements should be obtained. If signs of fluid overload are absent, a diagnostic fluid challenge with 300 to 500 mL of crystalloid or 250 mL of colloid is helpful. A favorable response, as indicated by an increase in blood pressure and a decrease in heart rate (or an increase in cardiac output as measured using a
noninvasive monitor) supports a diagnosis of hypovolemia and may indicate the need for additional fluid boluses. Obvious bleeding in the setting of anemia and hypotension necessitates blood transfusion. The absence of a quick response to intravenous fluid volume challenge should prompt further evaluation. Administration of an inotrope is appropriate should ventricular dysfunction be detected by echocardiography. Direct intraarterial pressure measurement is invaluable in this setting.

If signs of fluid overload are present, intravenous furosemide in addition to an inotrope is indicated.

*The patient’s axillary temperature is 35.5°C. Does the absence of obvious fever exclude sepsis?*

No. Anesthesia is commonly associated with altered temperature regulation. Moreover, correlation between axillary and core temperatures is quite variable (see Chapter 52). A high index of suspicion is therefore required to diagnose sepsis. Leukocytosis is common following surgery and is not a reliable indicator of sepsis in this setting.

The mechanism of shivering in patients recovering from anesthesia is poorly understood. Although shivering is common in patients who become hypothermic during surgery (and presumably functions to raise body temperature back to normal), its relation to body temperature is inconsistent. Anesthetics probably alter the normal behavior of hypothalamic thermoregulatory centers. In contrast, infectious agents, circulating toxins, or immune reactions cause the release of cytokines (interleukin-1 and tumor necrosis factor) that stimulate the hypothalamus to synthesize prostaglandin (PG) E₂. The latter, in turn, activates neurons responsible for heat production, resulting in intense shivering.

*How can the shivering be stopped?*

Regardless of its cause, shivering has the undesirable effects of markedly increasing metabolic oxygen demand (100–200%) and CO₂ production. Both cardiac output and minute ventilation must therefore increase, and these effects are often poorly tolerated by patients with limited cardiac or pulmonary reserve. Although the ultimate therapeutic goal is to correct the underlying problem, additional measures are indicated in this patient. Supplemental oxygen therapy addresses hypoxemia. Meperidine in small doses (12.5–25 mg intravenously) frequently terminates shivering regardless of the cause. Shivering associated with sepsis and immune
reactions can also be moderated or abolished by prostaglandin synthetase inhibitors (aspirin, acetaminophen, and nonsteroidal antiinflammatory agents), of which only acetaminophen would likely be appropriate until hemorrhage was ruled out because it does not affect platelet function.

**What was the outcome?**

Examination of the patient reveals warm extremities with a good pulse, even with the low blood pressure. The abdomen is soft and nontender. The irrigation fluid from the bladder is only slightly pink. A diagnosis of probable sepsis is made. Blood cultures are obtained and antibiotic therapy is initiated to cover gram-negative organisms and enterococci, the most common pathogens. The patient receives empiric antibiotic coverage and a dopamine infusion is initiated. In settings of redistributive, vasodilatory shock, additional vasoconstrictors (eg, vasopressin) may be needed. The shivering ceases following administration of meperidine, 12.5 mg intravenously. The blood pressure increases to 110/60 mm Hg and the heart rate slows to 90 beats/min following a 1000 mL intravenous fluid bolus and initiation of a 5-mcg/kg/min dopamine infusion. The serum sodium concentration was found to be 130 mEq/L. Four hours later, dopamine was no longer needed and was discontinued. The patient’s subsequent recovery was uneventful.

**SUGGESTED READINGS**

Krejewski W, Zdrojowy R, Tupikowski K, et al. How to lower postoperative
complications after radical cystectomy—a review. *Central Eur J Urol.*

KEY CONCEPTS

1. The hepatic artery supplies about 25% of the blood supply but 45% to 50% of the liver’s oxygen requirements, and the portal vein supplies 75% of the blood supply and the remaining 50% to 55% of oxygen requirements.

2. All coagulation factors, with the exception of factor VIII and von Willebrand factor, are produced by the liver. Vitamin K is a necessary cofactor in the synthesis of prothrombin (factor II) and factors VII, IX, and X.

3. Many “liver function” tests, such as serum transaminase measurements, reflect hepatocellular integrity more than hepatic function. Liver tests that measure hepatic synthetic function include serum albumin, prothrombin time (PT) or international normalized ratio (INR), serum cholesterol, and plasma pseudocholinesterase.

4. Albumin values less than 2.5 g/dL are generally indicative of chronic liver disease, acute stress, or severe malnutrition. Increased losses of albumin in the urine (nephrotic syndrome) or the gastrointestinal tract (protein-losing enteropathy) can also produce hypoalbuminemia.

5. The PT, which normally ranges between 11 and 14 s, depending on the control value, measures the activity of fibrinogen, prothrombin, and factors V, VII, and X. A prolonged INR reflects a patient with a dysfunctional liver. The effect on coagulation will depend on the balance between coagulation and anticoagulation factors. If production of protein C, protein S, and antithrombin 3, are affected more than the coagulation factors a normal or hypercoaguable state might exist. The INR was developed to monitor the effect of warfarin and that does not
affect the anticoagulant factors.

Operative procedures near the liver can reduce hepatic blood flow up to 60%. Although the mechanisms are not clear, they most likely involve sympathetic activation, local reflexes, and direct compression of vessels in the portal and hepatic circulations.

The neuroendocrine stress response to surgery and trauma is characterized by elevated circulating levels of catecholamines, glucagon, and cortisol and results in mobilization of carbohydrate stores and proteins, causing hyperglycemia and a negative nitrogen balance (catabolism).

All opioids can potentially cause spasm of the sphincter of Oddi and increase biliary pressure.

When liver tests are abnormal postoperatively, the usual cause is underlying liver disease or the surgical procedure itself.

FUNCTIONAL ANATOMY

The liver is the heaviest organ in the body, weighing approximately 1500 g in adults. It is separated by the falciform ligament into right and left anatomic lobes; the larger right lobe has two additional smaller lobes at its posterior–inferior surface, the caudate and quadrate lobes.

In contrast, surgeons describe the liver based on its blood supply. Thus, the right and left surgical lobes are defined by anatomists by the point of bifurcation of the hepatic artery and portal vein (porta hepatis); the falciform ligament therefore divides the left surgical lobe into medial and lateral segments. Surgical anatomy defines a total of eight segments.

The liver is made up of 50,000 to 100,000 discrete anatomic units called lobules. Each lobule is composed of plates of hepatocytes arranged cylindrically around a centrilobular vein (Figure 33–1). Four to five portal tracts, composed of hepatic arterioles, portal venules, bile canaliculi, lymphatics, and nerves, surround each lobule.
In contrast to a lobule, an *acinus*, the functional unit of the liver, is defined by a portal tract in the middle and centrilobular veins at the periphery. Cells closest to the portal tract (zone 1) are well oxygenated; those closest to centrilobular veins (zone 3) receive the least oxygen and are therefore most susceptible to ischemic injury.

Blood from hepatic arterioles and portal venules comingle in the *sinusoidal channels*, which lie between the cellular plates and serve as capillaries. These channels are lined by endothelial cells and by macrophages known as *Kupffer cells*. The Kupffer cells remove bacterial endotoxins, viruses, proteins, and particulate matter from the blood. The *space of Disse* lies between the sinusoidal capillaries and the hepatocytes. Venous drainage from the central veins of hepatic lobules coalesces to form the hepatic veins (right, middle, and left), which empty into the inferior vena cava (Figure 33–2). The caudate lobe is usually drained by its own set of veins.
Bile canaliculi originate between hepatocytes within each plate and join to form bile ducts. An extensive system of lymphatic channels also forms within the plates and is in direct communication with the space of Disse.

The liver is supplied by T6–T11 sympathetic nerve fibers, right and left vagal nerve parasympathetic fibers, and right phrenic nerve fibers. Some autonomic fibers synapse first in the celiac plexus, whereas others reach the liver directly via splanchnic nerves and vagal branches before forming the hepatic plexus. The majority of sensory afferent fibers travel with sympathetic fibers.

**Hepatic Blood Flow**

Normal hepatic blood flow is 25% to 30% of the cardiac output and is provided by the hepatic artery and portal vein. The hepatic artery supplies about 25% of the blood supply but 45% to 50% of the liver’s oxygen requirements, and the portal vein supplies 75% of the blood supply and the remaining 50% to 55%
(Figure 33–2). Hepatic arterial flow is dependent on metabolic demand (autoregulation), whereas flow through the portal vein is dependent on blood flow to the gastrointestinal tract and the spleen. A reciprocal, though somewhat limited, mechanism exists, such that a decrease in either hepatic arterial or portal venous flow results in a compensatory increase in the other.

The hepatic artery has $\alpha_1$-adrenergic vasoconstriction receptors as well as $\beta_2$-adrenergic, dopaminergic ($D_1$), and cholinergic vasodilator receptors. The portal vein has only $\alpha_1$-adrenergic and dopaminergic ($D_1$) receptors. Sympathetic activation results in vasoconstriction of the hepatic artery and mesenteric vessels, decreasing hepatic blood flow. $\beta$-Adrenergic stimulation vasodilates the hepatic artery; $\beta$-blockers reduce blood flow and, therefore, decrease portal pressure.

**Reservoir Function**

Portal vein pressure is normally only about 7 to 10 mm Hg, but the low resistance of the hepatic sinusoids allows relatively large blood flows through the portal vein. Small changes in hepatic venous tone and hepatic venous pressure thus can result in large changes in hepatic blood volume, allowing the liver to act as a blood reservoir (Figure 33–3). A decrease in hepatic venous pressure, as occurs during hemorrhage, shifts blood from hepatic veins and sinusoids into the central venous circulation and augments circulating blood volume. Blood loss can be reduced during liver surgery by lowering the central venous pressure, thereby reducing hepatic venous pressure and hepatic blood volume. In patients with congestive heart failure, the increase in central venous pressure is transmitted to the hepatic veins and causes congestion of the liver that can adversely affect liver function.
FIGURE 33–3 The role of the liver as a blood reservoir. (Modified with permission from Lautt WW, Greenway CV. Hepatic venous compliance and role of liver as a blood reservoir. Am J Physiol. 1976 Aug;231(2):292-295.)

**Metabolic Function**

The abundance of enzymatic pathways in the liver allows it to play a key role in the metabolism of carbohydrates, fats, proteins, and other substances (Figure 33–4 and Table 33–1). The final products of carbohydrate digestion are glucose, fructose, and galactose. With the exception of the large amount of fructose that is converted by the liver to lactate, hepatic conversion of fructose and galactose into glucose makes glucose metabolism the final common pathway for most carbohydrates.
FIGURE 33–4 Important metabolic pathways in hepatocytes. Although small amounts of adenosine triphosphate (ATP) are derived directly from some intermediary reactions, the overwhelming majority of ATP produced is the result of oxidative phosphorylation of the reduced forms of nicotinamide adenine dinucleotide (NADH) and nicotinamide adenine dinucleotide phosphate (NADPH).

All cells utilize glucose to produce energy in the form of adenosine triphosphate (ATP), either aerobically via the citric acid cycle or anaerobically via glycolysis. The liver and adipose tissue can also utilize the phosphogluconate pathway, which provides energy and fatty acid synthesis. Most of the glucose absorbed following a meal is normally stored as glycogen, which only the liver and muscle are able to store in significant amounts. When glycogen storage capacity is exceeded, excess glucose is converted into fat. Insulin enhances glycogen synthesis, and epinephrine and glucagon enhance glycogenolysis. Because glucose consumption averages 150 g/d, and hepatic glycogen stores are normally depleted after 24 h of fasting. After this period of fasting, gluconeogenesis, the de novo synthesis of glucose, is necessary to provide an uninterrupted supply of glucose for other organs.

The liver and kidney are unique in their capacity to form glucose from lactate, pyruvate, amino acids (mainly alanine), and glycerol (derived from fat metabolism). Hepatic gluconeogenesis is vital in the maintenance of a normal blood glucose concentration. Glucocorticoids, catecholamines, glucagon, and thyroid hormone greatly enhance gluconeogenesis, whereas insulin inhibits it.

When carbohydrate stores are saturated, the liver converts the excess ingested carbohydrates and proteins into fat. The fatty acids thus formed can be used immediately for fuel or stored in adipose tissue or the liver for later consumption. Nearly all cells utilize fatty acids derived from ingested fats or synthesized from intermediary metabolites of carbohydrates and protein as an energy source—only red blood cells and the renal medulla are limited to glucose utilization. Neurons normally utilize only glucose, but, after a few days of starvation, they can switch to ketone bodies, the breakdown products of fatty
acids that have been synthesized by the liver as an energy source.

To oxidize fatty acids, they are converted into acetylcoenzyme A (acetyl-CoA), which is then oxidized via the citric acid cycle to produce ATP. The liver is capable of high rates of fatty acid oxidation and can form acetoacetic acid (one of the ketone bodies) from excess acetyl-CoA. The acetoacetate released by hepatocytes serves as an alternative energy source for other cell types by reconversion into acetyl-CoA. Insulin inhibits hepatic ketone body production. Acetyl-CoA is also used by the liver for the production of cholesterol and phospholipids, which is necessary in the synthesis of cellular membranes throughout the body.

The liver performs a critical role in protein metabolism. The steps involved in protein metabolism include (1) deamination of amino acids, (2) formation of urea (to eliminate the ammonia produced from deamination), (3) interconversions between nonessential amino acids, and (4) formation of plasma proteins. Deamination is necessary for the conversion of excess amino acids into carbohydrates and fats. The enzymatic processes, most commonly transamination, convert amino acids into their respective keto acids and produce ammonia as a byproduct.

Ammonia formed from deamination (as well as that produced by colonic bacteria and absorbed through the gut) is highly toxic to tissues. Through a series of enzymatic steps, the liver combines two molecules of ammonia with CO₂ to form urea. The urea thus formed readily diffuses out of the liver and can then be excreted by the kidneys.

Nearly all plasma proteins, with the notable exception of immunoglobulins, are formed by the liver. These include albumin, α₁-antitrypsin and other proteases/elastases, and the coagulation factors. Albumin, the most abundant plasma protein, is responsible for maintaining a normal plasma oncotic pressure and is the principal binding and transport protein for fatty acids and a large number of hormones and drugs. Consequently, changes in albumin concentration can affect the concentration of the pharmacologically active, unbound fraction of many drugs.

All coagulation factors, with the exception of factor VIII and von Willebrand factor, are produced by the liver (Table 33–2 and Figure 33–5; see Chapter 51). The liver also produces anticoagulant factors (protein C, protein S, and antithrombin III). Vascular endothelial cells synthesize factor VIII, levels of which are therefore usually maintained in chronic liver disease. Vitamin K is a necessary cofactor in the synthesis of prothrombin (factor II) and factors VII, IX, and X. The liver also produces plasma cholinesterase (pseudocholinesterase), an
enzyme that hydrolyzes esters, including ester local anesthetics and some muscle relaxants, including succinylcholine. Other important proteins formed by the liver include protease inhibitors (antithrombin III, α₂-antiplasmin, and α₁-antitrypsin), transport proteins (transferrin, haptoglobin, and ceruloplasmin), complement, α₁-acid glycoprotein, C-reactive protein, and serum amyloid A.

Drug Metabolism

Many exogenous substances, including most drugs, undergo hepatic biotransformation, and the end products of these reactions are usually either inactivated or converted to more water-soluble substances that can be readily excreted in bile or urine. Hepatic biotransformations are often categorized as one of two types of reactions. *Phase I reactions* modify reactive chemical groups through mixed-function oxidases or the cytochrome P-450 enzyme systems, resulting in oxidation, reduction, deamination, sulfoxidation, dealkylation, or methylation. Barbiturates and benzodiazepines are inactivated by phase I reactions. *Phase II reactions*, which may or may not follow a phase I reaction, involve conjugation of the substance with glucuronide, sulfate, taurine, or glycine. The conjugated compound can then be readily eliminated in urine or bile.

Some enzyme systems, such as those of cytochrome P-450, can be induced by exposure to drugs such as ethanol, barbiturates, ketamine, and perhaps benzodiazepines. This can result in increased tolerance to the drugs’ effects. Conversely, some agents, such as cimetidine and chloramphenicol, can prolong the effects of other drugs by inhibiting these enzymes. Some drugs, including lidocaine, morphine, verapamil, labetalol, and propranolol, have very high rates of hepatic extraction from the circulation, and their metabolism is therefore highly dependent upon the rate of hepatic blood flow. As a result, a decrease in their metabolic clearance usually reflects decreased hepatic blood flow rather than hepatocellular dysfunction.

The liver plays a major role in hormone, vitamin, and mineral metabolism. It is an important site for the conversion of thyroxine (T<sub>4</sub>) into the more active triiodothyronine (T<sub>3</sub>). The liver is also the major site of degradation for thyroid hormone, insulin, steroid hormones (estrogen, aldosterone, and cortisol), glucagon, and antidiuretic hormone. Hepatocytes are the principal storage sites for vitamins A, B<sub>12</sub>, E, D, and K. Lastly, hepatic production of transferrin and haptoglobin is important because these proteins are involved in iron hemostasis, whereas ceruloplasmin is important in copper regulation.

Bile Formation

Bile (Table 33–3) plays an important role in absorption of fat and excretion of bilirubin, cholesterol, and many drugs. Hepatocytes continuously secrete bile salts, cholesterol, phospholipids, conjugated bilirubin, and other substances into
bile canaliculi.

Bile ducts from hepatic lobules join and eventually form the *right and left hepatic ducts*. These ducts, in turn, combine to form the *hepatic duct*, which together with the *cystic duct* from the gallbladder becomes the *common bile duct* ([Figure 33–6](figure33-6)). The gallbladder serves as a reservoir for bile. The bile acids formed by hepatocytes from cholesterol are essential for emulsifying the insoluble components of bile and facilitating the intestinal absorption of lipids. Defects in the formation or secretion of bile salts interfere with the absorption of fats and fat-soluble vitamins (A, D, E, and K). Because of limited stores of vitamin K, a deficiency of this fat-soluble vitamin can develop within a few days. **Vitamin K deficiency is manifested as a coagulopathy due to impaired formation of prothrombin and of factors VII, IX, and X.**
FIGURE 33-6  The biliary system. (Modified with permission from Guyton AC. Textbook of Medical Physiology. 7th ed. Philadelphia, PA: WB Saunders; 1986.)

Bilirubin is primarily the end product of hemoglobin metabolism, and it is formed from degradation of the heme ring in Kupffer cells. Bilirubin is then released into blood, where it readily binds to albumin. Hepatic uptake of bilirubin from the circulation is passive, but binding to intracellular proteins traps the bilirubin inside hepatocytes. Bilirubin is conjugated by the hepatocytes, primarily with glucuronide, and actively excreted into bile canaliculi.

**LIVER TESTS**

The most commonly performed liver tests are neither sensitive nor specific. No one laboratory test evaluates overall hepatic function, reflecting instead one aspect of hepatic function that must be interpreted in conjunction with other tests and clinical assessment of the patient.

Many “liver function” tests, such as serum transaminase measurements, reflect hepatocellular integrity more than hepatic function. Liver tests that measure hepatic synthetic function include serum albumin, prothrombin time (PT) or international normalized ratio (INR), serum cholesterol, and plasma pseudocholinesterase. Moreover, because of the liver’s large functional reserve,
substantial cirrhosis may be present with few or no laboratory abnormalities evident.

Liver abnormalities can often be divided into either parenchymal disorders or obstructive disorders based on laboratory tests (Table 33–4). Obstructive disorders primarily affect biliary excretion of substances, whereas parenchymal disorders result in generalized hepatocellular dysfunction.

**TABLE 33–4 Abnormalities in liver tests.**

**Serum Bilirubin**

The normal total bilirubin concentration, composed of conjugated (direct), water-soluble and unconjugated (indirect), lipid-soluble forms, is less than 1.5
mg/dL (<25 mmol/L) and reflects the balance between bilirubin production and excretion. Jaundice is usually clinically obvious when total bilirubin exceeds 3 mg/dL. A predominantly conjugated hyperbilirubinemia (>50%) is associated with increased urinary urobilinogen and may reflect hepatocellular dysfunction, congenital (Dubin–Johnson or Rotor syndrome) or acquired intrahepatic cholestasis, or extrahepatic biliary obstruction. Hyperbilirubinemia that is primarily unconjugated may be seen with hemolysis or with congenital (Gilbert or Crigler–Najjar syndrome) or acquired defects in bilirubin conjugation. Unconjugated bilirubin is neurotoxic, and high levels may produce encephalopathy.

**Serum Aminotransferases (Transaminases)**

These enzymes are released into the circulation as a result of hepatocellular injury or death. Two aminotransferases are most commonly measured: aspartate aminotransferase (AST), also known as serum glutamic-oxaloacetic transaminase (SGOT); and alanine aminotransferase (ALT), also known as serum glutamic pyruvic-transferase (SGPT).

**Serum Alkaline Phosphatase**

Alkaline phosphatase is produced by the liver, bone, small bowel, kidneys, and placenta and is excreted into bile. Normal serum alkaline phosphatase activity is 25 to 85 IU/L; children and adolescents have much higher levels, reflecting active growth. Most circulating alkaline phosphatase is normally derived from bone; however, with biliary obstruction, more hepatic alkaline phosphatase is synthesized and released into the circulation.

**Serum Albumin**

The normal serum albumin concentration is 3.5 to 5.5 g/dL. Because its half-life is approximately 2 to 3 weeks, albumin concentration may initially be normal with acute liver disease. Albumin values less than 2.5 g/dL are generally indicative of chronic liver disease, acute stress, or severe malnutrition. Increased losses of albumin in the urine (nephrotic syndrome) or the gastrointestinal tract (protein-losing enteropathy) can also produce hypoalbuminemia.

**Blood Ammonia**
Significant elevations of blood ammonia levels usually reflect disruption of hepatic urea synthesis. Normal whole blood ammonia levels are 47 to 65 mmol/L (80–110 mg/dL). Marked elevations usually reflect severe hepatocellular damage and may cause encephalopathy.

**Prothrombin Time**

The PT, which normally ranges between 11 and 14 s, measures the activity of fibrinogen, prothrombin, and factors V, VII, and X. The relatively short half-life of factor VII (4–6 h) makes the PT useful in evaluating hepatic synthetic function of patients with acute or chronic liver disease. Prolongations of the PT greater than 3 to 4 s from the control are considered significant and usually correspond to an INR greater than 1.5. This INR reflects liver dysfunction but not the degree of coagulopathy. If protein C, protein S, and antithrombin 3 are more depressed than the coagulation factors the patient may have normal clotting or be hypercoaguable. The INR was designed to reflect warfarin activity not liver function. This is of great clinical importance as a prolonged INR after liver surgery may result in venous thromboembolic prophylaxis being withheld until the INR normalizes. This may leave the patient at increased risk for a pulmonary embolus. *Because only 20% to 30% of normal factor activity is required for normal coagulation, prolongation of the PT usually reflects either severe liver disease or vitamin K deficiency.* See **Table 33–5** for a list of coagulation test abnormalities. Patients are increasingly treated with factor Xa inhibitors (eg, apixaban, rivaroxaban) for prevention of thrombosis. Direct assays of anti-factor Xa activity may be employed to monitor their effects. The direct thrombin inhibitor dabigatran is also currently prescribed for prophylaxis.

**TABLE 33–5  Coagulation test abnormalities.**

---
Point-of-Care Viscoelastic Coagulation Monitoring

This technology provides a “real time” assessment of the coagulation status and utilizes thromboelastograph (TEG), rotation thromboelastometry (ROTEM), or Sonoclot analysis to assess global coagulation via the viscoelastic properties of whole blood (Figure 33–7). A clear picture is provided of the global effect of balance between the procoagulant and anticoagulant systems and the profibrinolytic and antifibrinolytic systems and the resultant clot tensile strength, allowing precise management of hemostatic therapy. The rate of clot formation, the strength of the clot, and the impact of any clot lysis can be observed. The presence of disseminated intravascular coagulation can be evaluated, as can the effect of heparin or heparinoid activity. In addition, platelet function can be assessed, including the effects of platelet inhibition. Viscoelastic coagulation monitoring is particularly important when assessing the coagulation and thromboembolic risk of the patient who has a prolonged INR from liver dysfunction and has undergone, or is about to undergo, procedural care. Coagulopathy is a balance of the procoagulant and anticoagulant factors produced by the liver, and the INR only examines the procoagulant side. A patient with an INR of 3, for example, may have also have anticoagulant factors so reduced that in fact the patient is in a hypercoagulable state and thereby actually at increased risk for venous thromboembolism. This risk can be readily evaluated by viscoelastic testing.

EFFECT OF ANESTHESIA ON HEPATIC FUNCTION

Hepatic blood flow usually decreases during regional and general anesthesia, and multiple factors are responsible, including both direct and indirect effects of anesthetic agents, the type of ventilation employed, and the type of surgery being performed.

Decreases in cardiac output reduce hepatic blood flow. The hemodynamic effects of ventilation can also have a significant impact on hepatic blood flow. Controlled positive-pressure ventilation with high mean airway pressures reduces venous return and cardiac output, and can compromise hepatic blood flow. The former increases hepatic venous pressure, whereas the latter can reduce blood pressure and increase sympathetic tone. Positive end-expiratory pressure (PEEP) further accentuates these effects.

Operative procedures near the liver can reduce hepatic blood flow up to 60%. Although the mechanisms are not clear, they most likely involve sympathetic activation, local reflexes, and direct compression of vessels in the portal and hepatic circulations.

β-Adrenergic blockers, α₁-adrenergic agonists, H₂-receptor blockers, and vasopressin reduce hepatic blood flow. Dopamine infusions (0.5–2.5 mcg/kg/min) may increase liver blood flow.
**Metabolic Functions**

The effects of the various anesthetic agents on hepatic metabolism are poorly defined. An endocrine stress response secondary to fasting and surgical trauma is generally observed. The neuroendocrine stress response to surgery and trauma is characterized by elevated circulating levels of catecholamines, glucagon, and cortisol and results in the mobilization of carbohydrate stores and protein, causing hyperglycemia and negative nitrogen balance (catabolism). The neuroendocrine stress response may be at least partially blunted by regional anesthesia, deep general anesthesia, or pharmacological blockade of the sympathetic system, with regional anesthesia having the most salutary effect on catabolism. All opioids can potentially cause spasm of the sphincter of Oddi and increase biliary pressure. Naloxone and glucagon may relieve opioid-induced spasm.

Procedures in close proximity to the liver frequently result in modest elevations in lactate dehydrogenase and transaminase concentrations regardless of the anesthetic agent or technique employed. When liver function tests are abnormal postoperatively, the usual cause is underlying liver disease or the surgical procedure itself. Persistent abnormalities in liver tests may be indicative of viral hepatitis, sepsis, idiosyncratic drug reactions, or surgical complications. **Postoperative jaundice can result from a variety of factors (Table 33–6), but the most common cause is overproduction of bilirubin because of resorption of a large hematoma or red cell breakdown following transfusion.** Nonetheless, all other causes should be considered. Correct diagnosis requires a careful review of preoperative liver function and of intraoperative and postoperative events, such as transfusions, sustained hypotension or hypoxemia, and drug exposure. Desflurane, sevoflurane, and isoflurane have minimal, if any, direct adverse effect upon hepatocytes.

Coagulopathy in a Patient with Liver Disease (also see Chapter 51)

A 52-year-old man with a long history of alcohol abuse presents for a splenorenal shunt after three major episodes of upper gastrointestinal hemorrhage from esophageal varices. Coagulation studies reveal a PT of 17 s (control: 12 s), INR of 1.7, and a partial PT of 43 s (control: 29 s). The platelet count is 75,000/μL.

What factors can contribute to excessive bleeding during and following surgery?

Hemostasis following trauma or surgery is dependent on three major processes: (1) vascular spasm, (2) formation of a platelet plug (primary hemostasis), and (3) coagulation of blood (secondary hemostasis) in addition to adequate surgical control of bleeding sites. The first two are nearly immediate (seconds), whereas the third is delayed (minutes). A defect in any of these processes can lead to a bleeding diathesis and increased blood loss.

Outline the mechanisms involved in primary hemostasis.
Injury to smaller blood vessels normally causes localized spasm as a result of the release of humoral factors from platelets and local myogenic reflexes. Sympathetic-mediated vasoconstriction is also operative in medium-sized vessels. Exposure of circulating platelets to the damaged endothelial surface causes them to undergo a series of changes that results in the formation of a platelet plug. If the break in a vessel is small, the plug itself can often completely stop bleeding. If the break is large, however, coagulation of blood is also necessary to stop the bleeding.

Formation of the platelet plug can be broken down into three stages: (1) adhesion, (2) release of platelet granules, and (3) aggregation. Following injury, circulating platelets adhere to subendothelial collagen via specific glycoprotein (GP) receptors on their membrane. This interaction is stabilized by a circulating GP called von Willebrand factor (vWF), which forms additional bridges between subendothelial collagen and platelets via GPIb. Collagen (as well as epinephrine and thrombin) activates platelet membrane-bound phospholipases A and C, which, in turn, results in the formation of thromboxane A\(_2\) (TXA\(_2\)) and platelet degranulation. TXA\(_2\) is a potent vasoconstrictor that also promotes platelet aggregation. Platelet granules contain a large number of substances, including adenosine diphosphate (ADP), factor V, vWF, fibrinogen, and fibronectin. These factors attract and activate additional platelets. ADP alters platelet membrane GP\(\text{IIb/IIIa}\), which facilitates the binding of fibrinogen to activated platelets.

Describe the mechanisms involved in normal coagulation.

Coagulation, often referred to as secondary hemostasis, involves formation of a fibrin clot, which usually binds and strengthens a platelet plug. Fibrin can be formed via one of two pathways (extrinsic or intrinsic; see Figure 33–5) that involve calcium and activation of soluble coagulation precursor proteins in blood (see Table 33–2). Regardless of which pathway is activated, the coagulation cascade ends in the conversion of fibrinogen to fibrin. The extrinsic pathway of the coagulation cascade is triggered by the release of a tissue lipoprotein, thromboplastin, from the membranes of injured cells and is likely the more important pathway. The intrinsic pathway can be triggered by the interaction between subendothelial collagen with circulating Hageman factor (XII), high-molecular-weight kininogen, and prekallikrein. The latter two substances are also involved in the formation of bradykinin.
Thrombin plays a central role in coagulation because it not only activates platelets, but also accelerates conversion of factors V, VIII, and XIII to their active forms. Conversion of prothrombin to thrombin is markedly accelerated by activated platelets. Thrombin then converts fibrinogen to soluble fibrin monomers that polymerize on the platelet plug. The cross-linking of fibrin polymers by factor XIII is necessary to form a strong, insoluble fibrin clot. Finally, retraction of the clot, which requires platelets, expresses fluid from the clot and helps pull the walls of the damaged blood vessel together.

**What prevents coagulation of blood in normal tissues?**

The coagulation process is limited to injured areas by localization of platelets to the injured area and by maintenance of normal blood flow in uninjured areas. Normal endothelium produces prostacyclin (prostaglandin I$_2$, PGI$_2$), which is a potent vasodilator that also inhibits platelet activation and helps to confine the primary hemostatic process to the injured area. Normal blood flow is important in clearing activated coagulation factors, which are taken up by the monocyte–macrophage scavenger system. Multiple inhibitors of coagulation are normally present in plasma, including antithrombin III, protein C, protein S, and tissue factor pathway inhibitor. Antithrombin III complexes with and inactivates circulating coagulation factors (with the notable exception of factor VII), and protein C specifically inactivates factors V and VIII. Heparin exerts its anticoagulant activity by augmenting the activity of antithrombin III. Protein S enhances the activity of protein C, and deficiencies of protein C and protein S lead to hypercoagulability. Tissue factor pathway inhibitor antagonizes the action of activated factor VII.

**What is the role of the fibrinolytic system in normal hemostasis?**

The fibrinolytic system is normally activated simultaneously with the coagulation cascade and functions to maintain the fluidity of blood during coagulation. It is also responsible for clot lysis once tissue repair begins. When a clot is formed, a large amount of the protein plasminogen is incorporated. Plasminogen is then activated by tissue plasminogen activator (tPA), which is usually released by endothelial cells in response to thrombin, and by Hageman factor (XII). The resulting formation of plasmin degrades fibrin and fibrinogen, as well as other coagulation factors. Urokinase (found in urine) and streptokinase (a product of bacteria) are also
potent activators of plasminogen to plasmin. The action of tPA is localized because (1) it is absorbed into the fibrin clot, (2) it activates plasminogen more effectively on the clot, (3) free plasmin is rapidly neutralized by a circulating α2-antiplasmin, and (4) circulating tPA is cleared by the liver. Plasmin degrades fibrin and fibrinogen into small fragments. These fibrin degradation products possess anticoagulant activity because they compete with fibrinogen for thrombin; they are normally cleared by the monocyte–macrophage system. The drugs ε-aminocaproic acid (EACA) and tranexamic acid inhibit the conversion of plasminogen to plasmin. Endothelium also normally secretes a plasminogen activator inhibitor (PAI-1) that antagonizes tPA.

What hemostatic defects are likely to be present in this patient?

Multifactorial coagulopathy often develops in patients with advanced liver disease. Three major causes are usually responsible: (1) vitamin K deficiency due to dietary deficiency or to impaired absorption or storage, (2) impaired hepatic synthesis of coagulation factors, and (3) splenic sequestration of platelets resulting from hypersplenism. To complicate matters further, patients with cirrhosis typically have multiple potential bleeding sites (esophageal varices, gastritis, peptic ulcers, and hemorrhoids) and frequently require multiple blood transfusions. With severe liver disease, patients may also have decreased synthesis of coagulation inhibitors and may fail to clear activated coagulation factors and fibrin split products because of impaired Kupffer cell function; the resultant coagulation defect resembles, and becomes indistinguishable from, disseminated intravascular coagulation (DIC).

What is DIC?

In DIC, the coagulation cascade is activated by the release of endogenous tissue thromboplastin or thromboplastin-like substances, or by direct activation of factor XII by endotoxin or foreign surfaces. Widespread deposition of fibrin in the microcirculation results in consumption of coagulation factors, secondary fibrinolysis, acute severe thrombocytopenia, and a microangiopathic hemolytic anemia. Diffuse bleeding, and, in some cases, thromboembolic phenomena, usually follows. Treatment is generally aimed at the underlying cause. Supportive measures include transfusion of coagulation factors and platelets. Heparin therapy is controversial but may benefit patients with thromboembolic phenomena.
What is primary fibrinolysis?

This bleeding disorder is due to uncontrolled fibrinolysis. Patients may have a deficiency of α₂-antiplasmin or impaired clearance of tPA. The latter may be common in patients with severe liver disease and during the anhepatic phase of liver transplantation. The disorder may occasionally be encountered in patients with carcinoma of the prostate. Diagnosis is often difficult, but is suggested by a bleeding diathesis with a low fibrinogen level but relatively normal coagulation tests and platelet count (as noted next). Treatment includes fresh frozen plasma or cryoprecipitate and possibly either EACA or tranexamic acid.

How are coagulation tests helpful in evaluating inadequate hemostasis?

The diagnosis of coagulation abnormalities can be facilitated by measurement of the activated partial thromboplastin time (aPTT), PT, thrombin time (TT), fibrin degradation products, and fibrinogen level (see Table 33–5). The aPTT measures the intrinsic pathway (factors I, II, V, VIII, IX, X, XI, and XII). The whole blood clotting time and activated clotting time (ACT) also measure the intrinsic pathway. In contrast, the PT measures the extrinsic pathway (factors I, II, V, and VII). The TT specifically measures conversion of fibrinogen to fibrin (factors I and II). The normal plasma fibrinogen level is 200 to 400 mg/dL (5.9–11.7 μmol/L). Because heparin therapy primarily affects the intrinsic pathway, in low doses it usually prolongs the aPTT only. In high doses, heparin also prolongs the PT. In contrast, warfarin primarily affects vitamin K–dependent factors (II, VII, IX, and X), so the PT is prolonged at usual doses, and the aPTT is prolonged only at high doses. In vivo plasmin activity can be evaluated by measuring circulating levels of peptides cleaved from fibrin and fibrinogen by plasmin, namely fibrin degradation products (FDPs) and d-dimers. Patients with primary fibrinolysis usually have elevated FDPs, but normal d-dimer levels.

What tests are most helpful in evaluating inadequate primary hemostasis?

The most commonly performed tests include a platelet count and a bleeding time, but also include TEG, ROTEM, and Sonoclot analysis (see Figure 33–7 and Chapter 51). Patients with normally functioning platelets
and platelet counts above 100,000/μL have normal primary hemostasis. The normal platelet count is 150,000 to 450,000/μL, and the bleeding time is generally not affected by the platelet count when the latter is greater than 100,000/μL. When the platelet count is 50,000/μL or greater, excessive bleeding generally occurs only with severe trauma or extensive surgery. In contrast, patients with platelet counts less than 20,000/μL often develop significant bleeding following even minor trauma. However, patients with liver cirrhosis may be thrombocytopenic but have increased levels of vWF, resulting in very active platelets that may compensate for the low count. Thrombocytopenia usually results from one of three mechanisms: (1) decreased platelet production, (2) splenic sequestration of platelets, or (3) increased platelet destruction. The third mechanism may fall under one of two categories of destruction: immune or nonimmune. Nonimmune destruction includes vasculitis or DIC.

A prolonged bleeding time with a normal platelet count implies a qualitative platelet defect. Although the bleeding time is somewhat dependent on the technique employed, values longer than 10 min are generally considered abnormal. Significant intraoperative and postoperative bleeding may be expected when the bleeding time exceeds 15 min. Specialized testing is required to diagnose specific platelet functional defects.

*What are the most common causes of qualitative platelet defects?*

The most common platelet defect is due to inhibition of TXA₂ production by aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs). In contrast to aspirin, which irreversibly acetylates and inactivates cyclooxygenase for the life of the platelet (up to 8 days), enzyme inhibition by other NSAIDs is reversible and generally lasts only 24 h. Increasingly patients with cardiac stents are treated with a variety of antiplatelet agents such as clopidogrel, which impair platelet function for the life of the platelet. Assays of platelet function are available to determine the degree to which platelet function is inhibited.

*What is von Willebrand disease?*

The most common inherited bleeding disorder (1:800–1000 patients) is *von Willebrand disease*. Patients with this disorder produce either a defective vWF or low levels of a normal vWF (normal: 5–10 mg/L). Most
patients are heterozygous and have relatively mild hemostatic defects that become clinically apparent only when they are subjected to major surgery or trauma or following ingestion of NSAIDs. In addition to helping link platelets, vWF serves as a carrier for coagulation factor VIII. As a result, these patients typically have a prolonged bleeding time, decreased plasma vWF concentration, and decreased factor VIII activity. Acquired forms of von Willebrand disease may be encountered in patients with some immune disorders and those with tumors that absorb vWF onto their surface. At least three forms of the disease are recognized, ranging in severity from mild to severe.

Treatment with desmopressin (DDAVP) can raise vWF levels in some patients with mild von Willebrand disease (as well as normal individuals). The drug is usually administered at a dose of 0.3 mcg/kg intravenously 30 min prior to surgery. Patients who do not respond to DDAVP should receive cryoprecipitate or factor VIII concentrates, both of which are rich in vWF; prophylactic infusions are generally recommended before and after surgery twice a day for 2 to 4 days to help assure surgical hemostasis.

**What other hereditary hemostatic defects may be encountered in anesthetic practice?**

The most common inherited secondary hemostasis defect is factor VIII deficiency (hemophilia A), an X-linked abnormality estimated to affect 1:10,000 males. Disease severity is generally inversely related to factor VIII activity. Most symptomatic patients experience hemarthrosis, bleeding into deep tissues, and hematuria, and usually have less than 5% of normal factor VIII activity. Classically, patients present with a prolonged aPTT, but a normal PT and bleeding time. The diagnosis is confirmed by measuring factor VIII activity in blood. Affected patients generally do not experience increased bleeding during surgery when factor VIII levels are more than 30% of normal, but most clinicians recommend increasing factor VIII levels to more than 50% of normal prior to surgery. Normal (fresh frozen) plasma, by definition, is considered to have 1 U of factor VIII activity per milliliter. In contrast, cryoprecipitate has 5 to 10 U/mL, whereas factor VIII concentrates have approximately 40 U/mL. Each unit of factor VIII transfused is estimated to raise factor VIII levels 2% per kilogram of body weight. Twice-a-day transfusions are generally recommended following surgery because of the relatively short half-life of factor VIII (8–12 h). Administration of DDAVP can raise factor VIII levels two- to threefold in
some patients. EACA or tranexamic acid may also be used as adjuncts. Recombinant factor VIII is now undergoing clinical trials.

**Hemophilia B** (also known as *Christmas disease*) is the result of an X-linked hereditary deficiency of factor IX. It is very similar to hemophilia A, but much less common (1:100,000 males). Measurement of factor IX levels establishes the diagnosis. Perioperative administration of fresh frozen plasma is generally recommended to maintain factor IX activity at more than 30% of normal. Recombinant or monoclonal purified factor IX is available.

Factor XIII deficiency is extremely rare, but notable in that the aPTT, PT, TT, and bleeding times are normal. The diagnosis requires measurement of factor XIII levels. Because only 1% of normal factor XIII activity is generally required, patients are treated by a single transfusion of fresh frozen plasma.

**Do normal laboratory values exclude a hemostatic defect?**

A bleeding diathesis may exist even in the absence of gross abnormalities on routine laboratory tests. Some hemostatic defects are often not detected by routine testing, but require additional specialized tests. A history of excessive bleeding after dental extractions, childbirth, minor surgery, minor trauma, or even during menstruation suggests a hemostatic defect. Conversely, there may be no excess bleeding despite abnormal laboratory testing. A family history of a bleeding diathesis may suggest an inherited coagulation defect, but such history is often absent because the increased bleeding is often minor and goes unnoticed.

Hemostatic defects can often be differentiated by their clinical presentation. Bleeding in patients with primary hemostatic defects usually immediately follows minor trauma, is confined to superficial sites (skin or mucosal surfaces), and often can be controlled by local compression. Small pinpoint hemorrhages from capillaries in the dermis (petechiae) are typically present on examination. Bleeding into subcutaneous tissues (ecchymosis) from small arterioles or venules is also common in patients with platelet disorders. In contrast, bleeding that results from secondary hemostatic defects is usually delayed following injury, is typically deep (subcutaneous tissues, joints, body cavities, or muscles), and is often difficult to stop even with compression. Hemorrhages may be palpable as hematomas or may go unnoticed when located deeper (retroperitoneal). Coagulation may be impaired by systemic hypothermia or by subnormal
temperature at the site of bleeding, even when coagulation test results (PT, aPTT, bleeding time) are normal and there is no history of hemostatic defects. Most laboratory tests are carried out at body temperature and may not reflect the effects of hypothermia.

**SUGGESTED READINGS**

Anesthesia for Patients with Liver Disease

Michael Ramsay, MD, FRCA

KEY CONCEPTS

1. Because of increased perioperative risk, patients with acute hepatitis should have any elective surgery postponed until the acute hepatitis has resolved, as indicated by the normalization of liver tests.

2. Isoflurane and sevoflurane are the volatile agents of choice for patients with significant liver disease because they preserve hepatic blood flow and oxygen delivery. Factors known to reduce hepatic blood flow, such as hypotension, excessive sympathetic activation, and high mean airway pressures during controlled ventilation, should be avoided.

3. In evaluating patients for chronic hepatitis, laboratory test results may show only a mild elevation in serum aminotransferase activity and often correlate poorly with disease severity.

4. Liver cirrhosis refers to the damaging effects to the liver of inflammation, hepatocellular injury, and the resulting fibrosis and regeneration of hepatocytes.

5. Liver cirrhosis leads to portal hypertension, varices, and widespread endothelial damage from toxins not cleared by the liver that may cause multiorgan dysfunction.

6. Massive bleeding from gastrointestinal varices is a major cause of morbidity and mortality in patients with liver disease, and, in addition to the cardiovascular effects of acute blood loss, the absorbed nitrogen load from the breakdown of blood in the gastrointestinal tract can precipitate hepatic encephalopathy.

7. Cardiovascular changes observed in cirrhotic patients are usually those
of hyperdynamic circulation, although clinically significant cirrhotic cardiomyopathy is often present and not recognized.

8 The effects of hepatic cirrhosis on pulmonary arterioles may result in vasodilation, causing shunts and chronic hypoxemia, or conversely lead to pulmonary vasoconstriction and medial hyperplasia, causing an increase in vascular resistance and pulmonary hypertension.

9 Hepatorenal syndrome is a functional renal defect in patients with cirrhosis that usually follows gastrointestinal bleeding, aggressive diuresis, sepsis, or major surgery. It is characterized by progressive oliguria with avid sodium retention, azotemia, intractable ascites, and a very high mortality rate.

10 Factors known to precipitate hepatic encephalopathy in patients with cirrhosis include gastrointestinal bleeding, increased dietary protein intake, hypokalemic alkalosis from vomiting or diuresis, infections, worsening liver function, and drugs with central nervous system depressant activity.

11 Following the removal of large amounts of ascitic fluid, aggressive intravenous fluid replacement is often necessary to prevent profound hypotension and acute kidney injury or failure.

The prevalence of liver disease is increasing. Cirrhosis, the terminal pathology of most liver diseases, has a general population incidence as high as 5% in some autopsy series. It is a major cause of death in men in their fourth and fifth decades of life, and mortality rates are increasing. Ten percent of the patients with liver disease undergo operative procedures during the final 2 years of their lives. The liver has remarkable functional reserve, and thus overt manifestations of hepatic disease are often absent until extensive damage has occurred. When patients with little hepatic reserve come to the operating room, effects from anesthesia and the surgical procedure can precipitate hepatic decompensation and frank hepatic failure.

**COAGULATION IN LIVER DISEASE**

The hemostatic changes that occur with liver disease may cause hypercoagulation and thrombosis, as well as an increased risk of bleeding. The causes of excessive bleeding primarily involve thrombocytopenia, endothelial dysfunction, portal hypertension, kidney failure, and sepsis (see Chapters 31 and 51). Clot breakdown may be enhanced by an imbalance of the fibrinolytic
system.

Chronic liver disease is characterized by the impaired synthesis of coagulation factors, resulting in prolongation of the prothrombin time (PT) and international normalized ratio (INR) (**Table 34–1**). The INR was designed to monitor the anticoagulant effect of warfarin, not the anticoagulant effect of liver dysfunction. In liver dysfunction, the anticoagulant factors (protein C, antithrombin, and tissue factor pathway inhibitor) are also reduced and may balance out any effect of a prolonged PT. This may be confirmed by assessing thrombin generation in the presence of endothelial-produced thrombomodulin. Adequate thrombin production requires an adequate number of functioning platelets. If the platelet count is greater than 60,000/μL, coagulation may well be normal in a patient with severe cirrhosis. In fact, more recently it has been shown that an increased von Willebrand factor (vWF) in liver disease may result in activated platelets allowing normal or increased coagulation despite a much lower platelet count. It is important to use point-of-care global viscoelastic coagulation testing to fully understand the state of coagulation (see later discussion).

¹PT, prothrombin time; PTT, partial thromboplastin time; TT, thrombin time; N, normal; DIC, disseminated intravascular coagulation.

Cirrhotic patients will typically have hyperfibrinolysis. However, individual laboratory tests may not give a true picture of the state of fibrinolysis. Thromboelastography (TEG), rotational thromboelastometry (ROTEM), and Sonoclot viscoelastic coagulation testing technologies are the optimal methods of demonstrating the global state of the coagulation system at a specific moment in time in any patient with liver disease (see **Chapter 51**).
Hepatitis

**ACUTE HEPATITIS**

Acute hepatitis is usually the result of a viral infection, drug reaction, or exposure to a hepatotoxin. The illness represents acute hepatocellular injury with a variable degree of cellular necrosis. Clinical manifestations depend on the severity of the inflammatory reaction and on the extent of necrosis. Mild inflammatory reactions may present merely as asymptomatic elevations in the serum transaminases, whereas massive hepatic necrosis presents as acute fulminant hepatic failure.

**Viral Hepatitis**

Viral hepatitis is most commonly due to hepatitis A, B, or C viral infection. At least two other hepatitis viruses have also been identified: hepatitis D (delta virus) and hepatitis E (enteric non-A, non-B). Hepatitis types A and E are transmitted by the fecal–oral route, whereas hepatitis types B and C are transmitted primarily percutaneously and by contact with body fluids. Hepatitis D is unique in that it may be transmitted by either route and requires the presence of hepatitis B virus in the host to be infective. Other viruses may also cause hepatitis, including Epstein–Barr, herpes simplex, cytomegalovirus, and coxsackieviruses.

Patients with viral hepatitis often have a 1- to 2-week mild prodromal illness (fatigue, malaise, low-grade fever, or nausea and vomiting) that may or may not be followed by jaundice. The jaundice typically lasts 2 to 12 weeks, but complete recovery, as evidenced by serum transaminase measurements, usually takes 4 months. Serological testing is necessary to determine the causative viral agent. The clinical course tends to be more complicated and prolonged with hepatitis B and C viruses relative to other types of viral hepatitis. Cholestasis (see later discussion) may be a major manifestation. Rarely, fulminant hepatic failure (massive hepatic necrosis) can develop.

The incidence of chronic active hepatitis is 3% to 10% following infection with hepatitis B virus and at least 50% following infection with hepatitis C virus. A small percentage of patients (mainly immunosuppressed patients and those on long-term hemodialysis regimens) become asymptomatic infectious carriers following infection with hepatitis B virus, and up to 30% of these patients remain infectious with the hepatitis B surface antigen (HBsAg) persisting in
their blood. Most patients with chronic hepatitis C infection seem to have very low, intermittent, or absent circulating viral particles and are therefore not highly infective. Approximately 0.5% to 1% of patients with hepatitis C infection become asymptomatic infectious carriers, and infectivity correlates with the detection of hepatitis C viral RNA in peripheral blood. Such infectious carriers pose a major health hazard to operating room personnel.

In addition to “universal precautions” for avoiding direct contact with blood and secretions (gloves, mask, protective eyewear, and not recapping needles), immunization of health care personnel is highly effective against hepatitis B infection. A vaccine for hepatitis C is not available; moreover, unlike hepatitis B infection, hepatitis C infection does not seem to confer immunity to subsequent exposure. Postexposure prophylaxis with hyperimmune globulin is effective for hepatitis B, but not hepatitis C. Effective therapies now exist for hepatitis C, but continued hepatocellular carcinoma surveillance remains important for these patients.

**Drug-Induced Hepatitis**

Drug-induced hepatitis (Table 34–2) can result from direct, dose-dependent toxicity of a drug or drug metabolite, an idiosyncratic drug reaction, or a combination of these two causes. The clinical course often resembles viral hepatitis, making diagnosis difficult. Alcoholic hepatitis is probably the most common form of drug-induced hepatitis, but the etiology may not be obvious from the history. Chronic alcohol ingestion can also result in hepatomegaly from fatty infiltration of the liver, which reflects impaired fatty acid oxidation, increased uptake and esterification of fatty acids, and diminished lipoprotein synthesis and secretion. Acetaminophen ingestion of 25 g or more usually results in fatal fulminant hepatotoxicity. A few drugs, such as chlorpromazine and oral contraceptives, may cause cholestatic-type reactions (see later discussion). Ingestion of potent hepatotoxins, such as carbon tetrachloride and certain species of mushrooms (*Amanita, Galerina*), also may result in fatal hepatotoxicity.

Because of increased perioperative risk, patients with acute hepatitis should have elective surgery postponed until the illness has resolved, as indicated by the normalization of liver tests. In addition, acute alcohol toxicity greatly complicates anesthetic management, and acute alcohol withdrawal during the perioperative period may be associated with a mortality rate as high as 50%. Only emergent surgery should be considered for patients presenting in acute alcohol withdrawal. Patients with hepatitis are at risk of deterioration of hepatic function and the development of complications from hepatic failure, such as encephalopathy, coagulopathy, or hepatorenal syndrome.
Laboratory evaluation of the patient with hepatitis should include blood urea nitrogen, serum electrolytes, creatinine, glucose, transaminases, bilirubin, alkaline phosphatase, albumin, platelet count, and PT. Serum should also be checked for HBsAg whenever possible. A blood alcohol level is useful if the history or physical examination is compatible with ethanol intoxication. Hypokalemia and metabolic alkalosis are not uncommon and are usually due to vomiting. Concomitant hypomagnesemia may be present in chronic alcoholics and predisposes to cardiac arrhythmias. The elevation in serum transaminases does not necessarily correlate with the amount of hepatic necrosis. The serum alanine aminotransferase (ALT) is generally higher than the serum aspartate aminotransferase (AST), except in alcoholic hepatitis, where the reverse occurs. Bilirubin and alkaline phosphatase are usually only moderately elevated, except with the cholestatic variant of hepatitis. The PT is the best indicator of hepatic synthetic function. Persistent prolongation of longer than 3 s (INR ≥1.5) following administration of vitamin K is indicative of severe hepatic dysfunction. Hypoglycemia is not uncommon. Hypoalbuminemia is usually not present except in protracted cases, with severe malnutrition, or when chronic liver disease is present.

If a patient with acute hepatitis must undergo an emergent operation, the preanesthetic evaluation should focus on determining the cause and the degree of hepatic impairment. Information should be obtained regarding recent drug exposures, including alcohol intake, intravenous drug use, recent transfusions, and prior anesthetics. The presence of nausea or vomiting should be noted, and, if present, dehydration and electrolyte abnormalities should be anticipated and corrected. Changes in mental status may indicate severe hepatic impairment. Inappropriate behavior or obtundation in alcoholic patients may be signs of acute intoxication, whereas tremulousness, irritability, tachycardia, and hypertension usually reflect withdrawal. Fresh frozen plasma may be necessary to correct coagulopathy. Premedication is generally not given in patients with advanced liver disease. However, benzodiazepines and thiamine are indicated in alcoholic patients with, or at risk for, acute alcohol withdrawal; nevertheless, benzodiazepines must be administered cautiously, as they may precipitate hepatic coma in an encephalopathic patient. This may be reversed in some patients with flumazenil.

**Intraoperative Considerations**

The goal of intraoperative management is to preserve existing hepatic function. Some patients with viral hepatitis may exhibit increased central nervous system
sensitivity to anesthetics, whereas alcoholic patients will often display cross-
tolerance to both intravenous and volatile anesthetics. Alcoholic patients also 
require close cardiovascular monitoring because the cardiac depressant effects of 
alcohol are additive to those of anesthetics; moreover, alcoholic cardiomypathy 
may be present in alcoholic patients.

Inhalation anesthetics are generally preferable to intravenous agents because 
most of the latter are dependent on the liver for metabolism, elimination, or both. 
Standard induction doses of intravenous induction agents can generally be used 
because their action is terminated by redistribution rather than metabolism or 
excretion. A prolonged duration of action, however, may be encountered with 
large or repeated doses of intravenous agents, particularly opioids. Isoflurane 
and sevoflurane are the volatile agents of choice for patient with significant liver 
disease because they preserve hepatic blood flow and oxygen delivery. Factors 
known to reduce hepatic blood flow, such as hypotension, excessive sympathetic 
activation, and high mean airway pressures during controlled ventilation, should 
be avoided. Regional anesthesia, including major conduction blockade, may be 
employed in the absence of coagulopathy, provided hypotension is avoided.

**CHRONIC HEPATITIS**

Chronic hepatitis is defined as persistent hepatic inflammation for longer than 6 
months, as evidenced by elevated serum aminotransferases. Patients can usually 
be classified as having one of three distinct syndromes based on a liver biopsy: 
chronic persistent hepatitis, chronic lobular hepatitis, or chronic active hepatitis. 
Patients with chronic active hepatitis have chronic hepatic inflammation with 
destruction of normal cellular architecture “piecemeal necrosis” on the biopsy. 
Evidence of cirrhosis is either present initially or eventually develops in 20% to 
50% of patients. Although chronic active hepatitis seems to have many causes, it 
occur most commonly as a sequel of hepatitis B or hepatitis C. Other causes 
include medications (methyldopa, isoniazid, and nitrofurantoin) and autoimmune 
disorders. Both immunological factors and a genetic predisposition may be 
responsible in most cases. Patients usually present with a history of fatigue and 
reoccur jaundice; extrahepatic manifestations, such as arthritis and serositis, are 
not uncommon. Manifestations of cirrhosis eventually predominate in patients 
with progressive disease. In evaluating patients for chronic hepatitis, 
laboratory test results may show only a mild elevation in serum aminotransferase 
activity and often correlate poorly with disease severity. Patients without chronic 
hepatitis B or C infection usually have a favorable response to 
immunosuppressants and are treated with long-term corticosteroid therapy with
or without azathioprine.

**Anesthetic Management**

Patients with chronic persistent or chronic lobular hepatitis should be treated similarly to those with acute hepatitis. In contrast, those with chronic active hepatitis should be assumed to already have cirrhosis and should be treated accordingly (as discussed next). Patients with autoimmune chronic active hepatitis may also present with problems related to other autoimmune manifestations (such as diabetes or thyroiditis) or to the long-term corticosteroid therapy that they have likely received.

---

**Cirrhosis**

Liver cirrhosis refers to the damaging effects to the liver of inflammation, hepatocellular injury, and the resulting fibrosis and regeneration of hepatocytes. Cirrhosis is a progressive disease that eventually results in hepatic failure. The most common cause of cirrhosis in the United States was chronic alcohol abuse, but that has now been overtaken by nonalcoholic steatohepatitis accompanying the massive increase in morbid obesity prevalence. Other causes include chronic active hepatitis (postnecrotic cirrhosis), chronic biliary inflammation or obstruction (primary biliary cirrhosis, sclerosing cholangitis), chronic right-sided congestive heart failure (cardiac cirrhosis), autoimmune hepatitis, hemochromatosis, Wilson disease, α₁-antitrypsin deficiency, and cryptogenic cirrhosis. Regardless of the cause, hepatocyte necrosis is followed by fibrosis and nodular regeneration. Distortion of the liver’s normal cellular and vascular architecture obstructs portal venous flow and leads to portal hypertension and varices. Impairment of the liver’s normal synthetic and other diverse metabolic functions, along with widespread endothelial damage from toxins not cleared by the liver, may cause multisystem dysfunction.

Clinically, signs and symptoms often do not correlate with disease severity. Manifestations are typically absent initially, but jaundice and ascites eventually develop in most patients. Other signs include spider angiomas, palmar erythema, gynecomastia, and splenomegaly. Moreover, cirrhosis is generally associated with the development of three major complications: (1) variceal hemorrhage from portal hypertension, (2) intractable fluid retention in the form of ascites and the hepatorenal syndrome, and (3) hepatic encephalopathy or coma. Approximately 10% of patients with cirrhosis also develop at least one episode
of spontaneous bacterial peritonitis, and some patients eventually develop hepatocellular carcinoma.

A few diseases can produce hepatic fibrosis without hepatocellular necrosis or nodular regeneration, resulting in portal hypertension and its associated complications with hepatocellular function often preserved. These disorders include schistosomiasis, idiopathic portal fibrosis (Banti syndrome), and congenital hepatic fibrosis. Obstruction of the hepatic veins or inferior vena cava (Budd–Chiari syndrome) can also cause portal hypertension. The latter may be the result of venous thrombosis (hypercoagulable state), a tumor thrombus (eg, renal carcinoma), or occlusive disease of the sublobular hepatic veins.

**Preoperative Considerations**

The detrimental effects of anesthesia and surgery on hepatic blood flow are discussed later in this section. Patients with cirrhosis are at increased risk of deterioration of liver function because of limited functional reserve. Successful anesthetic management of these patients is dependent on recognizing the multisystem nature of cirrhosis *(Table 34–3)* and controlling or preventing its complications.

**A. Gastrointestinal Manifestations**

Portal hypertension leads to the development of extensive portosystemic venous collateral channels. Four major collateral sites are generally recognized: gastroesophageal, hemorrhoidal, periumbilical, and retroperitoneal. Portal hypertension is often apparent preoperatively, as evidenced by dilated abdominal wall veins (*caput medusae*). Massive bleeding from gastroesophageal varices
is a major cause of morbidity and mortality in patients with liver disease, and, in addition to the effects of acute blood loss, the absorbed nitrogen load from the breakdown of blood in the gastrointestinal tract can precipitate hepatic encephalopathy.

The treatment of variceal bleeding is primarily supportive, but frequently involves endoscopic procedures for identification of the bleeding site(s) and therapeutic maneuvers, such as injection sclerosis of varices, monopolar and bipolar electrocoagulation, or application of hemoclips or bands. In addition to the risks posed by a patient who is physiologically fragile and acutely hypovolemic and hypotensive, anesthesia for such endoscopic procedures frequently involves the additional challenges of an encephalopathic and uncooperative patient and a stomach full of food and blood. Endoscopic unipolar electrocautery may adversely affect implanted cardiac pacing and defibrillator devices.

Blood loss should be replaced with intravenous fluids and blood products. Nonoperative treatment includes vasopressin, somatostatin, propranolol, and balloon tamponade with a Sengstaken–Blakemore tube. Vasopressin, somatostatin, and propranolol reduce the rate of blood loss. High doses of vasopressin can result in congestive heart failure or myocardial ischemia; concomitant infusion of intravenous nitroglycerin may reduce the likelihood of these complications and bleeding. Placement of a percutaneous transjugular intrahepatic portosystemic shunt (TIPS) can reduce portal hypertension and subsequent bleeding, but may increase the incidence of encephalopathy. When the bleeding fails to stop or recurs, emergency surgery may be indicated. Perioperative risk correlates with degree of hepatic impairment, based on clinical and laboratory findings. Child’s classification for evaluating hepatic reserve is shown in Table 34–4. Shunting procedures are generally performed on low-risk patients, whereas ablative surgery, esophageal transection, and gastric devascularization are reserved for high-risk patients.

B. Hematologic Manifestations

Anemia, thrombocytopenia, and, less commonly, leukopenia may be present. The cause of the anemia is usually multifactorial and includes blood loss, increased red blood cell destruction, bone marrow suppression, and nutritional deficiencies. Congestive splenomegaly secondary to portal hypertension is largely responsible for the thrombocytopenia and leukopenia. Coagulation factor deficiencies arise as a result of decreased hepatic synthesis. Enhanced fibrinolysis secondary to decreased clearance of activators of the fibrinolytic system may also contribute to the coagulopathy.

The need for preoperative blood transfusions should be balanced against the obligatory increase in nitrogen load. Protein breakdown from excessive blood transfusions can precipitate encephalopathy. Nevertheless, coagulopathy should be corrected before surgery. Clotting factors should be replaced with appropriate blood products, such as fresh frozen plasma and cryoprecipitate. Platelet transfusions should be considered immediately prior to surgery for platelet counts less than 75,000/μL. Assessment of integrity of the coagulation system by viscoelastic technology will provide specific management information.

C. Circulatory Manifestations

End-stage liver disease, and in particular, cirrhosis of the liver may be associated with disorders of all major organ systems (Tables 34–3 and 34–5). Cardiovascular changes observed in cirrhotic patients are usually those of a hyperdynamic circulation, although clinically significant cirrhotic cardiomyopathy is often present and not recognized (Table 34–6). There may be a reduced cardiac contractile response to stress, altered diastolic relaxation, downregulation of β-adrenergic receptors, and electrophysiological changes as a result of cirrhotic cardiomyopathy.

Echocardiographic examination of cardiac function may initially be interpreted as normal because of significant afterload reduction caused by low systemic vascular resistance. However, both systolic and diastolic dysfunction are often present. Noninvasive stress imaging is frequently used to assess coronary artery disease in patients older than age 50 years and in those with cardiac risk factors.

**Hepatopulmonary Syndrome**
- The effects of hepatic cirrhosis on pulmonary vascular resistance (PVR)
vessels may result in vasodilation, causing shunts and chronic hypoxemia, or conversely lead to pulmonary vasoconstriction and medial hyperplasia, causing an increase in vascular resistance and pulmonary hypertension. *Hepatopulmonary syndrome* (HPS; Table 34–7) is found in approximately 30% of liver transplant candidates and is characterized by a triad of decreased oxygen saturation in the presence of advanced liver disease and intrapulmonary arteriolar dilation. Intrapulmonary vascular dilation causes intrapulmonary right-to-left shunting and an increase in the alveolar-to-arterial oxygen gradient.

**Diagnostic criteria**

- Presence of liver disease, usually with portal hypertension and cirrhosis
- An alveolar to arterial oxygen gradient of >15 mm Hg
- Pulmonary arteriovenous connections demonstrated by:
  - A delayed contrast-enhanced (agitated saline) echocardiogram showing contrast in the left heart chambers 4–6 heartbeats after contrast appears in the right heart chambers
  - Brain uptake >6% following technetium-99m macroaggregated albumin lung perfusion scan

**Indications**

- Liver transplantation is the only therapy that will cure hepatopulmonary syndrome

Pulse oximetry may be used to screen for HPS, and room air SpO₂ less than 96% requires investigation. There is no medical treatment for HPS, which is progressive, but it is reversed over 6 months to 2 years by liver transplantation.
Portopulmonary Hypertension

Pulmonary vascular remodeling may occur in association with chronic liver disease, involving vascular smooth muscle proliferation, vasoconstriction, intimal proliferation, and eventual fibrosis, all presenting as obstruction causing an increased resistance to pulmonary blood flow. These pathological changes may result in pulmonary hypertension, and if associated with portal hypertension, the condition is termed portopulmonary hypertension (POPH; Table 34–8).

**TABLE 34–8 Clinical features of portopulmonary hypertension.**

<table>
<thead>
<tr>
<th>Feature</th>
</tr>
</thead>

<td>Right heart failure</td>
</tr>
<tr>
<td>Hepatic congestion</td>
</tr>
<tr>
<td>Increased liver transplantation mortality risk, especially if mean pulmonary artery pressure is (&gt;35 \text{ mm Hg})</td>
</tr>
</tbody>
</table>

The diagnostic criteria for POPH include a mean pulmonary artery pressure (mPAP) greater than 25 mm Hg at rest, and a PVR greater than 240 dyn·s·cm⁻⁵. The transpulmonary gradient of greater than 12 mm Hg (mPAP minus pulmonary arteriolar occlusion pressure [PAOP]) reflects the obstruction to flow and distinguishes the contribution of volume and resistance to the increase in mPAP.

POPH may be classified as mild (mPAP 25–35 mm Hg), moderate (mPAP >35 and <45 mm Hg), and severe (mPAP >45 mm Hg). Mild POPH is not associated with increased mortality at liver transplantation, although the immediate recovery period may be challenging if there is significant increase in cardiac output after reperfusion of the new graft. Moderate and severe POPH are associated with significant mortality at transplantation. However, the key factor is not mPAP, but rather right ventricular (RV) function.

The success of liver transplantation will depend on the right ventricle maintaining good function during and after the transplant procedure despite increases in cardiac output, volume, and PVR. If RV dysfunction or failure
occurs, graft congestion with possible graft failure and possible mortality may ensue. Assessment of the right ventricle using transesophageal echocardiography (TEE) is often helpful.

The role of liver transplantation in the management of POPH is not well defined. In some patients, pulmonary hypertension will reverse quickly after transplant; however, other patients may require months or years of ongoing vasodilator therapy. Yet other patients may continue to progress and eventually develop RV failure. Some patients with HPS develop pulmonary hypertension after liver transplantation, suggesting that both pathologies may occur simultaneously. Liver transplantation offers the best outcome in patients with POPH that is responsive to vasodilator therapy.

D. Respiratory Manifestations
Disturbances in pulmonary gas exchange and ventilatory mechanics are often present. Hyperventilation is common and results in a primary respiratory alkalosis. As previously noted, hypoxemia is frequently present and is due to right-to-left shunting of up to 40% of cardiac output. Shunting is due to an increase in both pulmonary arteriovenous communications (absolute) and ventilation/perfusion mismatching (relative). Elevation of the diaphragm from ascites decreases lung volumes, particularly functional residual capacity, and predisposes to atelectasis. Moreover, large amounts of ascites produce a restrictive ventilatory defect that increases the work of breathing. Severe hydrothorax is also frequently found.

Review of the chest radiograph and arterial blood gas measurements is useful preoperatively because atelectasis and hypoxemia are usually not evident on clinical examination. Paracentesis should be considered in patients with massive ascites and pulmonary compromise, but should be performed with caution because excessive fluid removal can lead to circulatory collapse.

E. Renal Manifestations and Fluid Balance
Derangements of fluid and electrolyte balance may manifest as ascites, edema, electrolyte disturbances, and hepatorenal syndrome (see below). Important mechanisms responsible for ascites include (1) portal hypertension, which increases hydrostatic pressure and favors transudation of fluid across the intestine into the peritoneal cavity; (2) hypoalbuminemia, which decreases plasma oncotic pressure and favors fluid transudation; (3) seepage of protein-rich lymphatic fluid from the serosal surface of the liver secondary to distortion and obstruction of lymphatic channels in the liver; and (4) avid renal sodium and
water retention.

Patients with cirrhosis and ascites have decreased renal perfusion, altered intrarenal hemodynamics, enhanced proximal and distal sodium reabsorption, and often an impairment of free water clearance. Hyponatremia and hypokalemia are common. The former is dilutional, whereas the latter is due to excessive urinary potassium losses from secondary hyperaldosteronism or from diuretics. The most severe expression of these abnormalities is seen with the development of hepatorenal syndrome. Patients with ascites have elevated levels of circulating catecholamines, probably due to enhanced sympathetic outflow. In addition to increased renin and angiotensin II, these patients are insensitive to circulating atrial natriuretic peptide.

**Hepatorenal syndrome** is a functional renal defect in patients with cirrhosis that usually follows gastrointestinal bleeding, aggressive diuresis, sepsis, or major surgery. It is characterized by increased renal vasoconstriction, which may be a response to splanchic vasodilation, reduced glomerular filtration rate, progressive oliguria with avid sodium retention, azotemia, intractable ascites, and very high mortality rate. Treatment is supportive and often unsuccessful unless liver transplantation is undertaken.

Judicious perioperative fluid management in patients with advanced liver disease is critical. The importance of preserving perioperative kidney function cannot be overemphasized. Overzealous preoperative diuresis should be avoided, and acute intravascular fluid deficits should be corrected with colloid infusions. Diuresis of ascites and edema fluid should be accomplished over several days. Loop diuretics are administered only after measures such as bed rest, sodium restriction (<2 g NaCl/d), and spironolactone administration are found to be ineffective. Daily body weight measurements are useful in preventing intravascular volume depletion during diuresis; in patients with both ascites and peripheral edema, no more than 1 kg/d should be lost during diuresis, and in those with ascites alone, no more than 0.5 kg/d should be lost. Hyponatremia (serum $[\text{Na}^+] < 130$ mEq/L) also requires water restriction (<1.5 L/d), and potassium deficits should be replaced preoperatively. Medical treatment includes albumin infusions in combination with vasoconstrictors such as vasopressin, midodrine, and norepinephrine, and perhaps the vasopressin analogue, terlipressin. Prolonged kidney impairment will result in acute tubular necrosis, and if this occurs a liver–kidney transplant may be indicated.

**F. Central Nervous System Manifestations**

Hepatic encephalopathy is characterized by mental status alterations with
fluctuating neurological signs (asterixis, hyperreflexia, or inverted plantar reflex) and characteristic electroencephalographic changes (symmetric high-voltage, slow-wave activity). This is associated with accumulation of neurotoxins, including ammonia and short-chain fatty acids. Some patients also have elevated intracranial pressure. Metabolic encephalopathy seems to be proportionately related to both the amount of hepatocellular damage present and the degree of shunting of portal blood away from the liver and directly into the systemic circulation. The accumulation of substances originating in the gastrointestinal tract (but normally metabolized by the liver) has been implicated. Factors known to precipitate hepatic encephalopathy include gastrointestinal bleeding, increased dietary protein intake, hypokalemic alkalosis from vomiting or diuresis, infections, worsening liver function, and drugs with central nervous system depressant activity.

Hepatic encephalopathy should be aggressively treated preoperatively. Precipitating causes should be corrected. Oral lactulose (30–50 mL every 8 h) or neomycin (500 mg every 6 h) is useful in reducing intestinal ammonia absorption. Lactulose acts as an osmotic laxative, and, like neomycin, likely inhibits ammonia production by intestinal bacteria. Sedatives, especially benzodiazepines, should be avoided as they may precipitate hepatic coma.

**Intraoperative Considerations**

Patients with postnecrotic cirrhosis due to hepatitis B or hepatitis C who are carriers of the virus may be infectious. Universal precautions are always indicated in preventing contact with blood and body fluids from all patients.

**A. Drug Responses**

The response to anesthetic agents is unpredictable in patients with cirrhosis. Changes in central nervous system sensitivity, volumes of distribution, protein binding, drug metabolism, and drug elimination are common. An increase in the volume of distribution for highly ionized drugs, such as neuromuscular blockers (NMBs), is due to the expanded extracellular fluid compartment; an apparent resistance may be observed, requiring larger than normal loading doses. However, smaller than normal maintenance doses of NMBs dependent on hepatic elimination (pancuronium, rocuronium, and vecuronium) are needed. The duration of action of succinylcholine may be prolonged because of reduced levels of pseudocholinesterase, but this is rarely of clinical consequence.
B. Anesthetic Technique
The cirrhotic liver is very dependent on hepatic arterial perfusion because of reduced portal venous blood flow. Preservation of hepatic arterial blood flow and avoidance of agents with potentially adverse effects on hepatic function are critical. Regional anesthesia may be used in patients without thrombocytopenia or coagulopathy, but hypotension must be avoided. A propofol induction followed by isoflurane or sevoflurane with an oxygen–air mixture is commonly employed for general anesthesia. Opioid supplementation reduces the dose of the volatile agent required, but the half-lives of opioids are often significantly prolonged, which may cause postoperative respiratory depression. Cisatracurium may be the NMB of choice because of its nonhepatic metabolism.

Preoperative nausea, vomiting, upper gastrointestinal bleeding, and abdominal distention due to massive ascites require a well-planned anesthetic induction. Preoxygenation and rapid-sequence induction/intubation with cricoid pressure are often performed. For unstable patients and those with active bleeding, either an awake intubation or a rapid-sequence induction using ketamine or etomidate and succinylcholine is suggested.

C. Monitoring
Pulse oximetry should be supplemented with arterial blood gas measurements to monitor acid–base status. Patients with large right-to-left intrapulmonary shunts may not tolerate the addition of nitrous oxide and may require positive end-expiratory pressure (PEEP) to treat ventilation/perfusion inequalities and associated hypoxemia. Patients receiving vasopressin infusions should be monitored for myocardial ischemia due to coronary vasoconstriction.

Continuous intraarterial pressure monitoring is often used because hemodynamic instability frequently occurs as a result of excessive bleeding and operative manipulations. Intravascular volume status is often difficult to optimize, and goal-directed hemodynamic and fluid therapy utilizing esophageal Doppler, arterial waveform analysis, pleth variability index (PVI), or TEE should be considered. Such approaches may be helpful in preventing acute kidney injury. Urinary output must be followed closely; mannitol may be considered for persistently low urinary outputs despite adequate intravascular fluid replacement.

D. Fluid Replacement
Most patients are sodium-restricted preoperatively, but preservation of intravascular volume and urinary output takes priority intraoperatively. The use
of predominantly colloid intravenous fluids (albumin) may be preferable to avoid sodium overload and to increase plasma oncotic pressure. Intravenous fluid replacement should take into account the excessive bleeding and fluid shifts that often occur in these patients during abdominal procedures. Venous engorgement from portal hypertension, varices, lysis of adhesions from previous surgery, and coagulopathy lead to excessive bleeding during surgical procedures, whereas evacuation of ascites and prolonged surgical procedures result in large fluid shifts. Following the removal of large amounts of ascitic fluid, aggressive intravenous fluid replacement is often necessary to prevent profound hypotension and acute kidney injury or failure. Liberal use of crystalloid solutions may result in widespread edema because of the low serum albumin, and colloid solutions are usually more appropriate.

Most preoperative patients are anemic and coagulopathic, and perioperative red blood cell transfusion may lead to hypocalcemia from impaired citrate metabolism in the cirrhotic liver. Citrate, the anticoagulant in stored red blood cell preparations, binds with plasma calcium, producing hypocalcemia. Intravenous calcium may be necessary (see Chapter 51).

**Hepatic Surgery**

Common hepatic procedures include repair of lacerations, drainage of abscesses, and resection of primary or metastatic neoplasms, and up to 80% to 85% of the liver can be resected in many patients. In addition, liver transplantation is performed in many centers. The perioperative care of patients undergoing hepatic surgery is often challenging because of coexisting medical problems and debilitation found in many patients with intrinsic liver disease, and because of the potential for significant operative blood loss. Hepatitis and cirrhosis greatly complicate anesthetic management and increase perioperative mortality. Multiple large-bore intravenous catheters and fluid blood warmers are necessary; rapid infusion devices facilitate management when massive blood transfusion is anticipated. Continuous intraarterial pressure monitoring is typically utilized.

Hemodynamic optimization is often complicated by the conflict between the need to maintain sufficient intravascular volume to ensure adequate hepatic perfusion and the need to keep central venous pressure low to minimize liver engorgement and surgical bleeding. Central venous pressure measurement is not an accurate monitor of volume status; we suggest goal-directed fluid therapy utilizing esophageal Doppler, arterial waveform analysis, PVI, or TEE. Care should be taken in placing an esophageal Doppler or TEE probe in a patient with
esophageal variceal disease.

Hypotensive anesthesia should be avoided because of its potentially deleterious effects on liver function. Administration of antifibrinolytics, such as \( \varepsilon \)-aminocaproic acid or tranexamic acid, may reduce operative blood loss, especially if fibrinolysis can be demonstrated by viscoelastic coagulation monitoring. Hypoglycemia, coagulopathy, and sepsis may occur following large liver resections. Drainage of an abscess or cyst may be complicated by peritoneal contamination. In the case of a hydatid cyst, spillage can cause anaphylaxis due to the release of *Echinococcus* antigens.

Postoperative complications include hepatic dysfunction, sepsis, and blood loss secondary to coagulopathy or surgical bleeding. Postoperative pain from the surgical incision may hinder postoperative mobilization and convalescence, but perioperative coagulopathy may limit the use of epidural analgesia. Transversus abdominis plane (TAP) blocks may be very effective. Postoperative mechanical ventilation may be necessary in patients who have undergone extensive resections or who are markedly debilitated.

**Liver Transplantation**

When a center opens a liver transplantation program, a credentialed director should be appointed who should be an anesthesiologist with experience and training in liver transplantation anesthesia. A dedicated team of anesthesiologists should be assembled to manage the perioperative course of all liver transplantation patients. This team should have a thorough understanding of the indications for, and contraindications to, liver transplantation (*Tables 34–9 and 34–10*), as well as the perioperative implications of associated comorbidities such as coronary artery disease, cirrhotic cardiomyopathy, portopulmonary hypertension, HPS, hepatorenal syndrome, and hepatic encephalopathy and cerebral edema. It has been demonstrated that such an approach improves outcomes, as measured by reduced blood transfusions, the need for postoperative mechanical ventilation, and the intensive care unit length of stay.

**Preoperative Considerations**

The *Model for End-stage Liver Disease (MELD)* score is used by the United Network for Organ Sharing (UNOS) to prioritize patients on the liver transplantation waiting list. The score is based on the patient’s serum bilirubin, serum creatinine, and INR, and is a predictor of survival time if the patient does not receive a liver transplant. A score of 20 predicts a 20% risk of mortality at 3 months, whereas a score of 40 predicts a 71% risk of mortality at 3 months (*Figure 34–1*).
 Multiply the resulting value by 10, and round to nearest whole number. The minimum for all values is 1.0; the maximum value for creatinine is 4.0.

Most liver transplant candidates have high MELD scores and present with jaundice, kidney failure, and coagulopathy. They may also be emaciated and have massive ascites, and some may have encephalopathy, HPS, cirrhotic cardiomyopathy, and POPH. These patients often have an increased cardiac index and reduced systemic vascular resistance.

Significant blood loss may be anticipated, and large-bore intravenous catheters should be placed for access. A rapid infusion pump should be available. Routine hemodynamic monitoring should include intraarterial pressure monitoring. TEE is routinely utilized in many centers. Pulmonary artery catheterization, once routine, has now been replaced by a central venous catheter at many centers, except when there is concern for POPH or cirrhotic
cardiomyopathy.

The immediate availability of intraoperative continuous venovenous hemodialysis (CVVHD) may be very helpful for volume and electrolyte management in the patient with marginal or no kidney function. In patients with significant electrolyte abnormalities, serum sodium and potassium can be closely managed by adjusting the CVVHD dialysate solution.

**Intraoperative Management**

As previously noted, hepatic disease causes endothelial dysfunction that impairs all organs of the body. The heart develops cirrhotic cardiomyopathy; the brain, encephalopathy and eventual cerebral edema; the kidneys, hepatorenal syndrome and eventual acute tubular necrosis; and the lungs, HPS or portopulmonary hypertension, or both. Therefore, each organ must be carefully managed throughout the operative procedure and postoperative period.

Maintenance of cerebral perfusion pressure (CPP) is particularly important in patients with cerebral edema, and some centers will monitor intracranial pressure. Additional cerebral protective measures include head elevation of 20°, mild hypothermia, and mild hypocarbia with vasopressor support to maintain mean arterial pressure. When the patient’s head is elevated, the arterial pressure transducer should be zeroed at the level of the external auditory meatus for accurate determination of CPP.

Coagulopathy is managed with the aid of a point-of-care viscoelastic coagulation assay device (TEG, ROTEM, or Sonoclot) or frequent assessment of conventional tests of coagulation. Blood loss may be large, and transfusions are targeted to maintain the hemoglobin level at greater than 7 g/dL.

Transfusions must be tempered to keep the central venous pressure (CVP) low during the liver dissection to reduce blood loss and minimize liver congestion, and during reperfusion and the remainder of the procedure to prevent graft congestion and hepatic dysfunction. Most coagulopathies will correct with the new liver if its function is good. Fibrinolysis, a low ionized calcium level, and hypothermia must be corrected, as these may promote bleeding. However, coagulation defects usually do not need to be treated preoperatively or intraoperatively unless bleeding is a problem. Intraoperative transfusion of platelets and fresh frozen plasma is associated with decreased long-term patient survival.

The liver transplantation surgical procedure is divided into three stages: the dissection (*preanhepatic*), *anhepatic*, and *neohepatic* periods.
The dissection (preanhepatic) phase is highlighted by the management of hemodynamic changes related to blood loss and surgical compression of major vessels. Surgical entry into a large varix may lead to large blood loss. Hyponatremia should be carefully managed without rapid serum sodium correction, because this may promote the development of osmotic demyelination syndrome. Hyperkalemia may require aggressive intervention with diuresis, transfusion of only washed packed red blood cells, or CVVHD. Citrate toxicity (hypocalcemia) may occur if blood is transfused; therefore, ionized calcium should be closely monitored, and calcium salts administered as necessary. A low CVP is helpful to minimize blood loss while systemic arterial pressure is maintained.

The anhepatic phase begins with the vascular occlusion of the inflow to the liver and ends with reperfusion. Some centers utilize venovenous bypass to prevent congestion of the visceral organs, improve venous return, and possibly protect kidney function.

In the neohepatic phase, two pathophysiological events may occur on opening the portal vein and allowing reperfusion of the graft. The first is a reperfusion syndrome caused by the cold, acidic, hyperkalemic solution that may contain emboli and vasoactive substances being flushed from the graft directly into the vena cava. This may cause hypotension, right heart dysfunction, arrhythmias, and even cardiac arrest, and may be preempted to some extent by the prophylactic administration of calcium chloride and sodium bicarbonate. The second syndrome that may occur is ischemia/reperfusion injury. This may result from impaired reperfusion due to severe endothelial dysfunction, and, in rare cases, may lead to primary nonfunction of the graft.

**Postoperative Management**

Patients who undergo liver transplantation are often severely debilitated and malnourished and have multiorgan dysfunction. They will need careful support and continuous monitoring until they have recovered. Early extubation is appropriate in patients who are comfortable, cooperative, and not excessively coagulopathic. Immunosuppression must be carefully managed to minimize risk of sepsis. A close watch of graft function must be maintained, with a low threshold for checking hepatic artery patency and flow. Postoperative bleeding, biliary leaks, and vascular thromboses may require surgical reexploration.

**SPECIAL SITUATIONS**
Patients with elevated intracranial pressure (ICP) and those at risk of its development should have ICP monitoring in place, if possible, to enable the appropriate management of CPP. The management of patients who are at risk of or have elevated ICP should include the following:

- ICP less than 20 mm Hg
- CPP greater than 50 mm Hg
- Mean arterial pressure greater than 60 mm Hg
- Proper bed position (elevate the head of the bed by 20–25°)
- Controlled airway and ventilation
- Controlled sedation (eg, propofol)
- Vasopressor support (eg, vasopressin, norepinephrine) when necessary
- Controlled hypothermia (32–33°C)
- Glycemic control
- Aggressive treatment of metabolic acidosis and coagulopathy
- CVVHD

**Pediatric Liver Transplantation**

Selected pediatric centers report 1-year survival rates of 90%. The use of reduced-size and living donor grafts has increased the organ availability in this patient population.

**Living Donor Transplantation**

The use of living donors has increased the pool of organs available for transplantation. However, this procedure does expose healthy individuals to morbidity and mortality risks. Informed consent from the donor must be obtained with the understanding that there is often a great deal of emotional pressure on family members to donate, and that consent must be freely given without coercion.

In most donor anesthesia protocols, maintenance of a CVP less than 5 cm H$_2$O is utilized to reduce intraoperative blood loss. Adequate postoperative analgesia is required so that comfortable donor patients may be extubated at the end of the procedure. TAP blocks meet this need. Complications of this surgery for the donor patient include transient hepatic dysfunction, wound infection,
postoperative bleeding, portal vein thrombosis, biliary leaks, and, rarely, death. An increased incidence of perioperative brachial plexus injury has been reported in donor patients.

CASE DISCUSSION

**Liver Transplantation**

A 23-year-old woman develops fulminant hepatic failure after ingesting wild mushrooms. She is not expected to survive without a liver transplant.

**What are the indications for liver transplantation?**

Orthotopic liver transplantation is usually performed in patients with end-stage liver disease who begin to experience life-threatening complications, especially when such complications become unresponsive to medical or nontransplant surgery. Transplantation is also carried out in patients with fulminant hepatic failure (from viral hepatitis or a hepatotoxin) when survival with medical management alone is judged unlikely. The MELD score is used to assess urgency for transplantation.

The most common indications for liver transplantation in children, in order of decreasing frequency, are biliary atresia, inborn errors of metabolism (usually α₁-antitrypsin deficiency, Wilson disease, tyrosinemia, and Crigler–Najjar type I syndrome), and postnecrotic cirrhosis.

The most common indications in adults are postnecrotic (nonalcoholic) cirrhosis, primary biliary cirrhosis, and sclerosing cholangitis, and, less commonly, primary malignant tumors in the liver.

**What factors have contributed to the recent success of liver transplantation?**

One-year survival rates for liver transplantations exceed 80% to 85% in some centers. Currently, 5-year survival rates are 50% to 60%. The success of this procedure owes much to the use of cyclosporine and tacrolimus for immunosuppressant therapy. These drugs selectively suppress the activities of helper T cells (CD4 lymphocytes) by inhibiting production of interleukin-2 (IL-2) and other cytokines. IL-2 is required for the generation
and proliferation of cytotoxic T cells responsible for graft rejection and for activating B cells responsible for T cell-dependent humoral responses. Cyclosporine is usually initially combined with corticosteroids and other agents (eg, mycophenolate and azathioprine). Tacrolimus has proved effective in cyclosporine-resistant rejection and is the preferred alternative to cyclosporine as the primary immunosuppressant agent. The use of anti-OKT-3, a monoclonal antibody directed against lymphocytes, has been extremely useful in treating steroid-resistant acute rejection.

Additional factors influencing the improvement in liver transplantation outcome include a greater understanding and experience with transplantation and improved assessment and monitoring with echocardiography.

**What are the phases of the transplantation surgical procedure?**

These procedures can be divided into three phases: a dissection (preanhepatic) phase, an anhepatic phase, and a neohepatic phase.

1. **Dissection (preanhepatic) phase:** Through a hockey stick incision, the liver is dissected so that it remains attached only by the inferior vena cava and portal vein. The hepatic artery, and common bile duct are ligated. Large abdominal varices may prolong the duration of, and increase the blood loss associated with, this phase.

2. **Anhepatic phase:** Once the donor liver graft is ready, the portal vein is clamped, followed by the inferior vena cava above and below the liver. The liver is then lifted out of the abdomen. Venovenous bypass maybe employed during this phase. The donor liver is then anastomosed to the supra- and infrahepatic inferior vena cavae and the portal vein.

3. **Revascularization and biliary reconstruction (neohepatic or postanhepatic) phase:** Following completion of the venous anastomoses, venous clamps are removed from the cava, allowing venous blood to return to the heart. Next, the portal vein is slowly opened, allowing blood to flush out preservation fluid and other substances accumulated in the liver during its ischemic time. This reperfusion may result in hypotension, arrhythmias, or cardiac arrest—a scenario termed the *reperfusion syndrome*. The circulation to the new liver is completed by anastomosing the hepatic artery. Lastly, the common bile duct of the donor liver is then usually anastomosed to the recipient using the recipient’s common bile duct or a Roux-en-Y choledochojejunostomy.
**What major problems complicate anesthesia for liver transplantation?**

Potential problems include multiorgan dysfunction caused by cirrhosis, massive blood loss, hemodynamic instability from clamping and unclamping the inferior vena cava and portal vein, metabolic consequences of the anhepatic phase, and air embolism and hyperkalemia.

Preoperative coagulation defects, thrombocytopenia, and previous abdominal surgery greatly increase blood loss. Extensive venous collaterals between the portal and systemic venous circulations also contribute to increased bleeding from the abdominal wall. Potential complications of massive blood transfusion include hypothermia, coagulopathies, hyperkalemia, citrate intoxication (hypocalcemia), and the potential transmission of infectious agents. Blood salvaging techniques are useful in reducing donor red blood cell transfusion.

**What is adequate venous access for these procedures?**

Bleeding is a recurring problem during each phase of liver transplantation. Adequate venous access is paramount in anesthetic management. Several large-bore (14-gauge or larger) intravenous catheters should be placed above the diaphragm. Specialized 8.5FR catheters can be placed in antecubital veins and used in conjunction with rapid infusion devices. Most centers place a large-bore central venous catheter. Efforts to minimize the risk of hypothermia should include the use of fluid warming and forced-air surface warming devices.

**What monitoring techniques are most useful during surgery?**

All patients require direct intraarterial pressure monitoring. A central venous catheter should be available. Goal-directed hemodynamic and fluid management utilizing arterial pulse wave analysis, esophageal Doppler, PVI, or TEE is common. Urinary output should be monitored throughout surgery via an indwelling urinary catheter.

Laboratory measurements constitute an important part of intraoperative monitoring. Serial hematocrit measurements guide red blood cell replacement. Similarly, frequent measurements of arterial blood gases, serum electrolytes, serum ionized calcium, and serum glucose are necessary to detect and appropriately treat metabolic derangements. Coagulation can be monitored by measuring PT, activated partial thromboplastin time,
fibrinogen level, and platelet counts, and by point-of-care viscoelastic coagulation analysis—TEG, ROTEM, or Sonoclot analysis. These latter modalities not only assess overall clotting and platelet function, but can also detect fibrinolysis.

**What anesthetic technique may be used for liver transplantation?**

Most patients should be considered as having a “full stomach,” often because of marked abdominal distention or recent upper gastrointestinal bleeding. General anesthesia is usually induced via a rapid sequence induction. The semiupright (back up) position during induction prevents rapid oxygen desaturation and facilitates ventilation until the abdomen is open. Hyperventilation should be avoided unless there is increased intracranial pressure. Anesthesia is generally maintained with a volatile agent (usually isoflurane or sevoflurane), and an intravenous opioid (usually fentanyl or sufentanil). The concentration of the volatile agent should be limited to less than 1 minimum alveolar concentration in patients with severe encephalopathy. Nitrous oxide is usually avoided. Many patients are routinely transferred to the intensive care unit intubated and mechanically ventilated at the end of the operative procedure, although immediate postoperative extubation may be considered if the patient is comfortable, cooperative, physiologically stable, and not hemorrhaging significantly.

**What physiological derangements are associated with the anhepatic phase?**

When the liver is removed, the large citrate load from blood products is no longer metabolized and results in hypocalcemia and secondary myocardial depression. Periodic calcium chloride administration (1 g) is necessary, but should be guided by ionized calcium concentration measurements to avoid hypercalcemia. Progressive acidosis is also encountered because acid metabolites from the intestines and lower body are not cleared by the liver. Sodium bicarbonate therapy may be necessary and should similarly be guided by arterial blood gas analysis. Excessive administration of sodium bicarbonate results in hypernatremia, hyperosmolality, and accentuation of the metabolic alkalosis that typically follows massive blood transfusions. Tromethamine should be considered when large amounts of alkali therapy are necessary. Although
hypoglycemia can occur during the anhepatic phase, hyperglycemia is a more common occurrence following reperfusion.

Pulmonary and systemic (paradoxic) air embolism can occur when the circulation is fully reestablished to the donor liver because air often enters hepatic sinusoids after harvesting. Systemic air embolism probably reflects the fact that many of these patients have extensive arteriovenous communications. The anhepatic phase ends when the three venous clamps are removed and the donor liver is perfused. Thromboembolic phenomena are also possible following reperfusion.

**What problems may be anticipated during the revascularization phase?**

Perfusion of the donor liver by the recipient’s blood often results in transiently increased serum potassium concentration of up to 1 to 2 mEq/L and increased systemic acidosis. Reperfusion releases potassium from any remaining preservative solution (115–120 mEq/L of potassium) still within the liver, as well as potassium released from tissues distal to venous clamps. Unclamping may also release a large acid load from ischemic tissue in the lower body (particularly without venovenous bypass); preemptive administration of sodium bicarbonate is advocated by some.

When the circulation to the new liver is established, the sudden increase in blood volume, acidosis, and hyperkalemia can produce tachyarrhythmias, or, more commonly, bradyarrhythmias. In addition to calcium chloride and sodium bicarbonate, inotropic support is also often required. Hyperfibrinolysis is commonly present and seems to be due to a marked increase in tissue plasminogen activator and a decrease in plasminogen activator inhibitor and α₂-antiplasmin during the anhepatic phase. Fibrinolysis can be detected by point-of-care viscoelastic coagulation analysis. ε-Aminocaproic acid or tranexamic acid, which inhibit the formation of plasmin, may be indicated in those instances, but should not be used prophylactically.

**What problems are encountered postoperatively?**

Patients often have an uncomplicated postoperative course and, after a sufficient period of observation in the intensive care unit, may be transferred directly to the nursing unit designed for liver transplant patients. Problems to anticipate include graft dysfunction or failure, persistent hemorrhage, fluid overload, metabolic abnormalities (particularly metabolic
alkalosis and hypokalemia), respiratory failure, pleural effusions, acute kidney injury or failure, systemic infections, and surgical complications (eg, bile leaks or stricture, or thrombosis of the hepatic or portal vessels). The last two complications may become suspect during ultrasound examination and are confirmed by angiography. Neurological complications include seizures, intracranial hemorrhage, encephalopathy, osmotic demyelination syndrome from a sudden increase in serum sodium, and immunosuppressant-related neurotoxicity. Contributory factors for acute kidney injury or failure include periods of hypotension, impaired kidney perfusion when the inferior vena cava is clamped (resulting in high pressures in the renal veins), and cyclosporine or antibiotic nephropathy. Measurement of immunosuppressant levels may be helpful in avoiding toxicity.

Prophylactic antibiotics and antifungal agents are routinely given in many centers because of a high incidence of infections.

Graft function is usually monitored by the PT, serum bilirubin, aminotransferase activity, and serum lactate measurements. Diagnosis requires liver biopsy.

SUGGESTED READINGS

Anesthesia for Patients with Endocrine Disease

**KEY CONCEPTS**

1. Diabetic autonomic neuropathy may limit the patient’s ability to compensate (with tachycardia and increased peripheral resistance) for intravascular volume changes and may predispose the patient to cardiovascular instability (eg, postinduction hypotension) and even sudden cardiac death.

2. Temporomandibular joint and cervical spine mobility should be assessed preoperatively in diabetic patients to reduce the likelihood of unanticipated difficult intubation. Difficult intubation has been reported in as many as 30% of persons with type 1 diabetes.

3. Sulfonylureas and metformin have long half-lives and many clinicians will discontinue them 24 to 48 h before surgery. They can be started postoperatively when the patient resumes oral intake.

4. Incompletely treated hyperthyroid patients may be chronically hypovolemic and prone to an exaggerated hypotensive response to induction of anesthesia.

5. Clinically hypothyroid patients are more susceptible to the hypotensive effect of anesthetic agents because of diminished cardiac output, blunted baroreceptor reflexes, and decreased intravascular volume.

6. Patients with glucocorticoid deficiency must receive adequate steroid replacement therapy during the perioperative period.

7. In patients with a pheochromocytoma, drugs or techniques that indirectly stimulate or promote the release of catecholamines (eg, ephedrine, hypoventilation, or bolus doses of ketamine), potentiate the arrhythmic effects of catecholamines (halothane), or consistently release histamine (eg, large doses of atracurium or morphine sulfate).
may precipitate hypertension and are best avoided.

Obese patients may be difficult to intubate as a result of limited mobility of the temporomandibular and atlantooccipital joints, a narrowed upper airway, and a shortened distance between the mandible and sternal fat pads.

The key to perioperative management of patients with carcinoid syndrome is to avoid anesthetic and surgical techniques or agents that could cause the tumor to release vasoactive substances.

The underproduction or overproduction of hormones can have life-threatening consequences. Therefore, it is not surprising that endocrinopathies affect anesthetic management. This chapter briefly reviews normal physiology and pathophysiology of four endocrine organs: the pancreas, the thyroid, the parathyroids, and the adrenal glands. It also considers obesity and carcinoid syndrome.

The Pancreas

Physiology

Adults normally secrete approximately 50 units of insulin each day from the β cells of the islets of Langerhans in the pancreas. The rate of insulin secretion is primarily determined by the plasma glucose concentration. Insulin, the most important anabolic hormone, has multiple metabolic effects, including facilitating glucose and potassium entry into adipose and muscle cells; increasing glycogen, protein, and fatty acid synthesis; and decreasing glycogenolysis, gluconeogenesis, ketogenesis, lipolysis, and protein catabolism.

In general, insulin stimulates anabolism and weight gain, whereas lack of insulin is associated with catabolism, a negative nitrogen balance, and weight loss (Table 35–1).

## DIABETES MELLITUS

### Clinical Manifestations

Diabetes mellitus is characterized by hyperglycemia and glycosuria arising from impairment of carbohydrate metabolism. The cause is an absolute or relative deficiency of insulin or of insulin responsiveness. The diagnosis is based on an elevated fasting plasma glucose greater than 126 mg/dL or glycated hemoglobin
(HbA1c) of 6.5% or greater. Values are sometimes reported for blood glucose, which runs 12% to 15% lower than plasma glucose. Even when testing whole blood, newer glucose meters calculate and display plasma glucose. Long-term complications of diabetes include retinopathy, kidney disease, hypertension, coronary artery disease, peripheral and cerebral vascular disease, and peripheral and autonomic neuropathies.

Diabetes is classified in multiple ways (Table 35–2). Type 1 (insulin-requiring due to endogenous insulin deficiency) and type 2 (insulin-resistant) diabetes are the most common and well known.

There are three life-threatening acute complications of diabetes and its treatment—diabetic ketoacidosis (DKA), hyperosmolar nonketotic coma, and hypoglycemia—in addition to other acute medical problems (such as sepsis) in which the presence of diabetes makes treatment more difficult. Decreased insulin activity allows the catabolism of free fatty acids into ketone bodies (acetoacetate and β-hydroxybutyrate), some of which are weak acids (see Chapter 50). Accumulation of these organic acids results in DKA, an anion-gap metabolic acidosis. DKA can easily be distinguished from lactic acidosis; lactic acidosis is identified by elevated plasma lactate (>6 mmol/L) and the absence of urine and plasma ketones. However, both DKA and starvation ketosis may occur concurrently with lactic acidosis, underscoring the need for measurement of lactate. DKA is associated with type 1 diabetes mellitus, but a rare individual
with DKA may appear phenotypically to have type 2 diabetes mellitus. Alcoholic ketoacidosis can follow heavy alcohol consumption (binge drinking) in a nondiabetic patient and may include a normal or slightly elevated blood glucose level. Such patients may also have a disproportionate increase in β-hydroxybutyrate compared with acetoacetate, in contrast to those with DKA.

Infection is a common precipitating cause of DKA in otherwise well-managed diabetic patients. DKA may be the initial presentation of a previously undiagnosed person with type 1 diabetes. Clinical manifestations of DKA include tachypnea (respiratory compensation for the metabolic acidosis), abdominal pain, nausea and vomiting, and changes in sensorium. The treatment of DKA should include correcting the often substantial hypovolemia, the hyperglycemia, and the total body potassium deficit. This is typically accomplished with a continuous infusion of isotonic fluids with potassium and an insulin infusion.

The goal for decreasing blood glucose in ketoacidosis should be 75 to 100 mg/dL/h or 10%/h. Therapy generally begins with an intravenous insulin infusion at 0.1 units/kg/h. DKA patients may be resistant to insulin, and the insulin infusion rate may need to be increased if glucose concentrations do not decrease. As glucose moves intracellularly, so does potassium. Although this can quickly lead to a critical level of hypokalemia if not corrected, overaggressive potassium replacement can lead to an equally life-threatening hyperkalemia. Potassium and blood glucose should be monitored frequently during treatment of DKA.

Several liters of 0.9% saline (1–2 L the first hour, followed by 200–500 mL/h) may be required to correct dehydration in adult patients. When plasma glucose decreases to 250 mg/dL, an infusion of D₅W should be added to the insulin infusion to decrease the possibility of hypoglycemia and to provide a continuous source of glucose (with the infused insulin) for eventual normalization of intracellular metabolism. Patients may benefit from monitoring of urinary output during initial treatment of DKA. Bicarbonate is rarely needed to correct severe acidosis (pH <7.1) as the acidosis will correct with volume expansion and with normalization of the plasma glucose concentration.

Ketoacidosis is not a feature of hyperosmolar nonketotic coma possibly because enough insulin is available to prevent ketone body formation. Instead, a hyperglycemia-induced diuresis leads to dehydration and hyperosmolality. Severe dehydration may eventually lead to kidney failure, lactic acidosis, and a predisposition to form intravascular thromboses. Hyperosmolality (frequently exceeding 360 mOsm/L) induces dehydration of neurons, causing altered mental
status and seizures. Severe hyperglycemia causes a factitious hyponatremia: each 100 mg/dL increase in plasma glucose lowers plasma sodium concentration by 1.6 mEq/L. Treatment includes fluid resuscitation with normal saline, relatively small doses of insulin, and potassium supplementation.

Hypoglycemia in the diabetic patient is the result of an absolute or relative excess of insulin relative to carbohydrate intake and exercise. Furthermore, diabetic patients are incompletely able to counter hypoglycemia despite secreting glucagon or epinephrine (counterregulatory failure). The dependence of the brain on glucose as an energy source makes it the organ most susceptible to episodes of hypoglycemia. If hypoglycemia is not treated, mental status changes can progress from anxiety, lightheadedness, headache, or confusion to convulsions and coma. Systemic manifestations of hypoglycemia result from catecholamine discharge and include diaphoresis, tachycardia, and nervousness. Most of the signs and symptoms of hypoglycemia will be masked by general anesthesia. Although the lower boundary of normal plasma glucose levels is ill-defined, medically important hypoglycemia is present when plasma glucose is less than 50 mg/dL. The treatment of hypoglycemia in anesthetized or critically ill patients consists of intravenous administration of 50% glucose (each milliliter of 50% glucose will raise the blood glucose of a 70-kg patient by approximately 2 mg/dL). Awake patients can be treated orally with fluids containing glucose or sucrose.

Anesthetic Considerations

A. Preoperative
Abnormally elevated hemoglobin A\textsubscript{1c} concentrations identify patients who have maintained poor control of blood glucose over time. These patients are at greater risk for perioperative hyperglycemia, perioperative complications, adverse outcomes, and increased costs. The perioperative morbidity of diabetic patients is related to their preexisting end-organ damage. Unfortunately, many surgical patients with type 2 diabetes mellitus may be unaware of their condition.

A preoperative chest radiograph is not routinely indicated in diabetic patients. Diabetic patients have an increased incidence of ST-segment and T-wave-segment abnormalities on preoperative electrocardiograms (ECGs). Myocardial ischemia or old infarction may be evident on an ECG despite a negative history. Diabetic patients with hypertension have a 50% likelihood of coexisting diabetic autonomic neuropathy (Table 35–3). Reflex dysfunction of the autonomic nervous system may be increased by old age, diabetes of longer than 10 years’
duration, coronary artery disease, or β-adrenergic blockade. Diabetic autonomic neuropathy may limit the patient’s ability to compensate (with tachycardia and increased peripheral resistance) for intravascular volume changes and may predispose the patient to cardiovascular instability (eg, postinduction hypotension) and even sudden cardiac death. Autonomic dysfunction contributes to delayed gastric emptying (diabetic gastroparesis). Premedication with a nonparticulate antacid and metoclopramide is often used in obese diabetic patients with signs of cardiac autonomic dysfunction. However, autonomic dysfunction of the gastrointestinal tract may be present without any signs of cardiac involvement. Diabetic neuropathy may also lead to silent (painless) myocardial ischemia.

**TABLE 35–3 Clinical signs of diabetic autonomic neuropathy.**

<sup>1</sup>Normal heart rate variability during voluntary deep breathing (6 breaths/min) should be >10 beats/min.

Diabetic renal dysfunction is manifested first by proteinuria and later by elevated serum creatinine. By these criteria, most patients with type 1 diabetes have evidence of kidney disease by 30 years of age. Chronic hyperglycemia leads to glycosylation of tissue proteins and reduced mobility of joints. Temporomandibular joint and cervical spine mobility should be assessed preoperatively in diabetic patients to reduce the likelihood of unanticipated difficult intubations. Difficult intubation has been reported in as many as 30% of persons with type 1 diabetes.

**B. Intraoperative**

The goal of intraoperative blood glucose management is to avoid hypoglycemia
while maintaining blood glucose below 180 mg/dL. Attempting to maintain strict euglycemia is imprudent; “loose” blood glucose control (>180 mg/dL) also carries risk. The exact range over which blood glucose should be maintained in critical illness has been the subject of several much-discussed clinical trials. Hyperglycemia has been associated with hyperosmolarity, infection, poor wound healing, and increased mortality. Severe hyperglycemia may worsen neurological outcome following an episode of cerebral ischemia and may compromise outcome following cardiac surgery or after an acute myocardial infarction. Maintaining blood glucose control (<180 mg/dL) in patients undergoing cardiopulmonary bypass decreases infectious complications. A benefit of true “tight” control (<150 mg/dL) during surgery or critical illness has not yet been demonstrated convincingly and in some studies has been associated with worse outcome than “looser” control in both critically ill adults and children.

Despite lack of consensus regarding the appropriate target blood glucose, perioperative glucose management has been used as a measurement of “quality” anesthetic care. Consequently, one should ensure that one’s glucose management protocols align with institutional and national expectations. Control of blood glucose in pregnant diabetic patients improves fetal outcome. Nonetheless, as noted earlier, the brain’s dependence on glucose as an energy supply makes it essential that hypoglycemia be avoided. Because of an increased incidence of and risk from infections, strict attention to aseptic technique and meticulous wound care are especially important in patients with diabetes.

There are several common perioperative management regimens for insulin-dependent diabetic patients. In the most time-honored approach (which we do not recommend because it is not terribly effective), the patient receives half of the usual morning intermediate-acting insulin dose (Table 35–4). To decrease the risk of hypoglycemia, insulin is administered after intravenous access has been established and the morning blood glucose level is checked. For example, a patient who normally takes 30 units of NPH (neutral protamine Hagedorn; intermediate-acting) insulin and 10 units of regular or Lispro (short-acting) insulin or insulin analogue each morning and whose blood glucose is at least 150 mg/dL would receive 15 units (half the normal 30-unit morning dose) of NPH subcutaneously before surgery along with an infusion of 5% dextrose solution (1.5 mL/kg/h). Absorption of subcutaneous or intramuscular insulin depends on tissue blood flow, however, and can be unpredictable during surgery. Intraoperative hyperglycemia (>180 mg/dL) may be treated with boluses of intravenous regular insulin. One unit of regular insulin given to an adult usually
lowers plasma glucose by 25 to 30 mg/dL.

$^1$NPH, neutral protamine Hagedorn.

A better method, feasible in all but short procedures, is to administer regular insulin as a continuous infusion. The advantage of this technique is more precise control of insulin delivery than can be achieved with a subcutaneous or intramuscular injection of NPH insulin, particularly in conditions associated with poor skin and muscle perfusion. Regular insulin can be added to normal saline in a concentration of 1 unit/mL and the infusion begun at 0.1 unit/kg/h or less. As blood glucose fluctuates, the insulin infusion can be adjusted up or down as required. Dedication of a small-gauge intravenous line for the dextrose infusion prevents interference with other intraoperative fluids and drugs. Supplemental dextrose can be administered if the patient becomes hypoglycemic (<100 mg/dL). It must be stressed that these doses are approximations and do not apply to patients in catabolic states (eg, sepsis, hyperthermia).

The dose required may be approximated by the following formula:

$$\text{Unit per hour} = \frac{\text{Plasma glucose (mg/dL)}}{150}$$

A reasonable target for the intraoperative maintenance of blood glucose is less than 180 mg/dL and greater than 85 mg/dL.

When administering an intravenous insulin infusion to surgical patients, adding some (eg, 20 mEq) KCl to each liter of maintenance fluid may be useful, as insulin causes an intracellular potassium shift. Because individual insulin needs can vary dramatically, any formula should be considered only a crude
guideline. Periodic glucose measurements are required.

If the patient is taking an oral hypoglycemic agent preoperatively rather than insulin, the drug can be continued until the day of surgery. However, sulfonylureas and metformin have long half-lives and many clinicians will discontinue them 24 to 48 h before surgery. They can be started postoperatively when the patient resumes oral intake. Metformin is restarted if renal and hepatic function remain adequate. The effects of oral hypoglycemic drugs with a short duration of action can be prolonged in the presence of kidney failure. Many patients maintained on oral antidiabetic agents will require insulin treatment during the intraoperative and postoperative periods. The stress of surgery causes elevations in counterregulatory hormones (eg, catecholamines, glucocorticoids, growth hormone) and inflammatory mediators such as tumor necrosis factor and interleukins. Each of these contributes to stress hyperglycemia, increasing insulin requirements. In general, type 2 diabetic patients tolerate minor, brief surgical procedures without requiring any exogenous insulin. However, many ostensibly “nondiabetic” patients show pronounced hyperglycemia during critical illness and require a period of insulin therapy.

The key to any diabetic management regimen is to monitor plasma glucose levels frequently. Patients receiving insulin infusions intraoperatively may need to have their glucose measured hourly. Those with type 2 diabetes vary in their ability to produce and respond to insulin. Likewise, insulin requirements vary with the extensiveness of the surgical procedure. Bedside glucose meters are capable of determining the glucose concentration in a drop of blood within a minute. These devices measure the color conversion of a glucose oxidase–impregnated strip. Their accuracy depends, to a large extent, on adherence to the device’s specific testing protocol but in no way reproduces the accuracy of standard laboratory testing, particularly at the extremes of glucose concentrations. Monitoring urine glucose is of value only for detecting glycosuria.

Patients who take NPH or other protamine-containing insulin preparations have an increased risk of adverse reactions to protamine sulfate, including anaphylactoid reactions and death. Unfortunately, operations that require the use of heparin and subsequent reversal with protamine (eg, coronary artery bypass grafting) are more common in diabetic patients. Based on immunological principles and our clinical experience, we do not advocate administering protamine test doses prior to the full reversal dose, although this is recommended by some clinicians.

Patients who use subcutaneous insulin infusion pumps for management of
type 1 diabetes can leave the pump programmed to deliver “basal” amounts of regular insulin (or insulin glargine) when fasting. By definition, the basal rate is the amount of insulin required during fasting. Patients can safely undergo short outpatient surgery with the pump on the basal setting. If more extensive inpatient procedures are required, these patients will normally suspend their pumps and be managed with intravenous insulin infusions and periodic blood glucose measurements, as described earlier.

C. Postoperative

Close monitoring of blood glucose must continue postoperatively. There is considerable patient-to-patient variation in onset and duration of action of insulin preparations (Table 35–5). For example, the onset of action of subcutaneous regular insulin is less than 1 h, but in rare patients its duration of action may continue for 6 h. NPH insulin typically has an onset of action within 2 h, but the action can last longer than 24 h.

The Thyroid

**Physiology**

Dietary iodine is absorbed by the gastrointestinal tract, converted to iodide ion, and actively transported into the thyroid gland. Once in the gland, iodide is oxidized back to iodine, which is bound to the amino acid tyrosine. The end result is two hormones—triiodothyronine (T₃) and thyroxine (T₄)—which are bound to proteins and stored within the thyroid. Although the gland releases more T₄ than T₃, the latter is more potent and less protein bound. Of all circulating T₃, most is formed peripherally from partial deiodination of T₄. An elaborate feedback mechanism controls thyroid hormone synthesis and involves the hypothalamus (thyrotropin-releasing hormone [TRH]), the anterior pituitary
(thyroid-stimulating hormone [TSH]), autoregulation, and the adequacy of iodine intake.

Thyroid hormone (T₃) increases carbohydrate and fat metabolism and is an important factor in determining growth and metabolic rate. An increase in metabolic rate is accompanied by an increase in oxygen consumption and CO₂ production. Heart rate and contractility are also increased, presumably from direct actions of thyroid on contractile proteins and other internal protein alterations.

**HYPERTHYROIDISM**

**Clinical Manifestations**

Excess thyroid hormone levels can be caused by Graves disease, toxic multinodular goiter, TSH-secreting pituitary tumors, “toxic” or “hot” thyroid adenomas, or overdosage (accidental or intentional) of thyroid hormone. Clinical manifestations of excess thyroid hormone concentrations include weight loss, heat intolerance, muscle weakness, diarrhea, hyperactive reflexes, and nervousness. A fine tremor, exophthalmos, or goiter may be noted, particularly when the cause is Graves disease. New onset of atrial fibrillation is a classic presentation of hyperthyroidism, but cardiac signs may also include sinus tachycardia and congestive heart failure. The diagnosis of hyperthyroidism is confirmed by abnormal thyroid function tests, which may include an elevation in serum T₄ and serum T₃ and a reduced TSH level.

Medical treatment of hyperthyroidism relies on drugs that inhibit thyroid hormone synthesis (eg, propylthiouracil, methimazole), prevent hormone release (eg, potassium, sodium iodide), or mask the signs of adrenergic overactivity (eg, propranolol). In addition, although β-adrenergic antagonists do not affect thyroid gland function, they do decrease the peripheral conversion of T₄ to T₃. Radioactive iodine destroys thyroid cell function and may result in hypothyroidism. Radioactive iodine is not recommended for pregnant patients. Subtotal thyroidectomy is rarely used as an alternative to medical therapy but is typically reserved for patients with large toxic multinodular goiters or solitary toxic adenomas. Graves disease is usually treated with so-called antithyroid drugs or radioactive iodine.

**Anesthetic Considerations**
A. Preoperative
All elective surgical procedures, including subtotal thyroidectomy, should be postponed until the patient is rendered clinically and chemically euthyroid with medical treatment. The patient should have normal $T_3$ and $T_4$ concentrations, and should not have resting tachycardia. Antithyroid medications and β-adrenergic antagonists are continued through the morning of surgery. Administration of propylthiouracil and methimazole is particularly important because of their relatively short half-lives.

Patients with larger goiters or thyroid masses will often have preoperative CT or MR imaging studies to rule out extension into the mediastinum. Such extension might mandate sternotomy for complete resection.

B. Intraoperative
Cardiovascular function and body temperature should be closely monitored in patients with a history of hyperthyroidism. When emergency surgery must proceed despite clinical hyperthyroidism, the hyperdynamic circulation can be controlled intraoperatively with an esmolol infusion. The exophthalmos of Graves disease increases the risk of corneal abrasion or ulceration.

Ketamine, indirect-acting adrenergic agonists (ephedrine), and other drugs that stimulate the sympathetic nervous system are best avoided in patients with current or recently corrected hyperthyroidism because of the possibility of exaggerated elevations in blood pressure and heart rate. Incompletely treated hyperthyroid patients may be hypovolemic and prone to an exaggerated hypotensive response to induction of anesthesia. Adequate anesthetic depth must be obtained before laryngoscopy or surgical stimulation to avoid tachycardia, hypertension, and ventricular arrhythmias.

Thyrotoxicosis is associated with an increased incidence of myopathies and myasthenia gravis; therefore, neuromuscular blocking agents (NMBs) should be administered cautiously. Hyperthyroidism does not increase anesthetic requirements; that is, there is no increase in minimum alveolar concentration.

C. Postoperative
The most serious threat to a hyperthyroid patient undergoing surgery is thyroid storm, which is characterized by hyperpyrexia, tachycardia, altered consciousness (eg, agitation, delirium, coma), and hypotension. Thyroid storm is a medical emergency that requires aggressive management and monitoring (see Case Discussion, Chapter 56). The onset is usually 6 to 24 h after surgery but
can occur intraoperatively, mimicking malignant hyperthermia. Unlike malignant hyperthermia, thyroid storm is not associated with muscle rigidity, elevated creatine kinase, or a marked degree of metabolic (lactic) and respiratory acidosis. Treatment includes hydration and cooling, an esmolol infusion or another intravenous β-blocker (with a target of maintaining heart rate <100/min), propylthiouracil (250–500 mg every 6 h orally or by nasogastric tube) followed by sodium iodide (1 g intravenously over 12 h), and correction of any precipitating cause (eg, infection). Hydrocortisone (100–200 mg every 8 h) or the equivalent is recommended to prevent complications from coexisting adrenal gland suppression.

Thyroidectomy is associated with several potential surgical complications. Recurrent laryngeal nerve palsy will result in hoarseness (unilateral) or aphonia and stridor (bilateral). Vocal cord function can be evaluated by laryngoscopy immediately following “deep extubation”; however, this is rarely necessary. Immobility of one or both cords may require reintubation and exploration of the wound. Hematoma formation may cause airway compromise from collapse of the trachea, particularly in patients with tracheomalacia. Dissection of the hematoma into the compressible soft tissues of the neck may distort the airway anatomy and may make intubation difficult. Immediate treatment includes opening the neck wound and evacuating the clot, then reassessing the need for reintubation. Anesthesia staff in the postoperative setting must be prepared to open the surgical wound and relieve airway compression if the surgeon is unavailable.

Hypoparathyroidism from unintentional removal of all four parathyroid glands will cause acute hypocalcemia within 12 to 72 h (see the section on Clinical Manifestations under Hypoparathyroidism). Pneumothorax is a rare complication of neck exploration.

**HYPOTHYROIDISM**

**Clinical Manifestations**

Hypothyroidism can be caused by autoimmune disease (eg, Hashimoto thyroiditis), thyroidectomy, radioactive iodine, antithyroid medications, iodine deficiency, or failure of the hypothalamic–pituitary axis (secondary hypothyroidism). Hypothyroidism during neonatal development results in cretinism, a condition marked by physical and mental retardation. Clinical manifestations of hypothyroidism in the adult are usually subtle and include
infertility, weight gain, cold intolerance, muscle fatigue, lethargy, constipation, hypoactive reflexes, dull facial expression, and depression. In advanced cases heart rate, myocardial contractility, stroke volume, and cardiac output are all decreased, and extremities are cool and mottled because of peripheral vasoconstriction. Pleural, abdominal, and pericardial effusions are common. Hypothyroidism may be diagnosed by an elevated TSH concentration, or a reduced free (or total) T₃ level, or both. Primary hypothyroidism, the more common condition, is differentiated from secondary disease by an elevation in TSH in the former. Normal concentrations of TSH despite reduced T₃ concentrations (sometimes called “euthyroid sick” syndrome) are often seen after major operations and with critical illness. The treatment of hypothyroidism consists of oral replacement therapy with a thyroid hormone preparation, which takes several days to produce a physiological effect and several weeks to evoke clear-cut clinical improvement.

Myxedema coma results from extreme hypothyroidism and is characterized by coma, hypoventilation, hypothermia, hyponatremia (from inappropriate antidiuretic hormone secretion), and congestive heart failure. It is more common in elderly patients and may be precipitated by infection, surgery, or trauma. Myxedema coma is a life-threatening disease that can be treated with intravenous T₃. T₄ should not be used in this circumstance to avoid the need for peripheral conversion to T₃. The ECG should be monitored during therapy to detect myocardial ischemia or arrhythmias. Steroid replacement (eg, hydrocortisone, 100 mg intravenously every 8 h) is routinely given due to frequent coexisting adrenal gland suppression. Some patients may require ventilatory support and external warming.

**Anesthetic Considerations**

**A. Preoperative**

Patients with uncorrected severe hypothyroidism or myxedema coma must not undergo elective surgery. Such patients should be treated with T₃ intravenously prior to urgent or emergency surgery. Although a euthyroid state is ideal, mild to moderate hypothyroidism is not an absolute contraindication to necessary surgery, for example, urgent coronary bypass surgery. Symptomatic hypothyroid patients should receive minimal preoperative sedation given that they are prone to drug-induced respiratory depression. In addition, they may fail to respond to hypoxia with increased minute ventilation.
Patients who have been rendered euthyroid may receive their usual dose of thyroid medication on the morning of surgery; however, most commonly used preparations have long half-lives (the half-life of $T_4$ is about 8 days), and omission of a single dose should have no medical importance.

**B. Intraoperative**

Clinically hypothyroid patients are more susceptible to the hypotensive effect of anesthetic agents because of diminished cardiac output, blunted baroreceptor reflexes, and decreased intravascular volume. In this circumstance, ketamine or etomidate can be recommended for induction of anesthesia. The possibility of coexistent primary adrenal insufficiency should be considered in cases of refractory hypotension. **Other potential coexisting conditions include hypoglycemia, anemia, hyponatremia, difficulty during intubation because of a large tongue, and hypothermia from a low basal metabolic rate.**

**C. Postoperative**

Recovery from general anesthesia may be delayed in hypothyroid patients by hypothermia, respiratory depression, or slowed drug biotransformation; thus, these patients may require mechanical ventilation. Because hypothyroidism increases vulnerability to respiratory depression, a multimodal approach to postoperative pain management, rather than strict reliance on opioids is appropriate.

---

**The Parathyroid –Vitamin D–Bone–Kidney Axis**

**Physiology**

Parathyroid hormone (PTH) is the principal regulator of calcium homeostasis. It increases serum calcium concentrations directly by promoting resorption of bone and teeth, limiting renal excretion of calcium, and indirectly by stimulating vitamin D synthesis in the kidney to enhance gastrointestinal absorption. PTH decreases serum phosphate by increasing renal excretion. Two other recently identified hormones, fibroblast growth factor 23 (FGF23) and klotho, have effects on phosphate metabolism. FGF23 arises from bone and acts on the kidney to induce phosphaturia and to reduce production of vitamin D$_3$. FGF23 actions require that klotho activate the FGF receptor.

The effects of PTH on calcium serum levels are countered in lower animals
by calcitonin, a hormone excreted by parafollicular C cells in the thyroid. Although calcitonin is effective given as a pharmaceutical in humans, its role in normal human physiology is not clear (Table 35–6). Of total body calcium, 99% is in the skeleton. Of the calcium in the blood, 40% is bound to proteins and 60% is ionized or complexed to organic ions. Unbound ionized calcium is physiologically the most important fraction.

</tbody>
</table>

The remaining major player in this system, vitamin D, is a steroid hormone that can be absorbed via the gastrointestinal tract from food or synthesized from cholesterol derivatives. Conversion of 7-dehydrocalciiferol to vitamin D₃ is facilitated by exposure to ultraviolet light. Hydroxylation in the liver and kidneys yields 1,25(OH)₂D₃ (1,25-dihydroxyvitamin D₃), the active molecule that binds vitamin D receptors (VDRs) and produces its physiological actions. VDRs are located in the nucleus where, after binding vitamin D, they regulate expression of specific genes. 1,25(OH)₂D₃ promotes normal growth and remodeling of bone, in addition to helping to regulate calcium and phosphate concentrations.

### HYPERPARATHYROIDISM

#### Clinical Manifestations

Causes of primary hyperparathyroidism include parathyroid adenomas, hyperplasia of the parathyroid gland, and certain carcinomas. Secondary hyperparathyroidism is an adaptive response to hypocalcemia produced by conditions such as end-stage kidney disease or intestinal malabsorption syndromes. Ectopic hyperparathyroidism is due to production of PTH by rare tumors outside the parathyroid gland. Overall, the most common cause of
hypercalcemia in hospitalized patients is malignancy. Parathyroid hormone–related peptide may cause significant hypercalcemia when secreted by a tumor (eg, bronchogenic [lung] carcinoma or hepatoma). Bone invasion with osteolytic hypercalcemia may complicate multiple myeloma, lymphoma, or leukemia. Nearly all clinical manifestations of hyperparathyroidism are due to hypercalcemia (Table 35–7). Rarer causes of hypercalcemia include bone metastases of solid organ tumors, vitamin D intoxication, milk-alkali syndrome, lithium therapy, sarcoidosis, and prolonged immobilization. The treatment of hyperparathyroidism depends on the cause, but surgical removal of all four glands is often required in the setting of parathyroid hyperplasia. When there is a single adenoma, its removal cures many patients with sporadic primary hyperparathyroidism.

Anesthetic Considerations

In patients with hypercalcemia due to hyperparathyroidism, hydration with normal saline and diuresis facilitated by furosemide will usually decrease serum calcium to acceptable values (<14 mg/dL, 7 mEq/L, or 3.5 mmol/L). More aggressive therapy with the intravenous bisphosphonates pamidronate (Aredia) or etidronate (Didronel) may be necessary for patients with hypercalcemia of malignancy. Plicamycin (Mithramycin), glucocorticoids, calcitonin, or dialysis may be necessary when intravenous bisphosphonates are not sufficient or are contraindicated. Hypoventilation should be avoided, as acidosis increases ionized calcium. Elevated calcium levels can cause cardiac arrhythmias. The response to NMBs may be altered in patients with preexisting muscle weakness caused by the effects of calcium at the neuromuscular junction. Osteoporosis worsened by hyperparathyroidism predisposes patients to vertebral compression and bone fractures during anesthetic procedures, positioning, and transport. The notable postoperative complications of parathyroidectomy are similar to those for subtotal thyroidectomy.

HYPOPARATHYROIDISM

Clinical Manifestations

Hypoparathyroidism is usually due to deficiency of PTH following parathyroidectomy. Clinical manifestations of hypoparathyroidism are a result of hypocalcemia (Table 35–8), which can also be caused by kidney failure, hypomagnesemia, vitamin D deficiency, and acute pancreatitis (see Chapter 49). Hypoalbuminemia decreases total serum calcium (a 1-g/dL drop in serum albumin causes a 0.8-mg/dL decrease in total serum calcium), but ionized calcium, the active entity, is unaltered. The archetypical presentation of hypocalcemia is tetany, classically diagnosed by the Chvostek sign (painful twitching of the facial musculature following tapping over the facial nerve) or
the Trouseau sign (carpal spasm following inflation of an arm tourniquet above systolic blood pressure for 3 min). Treatment of symptomatic hypocalcemia consists of intravenous administration of calcium salts.

</tr>
</tbody>
</table>

\(^1\)ECG, electrocardiogram.

Mild hypocalcemia is common following cardiopulmonary bypass or infusion of albumin solutions. In many adult patients, this need not be treated as the response of the PTH–vitamin D axis will usually be sufficient to restore ionized calcium to normal values and mild hypocalcemia will usually have no hemodynamic consequences.

**Anesthetic Considerations**

Serum calcium must be normalized in any patient who presents with cardiac manifestations of severe hypocalcemia. Alkalosis from hyperventilation or sodium bicarbonate therapy will further decrease ionized calcium. Although citrate-containing blood products usually do not lower serum calcium significantly, they should be administered cautiously in patients with preexisting hypocalcemia. Other considerations include avoiding the bolus administration of albumin solutions (which bind and reduce ionized calcium concentrations) and being mindful of the possibility of hypocalcemia-induced coagulopathy.

**VITAMIN D DEFICIENCY**

A diet deficient in vitamin D combined with a lack of sun (ultraviolet light)
exposure will lead to rickets in children and osteomalacia in adults. Decreased concentrations of vitamin D, more common in the elderly, those who live in far northern latitudes, and those too frail or ill to spend time outdoors, have been associated with a great many conditions and diseases. Causal linkages have been hard to identify. Despite the great numbers of articles that have been written on this topic, we lack proper evidence regarding the vitamin D concentrations below which vitamin D replacement is mandatory, how best to replace vitamin D in those who require replacement, and indeed whether vitamin D replacement improves outcomes in those conditions in which reduced vitamin D concentrations have been associated with worse outcomes. The data are even murkier regarding vitamin D replacement in patients undergoing surgery.

---

**The Adrenal Gland**

### Physiology

The adrenal gland is divided into the cortex and medulla. The adrenal cortex secretes androgens, mineralocorticoids (eg, aldosterone), and glucocorticoids (eg, cortisol). The adrenal medulla secretes catecholamines (primarily epinephrine, but also small amounts of norepinephrine and dopamine). The adrenal androgens have almost no relevance for anesthetic management and will not be considered further.

Aldosterone is primarily involved with fluid and electrolyte balance. Aldosterone secretion causes sodium to be reabsorbed in the distal renal tubule in exchange for potassium and hydrogen ions. The net effect is an expansion in extracellular fluid volume caused by fluid retention, a decrease in plasma potassium, and metabolic alkalosis. Aldosterone secretion is stimulated by the renin–angiotensin system (specifically, angiotensin II), pituitary adrenocorticotropic hormone (ACTH), and hyperkalemia. Hypovolemia, hypotension, congestive heart failure, and surgery result in an elevation of aldosterone concentrations. Blockade of the renin–angiotensin–aldosterone system with angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, or both, is a cornerstone of therapy (and increases survival) in hypertension and chronic heart failure. Aldosterone receptor blockers (spironolactone or eplerenone) added to standard therapy prolong survival in patients with chronic heart failure.

Glucocorticoids are essential for life and have multiple physiological effects, including enhanced gluconeogenesis and inhibition of peripheral glucose
utilization. These actions tend to raise blood glucose and worsen diabetic control. Glucocorticoids are required for vascular and bronchial smooth muscle to respond to catecholamines. Because glucocorticoids are structurally related to aldosterone, most tend to promote sodium retention and potassium excretion (a mineralocorticoid effect). ACTH released by the anterior pituitary is the principal regulator of glucocorticoid secretion. Basal secretion of ACTH and glucocorticoids exhibits a diurnal rhythm. Stressful conditions promote secretion of ACTH and cortisol, while circulating glucocorticoids inhibit ACTH and cortisol secretion. Under nonstressed conditions, endogenous production of cortisol, the most important endogenous glucocorticoid, averages 20 mg/d.

The structure, biosynthesis, physiological effects, and metabolism of catecholamines are discussed in Chapter 14. Epinephrine constitutes 80% of adrenal catecholamine output in humans. Catecholamine release is regulated mainly by sympathetic cholinergic preganglionic fibers that innervate the adrenal medulla. Stimuli include exercise, hemorrhage, surgery, hypotension, hypothermia, hypoglycemia, hypercapnia, hypoxemia, pain, and fear.

**MINERALOCORTICOID EXCESS**

**Clinical Manifestations**

Hypersecretion of aldosterone by the adrenal cortex (primary aldosteronism) can be due to a unilateral adenoma (aldosteronoma or Conn syndrome), bilateral hyperplasia, or in very rare cases carcinoma of the adrenal gland. Some disease states stimulate aldosterone secretion by affecting the renin–angiotensin system. For example, congestive heart failure, hepatic cirrhosis with ascites, nephrotic syndrome, and some forms of hypertension (eg, renal artery stenosis) can cause secondary hyperaldosteronism. Although both primary and secondary hyperaldosteronism are characterized by increased levels of aldosterone, only the latter is associated with increased renin activity. The usual clinical manifestations of mineralocorticoid excess include hypokalemia and hypertension, and an increased ratio of aldosterone–plasma renin activity has been noted in laboratory studies.

**Anesthetic Considerations**

Fluid and electrolyte disturbances can be corrected preoperatively using spironolactone. This aldosterone antagonist is a potassium-sparing diuretic with antihypertensive properties. Intravascular volume can be assessed preoperatively
by testing for orthostatic hypotension.

**MINERALOCORTICOID DEFICIENCY**

**Clinical Manifestations & Anesthetic Considerations**

Atrophy or destruction of both adrenal glands results in a combined deficiency of mineralocorticoids and glucocorticoids (see the section on Glucocorticoid Deficiency). Isolated deficiency of mineralocorticoid activity almost never occurs.

**GLUCOCORTICOID EXCESS**

**Clinical Manifestations**

Glucocorticoid excess may be due to exogenous administration of steroid hormones, intrinsic hyperfunction of the adrenal cortex (eg, adrenocortical adenoma), ACTH production by a nonpituitary tumor (ectopic ACTH syndrome), or hypersecretion by a pituitary adenoma (Cushing disease). Regardless of the cause, an excess of corticosteroids produces Cushing syndrome, characterized by muscle wasting and weakness, osteoporosis, central obesity, abdominal striae, glucose intolerance, menstrual irregularity, hypertension, and mental status changes.

**Anesthetic Considerations**

Patients with Cushing syndrome may be volume overloaded and have hypokalemic metabolic alkalosis resulting from the mineralocorticoid activity of glucocorticoids. These abnormalities should be corrected preoperatively in the manner previously described. Patients with osteoporosis are at risk for fracture during positioning. If the cause of Cushing syndrome is exogenous glucocorticoids, the patient’s adrenal glands may not be able to respond to perioperative stresses, and supplemental steroids are indicated (see the section on Glucocorticoid Deficiency). Likewise, patients undergoing adrenalectomy require intraoperative glucocorticoid replacement (in adults, intravenous hydrocortisone succinate, 100 mg every 8 h has been the traditional stress dose). Although many adrenal tumors are removed uneventfully during laparoscopic surgery, complications of adrenalectomy may include major blood loss and unintentional pneumothorax.
GLUCOCORTICOID DEFICIENCY

Clinical Manifestations

Primary adrenal insufficiency (Addison disease), caused by destruction of the adrenal gland, results in a combined mineralocorticoid and glucocorticoid deficiency. Clinical manifestations are due to aldosterone deficiency (hyponatremia, hypovolemia, hypotension, hyperkalemia, and metabolic acidosis) and cortisol deficiency (weakness, fatigue, hypoglycemia, hypotension, and weight loss).

Secondary adrenal insufficiency is a result of inadequate ACTH secretion by the pituitary. The most common cause of secondary adrenal insufficiency is prior administration of exogenous glucocorticoids. Because mineralocorticoid secretion is usually adequate in secondary adrenal insufficiency, fluid and electrolyte disturbances are not present. Acute adrenal insufficiency (addisonian crisis), however, can be triggered in steroid-dependent patients who do not receive appropriate glucocorticoid doses during periods of stress (eg, infection, trauma, surgery) and in patients who receive infusions of etomidate. The clinical features of this medical emergency include fever, abdominal pain, orthostatic hypotension, and hypovolemia that may progress to circulatory shock unresponsive to resuscitation.

Anesthetic Considerations

Patients with glucocorticoid deficiency must receive adequate steroid replacement therapy during the perioperative period. Patients who have received potentially suppressive doses of steroids (eg, the daily equivalent of 5 mg of prednisone) by any route of administration (topical, inhalational, or oral) for a period of more than 2 weeks any time in the previous 12 months may be unable to respond appropriately to surgical stress and should receive perioperative glucocorticoid supplementation.

What represents adequate steroid coverage is controversial, and there are those who advocate variable dosing based on the extent of the surgery. Although adults normally secrete 20 mg of cortisol daily, this may increase to more than 300 mg under conditions of maximal stress. Thus, a traditional recommendation was to administer 100 mg of hydrocortisone every 8 h beginning on the morning of surgery. An alternative low-dose regimen (25 mg of hydrocortisone at the time of induction followed by an infusion of 100 mg during the subsequent 24 h) maintains plasma cortisol levels equal to or higher than those reported in healthy
patients undergoing similar elective surgery. This second regimen might be particularly appropriate for diabetic patients, in whom glucocorticoid administration often interferes with control of blood glucose.

CATECHOLAMINE EXCESS

Clinical Manifestations

Pheochromocytoma is a catecholamine-secreting tumor that consists of cells originating from the embryonic neural crest. This tumor accounts for 0.1% of all cases of hypertension. Although the tumor is usually localized in a single adrenal gland, 10% to 15% are bilateral or extraadrenal. Approximately 10% of tumors are malignant. The cardinal manifestations of pheochromocytoma are paroxysmal hypertension, headache, sweating, and palpitations. Unexpected intraoperative hypertension and tachycardia during manipulation of abdominal structures may occasionally be the first indications of an undiagnosed pheochromocytoma. The pathophysiology, diagnosis, and treatment of these tumors require an understanding of catecholamine metabolism and of the pharmacology of adrenergic agonists and antagonists. The Case Discussion in Chapter 14 examines these aspects of pheochromocytoma management.

Anesthetic Considerations

Preoperative assessment should focus on the adequacy of α-adrenergic blockade and volume replacement. Specifically, resting arterial blood pressure, orthostatic blood pressure and heart rate, ventricular ectopy, and electrocardiographic evidence of ischemia should be evaluated.

A decrease in plasma volume and red cell mass contributes to the severe chronic hypovolemia seen in these patients. The hematocrit may be normal or elevated, depending on the relative contribution of hypovolemia and anemia. Preoperative α-adrenergic blockade with phenoxybenzamine (a noncompetitive inhibitor) helps correct the volume deficit, in addition to correcting hypertension. β Blockade should not be initiated prior to α blockade but may be added if there is a need to control heart rate and to reduce arrhythmias provoked by excess catecholamine concentrations. A decline in hematocrit should accompany the expansion of circulatory volume. An underlying anemia may be unmasked by volume expansion.

Potentially life-threatening variations in blood pressure—particularly during induction and manipulation of the tumor—indicate the usefulness of invasive
arterial pressure monitoring. Young patients with minimal or no heart disease do not need a central venous line. Patients with evidence of cardiac disease (or in whom cardiac disease is suspected) may benefit from having a central line (a convenient route of access for administering catecholamines, should they be required) and from intraoperative transesophageal echocardiography.

Intubation should not be attempted until a deep level of general anesthesia (possibly also including local anesthesia of the trachea) has been established. Intraoperative hypertension can be treated with phentolamine, nitroprusside, nicardipine, or clevidipine. Phentolamine specifically blocks α-adrenergic receptors and blocks the effects of excessive circulating catecholamines. Nitroprusside has a rapid onset of action, a short duration of action, and as a nitric oxide donor can be effective in cases where calcium channel blockers are ineffective. Nicardipine and clevidipine are being used more frequently preoperatively and intraoperatively. Drugs or techniques that indirectly stimulate or promote the release of catecholamines (eg, ephedrine, hypoventilation, or large bolus doses of ketamine), potentiate the arrhythmic effects of catecholamines (halothane), or consistently release histamine (eg, large doses of atracurium or morphine sulfate) are best avoided.

After ligation of the tumor’s venous supply, the primary problem frequently becomes hypotension from hypovolemia, persistent adrenergic blockade, and tolerance to the increased concentrations of endogenous catecholamines that have been abruptly withdrawn. Appropriate fluid resuscitation should reflect surgical bleeding and other sources of fluid loss. Assessment of intravascular volume can be guided by echocardiographic assessment of left ventricular filling using transesophageal echocardiography or other noninvasive measures of cardiac output and stroke volume. Infusions of adrenergic agonists, such as phenylephrine or norepinephrine, often prove necessary. Postoperative hypertension is rare and may indicate the presence of unresected occult tumors.

**OBESITY**

Overweight and obesity are classified using the body mass index (BMI). Overweight is defined as a BMI of 24 kg/m² or higher, obesity as a BMI of 30 or higher, and extreme obesity (formerly termed “morbid obesity”) as a BMI of more than 40. BMI is calculated by dividing the weight (in kilograms) by the height (in meters) squared. A great many BMI calculators are available online or as apps for smartphones. Health risks increase with the degree of obesity and with increased abdominal distribution of weight. Men with a waist measurement
of 40 in. or more and women with a waist measurement of 35 in. or more are at increased health risk. For a patient 1.8 m tall and weighing 70 kg, the BMI would be as shown in the following formula:

\[
\text{BMI} = \frac{\text{Weight (kg)}}{\text{Height [m]}^2} = \frac{70 \text{ kg}}{1.8^2} = \frac{70}{3.24}
\]

\[= 21.6 \text{ kg/m}^2\]

**Clinical Manifestations**

Obesity is associated with many diseases, including type 2 diabetes mellitus, hypertension, coronary artery disease, obstructive sleep apnea, degenerative joint disease (osteoarthritis), and cholelithiasis. Even in the absence of obvious coexisting disease, however, extreme obesity has profound physiological consequences. Oxygen demand, CO\textsubscript{2} production, and alveolar ventilation are elevated because metabolic rate is proportional to body weight. Excessive adipose tissue over the thorax decreases chest wall compliance even though lung compliance may remain normal. Increased abdominal mass forces the diaphragm cephalad, yielding lung volumes suggestive of restrictive lung disease. Reductions in lung volumes are accentuated by the supine and Trendelenburg positions. In particular, functional residual capacity may fall below closing capacity. If this occurs, some alveoli will close during normal tidal volume ventilation, causing a ventilation/perfusion mismatch.

Whereas obese patients are often hypoxemic, only a few are hypercapnic, which when present should be a warning of impending complications. Obstructive sleep apnea (OSA) is a complication of extreme obesity characterized by hypercapnia, cyanosis-induced polycythemia, right-sided heart failure, and somnolence. These patients appear to have blunted respiratory drive and often suffer from loud snoring and upper-airway obstruction during sleep. OSA patients often report dry mouths and daytime somnolence; bed partners frequently describe apneic pauses. OSA has also been associated with increased perioperative complications, including hypertension, hypoxia, arrhythmias, myocardial infarction, pulmonary edema, stroke, and death. The potential for difficult mask ventilation and difficult intubation, followed by upper airway obstruction during recovery, should be anticipated.

OSA patients are vulnerable during the postoperative period, particularly when sedatives or opioids have been given. OSA patients positioned supine are
unusually susceptible to upper airway obstruction. For patients with known or suspected OSA, postoperative continuous positive airway pressure (CPAP) should be considered until the anesthesiologist can be sure that the patient can protect his or her airway and maintain spontaneous ventilation without evidence of obstruction. Both the American Society of Anesthesiologists and the Society of Ambulatory Anesthesia offer guidelines on perioperative management of the patient with OSA (see Chapter 44).

An OSA patient’s heart has an increased workload, as cardiac output and blood volume increase to perfuse additional fat stores. Arterial hypertension leads to left ventricular hypertrophy. Elevations in pulmonary blood flow and pulmonary artery vasoconstriction from persistent hypoxia can lead to pulmonary hypertension and cor pulmonale.

Obesity is also associated with hiatal hernia, gastroesophageal reflux disease, delayed gastric emptying, and hyperacidic gastric fluid, as well as with an increased risk of gastric cancer. Fatty infiltration of the liver also occurs and may be associated with abnormal liver tests, but the extent of infiltration does not correlate well with the degree of liver test abnormality.

### Anesthetic Considerations

#### A. Preoperative

For the reasons outlined above, obese patients are at an increased risk for developing aspiration pneumonia. Pretreatment with nonparticulate antacid, H₂ antagonists, and metoclopramide should be considered. Premedication with respiratory depressant drugs must be avoided in patients with OSA.

Before anesthetizing extremely obese patients for major surgery one should attempt to assess cardiopulmonary reserve. Preoperative testing may include such items as chest radiograph, ECG, and arterial blood gas analysis. Physical signs of cardiac failure may be difficult to identify. Blood pressures must be taken with a cuff of the appropriate size. Potential sites for intravenous and intraarterial access should be checked in anticipation of technical difficulties. Obscured landmarks, difficult positioning, and extensive layers of adipose tissue may make regional anesthesia difficult with standard equipment and techniques. Obese patients may be difficult to intubate as a result of limited mobility of the temporomandibular and atlantooccipital joints, a narrowed upper airway, and a shortened distance between the mandible and sternal fat pads.

#### B. Intraoperative
Because of the risks of aspiration and hypoventilation, morbidly obese patients are often intubated for all but short general anesthetics. If intubation appears possibly to be difficult, we recommend using either video laryngoscopy or fiberoptic bronchoscopy. Positioning the patient on an intubating ramp is helpful. Auscultation of breath sounds may prove difficult. Even with controlled ventilation these patients may require increased inspired oxygen concentrations to prevent hypoxia, particularly in the lithotomy, Trendelenburg, or prone positions. Subdiaphragmatic abdominal laparotomy packs can cause further deterioration of pulmonary function and a reduction of arterial blood pressure by increasing the resistance to venous return. Volatile anesthetics may be metabolized more extensively in obese patients. Increased metabolism may explain the increased incidence of halothane hepatitis observed in obese patients. Obese patients may have a prolonged induction and emergence from inhaled anesthetics.

Theoretically, greater fat stores would increase the volume of distribution for lipid-soluble drugs (eg, benzodiazepines, opioids) relative to a lean person of the same body weight. However, the volume of distribution of, for example, fentanyl or sufentanil is so large that obesity has minimal influence. Water-soluble drugs (eg, NMBs) have small volumes of distribution, which are minimally increased by body fat. Therefore, the dosing of water-soluble drugs should be based on ideal body weight to avoid overdosage.

Although dosage requirements for epidural and spinal anesthesia are difficult to predict, obese patients typically require 20% to 25% less local anesthetic per blocked segment because of epidural fat and distended epidural veins. Continuous epidural anesthesia has the usual advantages of providing pain relief and potentially decreasing respiratory complications in the postoperative period. Regional nerve blocks, particularly when combined with multimodal pain control, have the additional advantages of not interfering with the postoperative deep vein thrombosis prophylaxis, rarely producing hypotension, and of reducing the need for opioids (see Chapter 48).

C. Postoperative
Respiratory failure is a major postoperative problem of morbidly obese patients. The risk of postoperative hypoxia is increased in these patients, especially when there is preoperative hypoxia, and with surgery involving the thorax or upper abdomen. An obese patient should remain intubated until there is no doubt that an adequate airway and tidal volume will be maintained, NMBs are completely reversed, and the patient is awake. This does not mean that all obese patients
need be ventilated overnight in an intensive care unit. If the patient is extubated in the operating room, supplemental oxygen should be provided during transportation to the postanesthesia care unit. A 45° modified sitting position will improve ventilation and oxygenation. The risk of hypoxia extends for several days into the postoperative period, and providing supplemental oxygen or CPAP, or both, should be routinely considered. Other common postoperative complications in obese patients include wound infection, deep venous thrombosis, and pulmonary embolism. Morbidly obese and OSA patients may be candidates for outpatient surgery provided they are adequately monitored and assessed postoperatively before discharge to home, and provided the surgical procedure will not require large doses of opioids for postoperative pain control. It is hard to conceive of a better indication for multimodal analgesia.

---

**Carcinoid Syndrome**

Carcinoid syndrome results from the secretion of vasoactive substances (eg, serotonin, kallikrein, histamine) from enteroeiphrine tumors (carcinoid tumors). Most of these tumors are located in the gastrointestinal tract, so their metabolic products are released into the portal circulation and largely metabolized by the liver before they can cause systemic effects. However, the products of nonintestinal tumors (eg, pulmonary, ovarian) or hepatic metastases bypass the portal circulation and can cause a variety of clinical manifestations. Many patients undergo surgery for resection of carcinoid tumors; most such patients have not experienced carcinoid syndrome.

**Clinical Manifestations**

The most common manifestations of carcinoid syndrome are cutaneous flushing, bronchospasm, profuse diarrhea, dramatic swings in arterial blood pressure (usually hypotension), and supraventricular arrhythmias (Table 35–9). **Carcinoid syndrome is associated with right-sided heart disease caused by valvular and myocardial plaque formation and, in some cases, implantation of tumors on the tricuspid and pulmonary valves.** The diagnosis of carcinoid syndrome is confirmed by detection of serotonin metabolites in the urine (5-hydroxyindoleacetic acid) or plasma or suggested by elevated plasma levels of chromogranin A. Treatment varies depending on tumor location but may include surgical resection, symptomatic relief, or specific serotonin and histamine antagonists. Somatostatin, an inhibitory peptide, reduces the release of

Anesthetic Considerations

The key to perioperative management of patients with carcinoid syndrome is to avoid anesthetic and surgical techniques or agents that could cause the tumor to release vasoactive substances. Regional anesthesia may limit release of stress hormones perioperatively. Large bolus doses of histamine-releasing drugs (eg, morphine and atracurium) should be avoided. Surgical manipulation of the tumor can cause a massive release of hormones. Monitoring likely will include an arterial line. If there are concerns about hemodynamic instability or intrinsic heart disease caused by carcinoid syndrome, transesophageal echocardiography may be helpful. Alterations in carbohydrate metabolism may lead to unsuspected hypoglycemia or hyperglycemia. Consultation with an endocrinologist may help clarify the role of antihistamine, antiserotonin drugs (eg, methysergide), octreotide (a long-acting somatostatin analogue), or antikallikrein drugs (eg, corticosteroids) in specific patients.

CASE DISCUSSION

Multiple Endocrine Neoplasia

An isolated thyroid nodule is discovered during physical examination of a 36-year-old woman complaining of diarrhea and headaches. Workup of the tumor reveals hypercalcemia and an elevated calcitonin level, which leads to the diagnosis of medullary cancer of the thyroid.
and primary hyperparathyroidism. During induction of general anesthesia for total thyroidectomy, the patient’s blood pressure rises to 240/140 mm Hg and her heart rate approaches 140 beats/min, with frequent premature ventricular contractions. The operation is canceled, an arterial line is inserted, and the patient is treated with intravenous esmolol and nicardipine.

**What could be the cause of this patient’s hypertensive crisis during induction of general anesthesia?**

Multiple endocrine neoplasia (MEN) is characterized by tumors in several endocrine organs. MEN type 1 consists of pancreatic (gastrinomas, insulinomas), pituitary, and parathyroid tumors. MEN type 2 consists of medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism (type 2a) or multiple mucosal neuromas (type 2b or type 3). The hypertensive episode in this case may be due to a previously undiagnosed pheochromocytoma. The pheochromocytoma in MEN may consist of small multiple tumors. These patients are typically young adults with strong family histories of MEN. If multiple surgeries are planned, pheochromocytoma resection will usually be scheduled first.

**What is calcitonin, and why is it associated with medullary cancer?**

Calcitonin is a polypeptide manufactured by the parafollicular cells (C cells) in the thyroid gland. It is secreted in response to increases in plasma ionic calcium and tends to lower calcium levels by affecting kidney and bone function. Therefore, it acts as an antagonist of parathyroid hormone (see Table 35–6).

**Why is this patient hypercalcemic if calcitonin lowers serum calcium?**

An excess or deficiency of calcitonin has minor effects in humans compared with the effects of parathyroid disorders. This patient’s hypercalcemia is most likely due to coexisting primary hyperparathyroidism (MEN type 2a).

**Are headache and diarrhea consistent with the diagnosis of MEN?**
The history of headaches suggests the possibility of pheochromocytoma, whereas diarrhea may be due to calcitonin or one of the other peptides often produced by medullary thyroid carcinoma (eg, ACTH, somatostatin, β-endorphin).

**What follow-up is required for this patient?**

Because of the life-threatening hemodynamic changes associated with pheochromocytoma, this entity must be medically controlled before any surgery can be considered (see Case Discussion, Chapter 14). Because MEN syndromes are hereditary, family members should be screened for early signs of pheochromocytoma, thyroid cancer, and hyperparathyroidism.

Anesthesia for Ophthalmic Surgery

KEY CONCEPTS

1. Any factor that increases intraocular pressure in the setting of an open globe may cause drainage of aqueous or extrusion of vitreous through the wound, serious complications that can permanently worsen vision.

2. Succinylcholine increases intraocular pressure by 5 to 10 mm Hg for 5 to 10 min after administration, principally through prolonged contracture of the extraocular muscles. However, in studies of hundreds of patients with open eye injuries, no patient experienced extrusion of ocular contents after administration of succinylcholine. Thus, succinylcholine is not contraindicated in cases of open eye injuries.

3. Traction on extraocular muscles, pressure on the eyeball, administration of a retrobulbar block, and trauma to the eye can elicit a wide variety of cardiac arrhythmias ranging from bradycardia and ventricular ectopy to sinus arrest or ventricular fibrillation.

4. Complications involving the intraocular expansion of gas bubbles injected by the ophthalmologist can be avoided by discontinuing nitrous oxide at least 15 min prior to the injection of air or sulfur hexafluoride, or by avoiding the use of nitrous oxide entirely.

5. Medications applied topically to mucosa are absorbed systemically at a rate intermediate between absorption following intravenous and subcutaneous injection.

6. Echothiophate is an irreversible cholinesterase inhibitor used in the treatment of glaucoma. Topical application leads to systemic absorption and an inhibition of plasma cholinesterase activity. Because succinylcholine is metabolized by this enzyme, echothiophate will prolong its duration of action.

7. The key to inducing anesthesia in a patient with an open eye injury is controlling intraocular pressure with a smooth induction. Coughing and
gagging during intubation is avoided by first achieving a deep level of anesthesia and profound paralysis.

The postretrobulbar block apnea syndrome is probably due to injection of local anesthetic into the optic nerve sheath, with spread into the cerebrospinal fluid.

Regardless of the anesthetic technique, American Society of Anesthesiologists standards for basic monitoring must be employed, and equipment and drugs necessary for airway management and resuscitation must be immediately available.

Ophthalmic surgery poses unique problems, including regulation of intraocular pressure, control of intraocular gas expansion, prevention of the oculocardiac reflex and management of its consequences, and management of systemic effects of ophthalmic drugs. Mastery of general and sedation anesthesia techniques for ophthalmic surgery and a thorough understanding of potentially complicating issues—including the comorbidities of an increasing geriatric patient population—are necessary for optimal perioperative outcomes. In addition, the majority of ophthalmic procedures are performed under topical or regional anesthesia. The anesthesiologist must be familiar with their potential complications, including those of the accompanying sedation, even if not personally administering the topical anesthetic or the block.

INTRAOCULAR PRESSURE DYNAMICS

**Physiology of Intraocular Pressure**

The eye can be considered a hollow sphere with a rigid wall. If the contents of the sphere increase, the normal intraocular pressure of 12 to 20 mm Hg will rise. For example, glaucoma is caused by an obstruction to aqueous humor outflow. Similarly, intraocular pressure will rise if the volume of blood within the globe is increased. A rise in venous pressure will increase intraocular pressure by decreasing aqueous drainage and increasing choroidal blood volume. Any event that alters arterial blood pressure or ventilation (eg, laryngoscopy, intubation, airway obstruction, coughing, Trendelenburg position) can also affect intraocular pressure (Table 36–1).

**TABLE 36–1**  The effect of cardiac and respiratory variables on intraocular pressure (IOP).¹
Alternatively, compressing the globe without a proportional change in the volume of its contents will increase intraocular pressure. Pressure on the eye from a malpositioned mask, improper prone positioning, or retrobulbar hemorrhage can lead to a marked increase in intraocular pressure, possible eye pain, and temporary or permanent visual changes.

Intraocular pressure helps to maintain the shape and the optical properties of the eye. Temporary variations in pressure are normally well tolerated. For example, blinking raises intraocular pressure by 5 mm Hg, and squinting (forced contraction of the orbicularis oculi muscles) may transiently increase intraocular pressure greater than 50 mm Hg. However, even brief episodes of increased intraocular pressure in patients with underlying low ophthalmic artery pressure (eg, from systemic hypotension, arteriosclerotic involvement of the retinal artery) may cause retinal ischemia.

When the globe is opened by surgical incision (Table 36–2) or traumatic perforation, intraocular pressure approaches atmospheric pressure. Any factor that increases intraocular pressure in the setting of an open globe may cause drainage of aqueous or extrusion of vitreous through the wound, serious complications that can permanently worsen vision.

Effect of Anesthetic Drugs on Intraocular Pressure

Most anesthetic drugs either reduce intraocular pressure or have no effect (Table 36–3). Intraocular pressure decreases with inhalational anesthetics in proportion to anesthetic depth. There are multiple causes for this: A drop in blood pressure reduces choroidal volume, relaxation of the extraocular muscles lowers wall tension, and pupillary constriction facilitates aqueous outflow. Intravenous anesthetics also decrease intraocular pressure, with the exception of ketamine, which usually raises arterial blood pressure and does not relax extraocular muscles.

1. ↓, decrease; ↑, increase; 0, no change; 0/1, conflicting reports.

Topically administered anticholinergic drugs result in pupillary dilation (mydriasis), which may precipitate or worsen angle-closure glaucoma. Systemically administered atropine or glycopyrrolate for premedication are not associated with intraocular hypertension, even in patients with glaucoma.

2. Succinylcholine increases intraocular pressure by 5 to 10 mm Hg for 5 to 10 min after administration, principally through prolonged contracture of the extraocular muscles. However, in studies of hundreds of patients with open eye injuries, no patient experienced extrusion of ocular contents after administration of succinylcholine. Thus, succinylcholine is not contraindicated in cases of open eye injuries. Nevertheless, dogma often trumps data and ophthalmic surgeons may request that it not be administered in certain circumstances. Unlike other skeletal muscle, extraocular muscles contain myocytes with multiple neuromuscular junctions, and depolarization of these cells by succinylcholine causes prolonged contracture. The resulting increase in intraocular pressure may
have several effects: it will cause spurious measurements of intraocular pressure during examinations under anesthesia in glaucoma patients, potentially leading to unnecessary surgery, and prolonged contracture of the extraocular muscles may result in an abnormal forced duction test, a maneuver utilized in strabismus surgery to evaluate the cause of extraocular muscle imbalance and to determine the type of surgical correction. Nondepolarizing neuromuscular blockers (NMBs) do not increase intraocular pressure, and we advocate that succinylcholine be reserved for rapid-sequence induction.

**THE OCULOCARDIAC REFLEX**

Traction on extraocular muscles, pressure on the eyeball, administration of a retrobulbar block, and trauma to the eye can elicit a wide variety of cardiac arrhythmias ranging from bradycardia and ventricular ectopy to sinus arrest or ventricular fibrillation. This reflex consists of a trigeminal (V1) afferent and a vagal efferent pathway. The *oculocardiac reflex* is most commonly encountered in children undergoing strabismus surgery, although it can be evoked in all age groups and during a variety of ocular procedures. In awake patients, the oculocardiac reflex may be accompanied by nausea.

Routine prophylaxis for the oculocardiac reflex is controversial, especially in adults. Anticholinergic medication is often helpful in preventing the oculocardiac reflex, and intravenous atropine or glycopyrrolate immediately prior to surgery is more effective than intramuscular premedication. However, anticholinergic medication should be administered with caution to any patient who has, or may have, coronary artery disease, because of the potential for increase in heart rate sufficient to induce myocardial ischemia. Ventricular tachycardia and ventricular fibrillation following administration of anticholinergic medication has also been reported. Retrobulbar blockade or deep inhalational anesthesia may also be of value in preempting the oculocardiac reflex, although administration of a retrobulbar block may itself initiate the oculocardiac reflex.

Management of the oculocardiac reflex includes (1) immediate notification of the surgeon and cessation of surgical stimulation until heart rate increases; (2) confirmation of adequate ventilation, oxygenation, and depth of anesthesia; (3) administration of intravenous atropine (10 mcg/kg) if bradycardia persists; and (4) in recalcitrant episodes, infiltration of the rectus muscles with local anesthetic.
INTRAOCULAR GAS EXPANSION

A gas bubble may be injected by the ophthalmologist into the posterior chamber during vitreous surgery. Intravitreal air injection will tend to flatten a detached retina and facilitate anatomically correct healing. Nitrous oxide administration is contraindicated in this circumstance: The bubble will increase in size if nitrous oxide is administered because nitrous oxide is 35 times more soluble than nitrogen in blood (see Chapter 8). Thus, it tends to diffuse into an air bubble more rapidly than nitrogen (the major component of air) is absorbed by the bloodstream. If the bubble expands after the globe is closed, intraocular pressure will rise.

Sulfur hexafluoride is an inert gas that is less soluble in blood than is nitrogen—and much less soluble than nitrous oxide. Its longer duration of action (up to 10 days) compared with an air bubble can provide a therapeutic advantage. The bubble size doubles within 24 h after injection, because nitrogen from inhaled air enters the bubble more rapidly than the sulfur hexafluoride diffuses into the bloodstream. Even so, unless high volumes of pure sulfur hexafluoride are injected, the slow bubble expansion does not typically raise intraocular pressure. If the patient is breathing nitrous oxide, however, the bubble will rapidly increase in size and may lead to intraocular hypertension. A 70% inspired nitrous oxide concentration will almost triple the size of a 1-mL bubble and may double the pressure in a closed eye within 30 min. Subsequent discontinuation of nitrous oxide will lead to reabsorption of the bubble, which has become a mixture of nitrous oxide and sulfur hexafluoride. The consequent fall in intraocular pressure may precipitate another retinal detachment.

Complications involving the intraocular expansion of gas bubbles can be avoided by discontinuing nitrous oxide at least 15 min prior to the injection of air or sulfur hexafluoride, or by avoiding the use of nitrous oxide entirely. Nitrous oxide should be avoided until the bubble is absorbed (5 days after air and 10 days after sulfur hexafluoride injection). Avoiding nitrous oxide seems the simplest approach in these patients.

SYSTEMIC EFFECTS OF OPHTHALMIC DRUGS

Topically applied eye drops are systemically absorbed by vessels in the conjunctival sac and the nasolacrimal duct mucosa (see Case Discussion, Chapter 13). One drop (typically, approximately 1/20 mL) of 10% phenylephrine contains approximately 5 mg of drug. Compare this dose with the intravenous dose of phenylephrine (0.05–0.1 mg) used to treat an adult patient with acute
hypotension. Medications applied topically to mucosa are absorbed systemically at a rate intermediate between absorption following intravenous and subcutaneous injection. The two patient populations most likely to require eye surgery, pediatric and geriatric, are at particular risk of the toxic effects of topically applied medications and should receive at most a 2.5% phenylephrine solution (Table 36–4).

²See Case Discussion, Chapter 13.

Echothiophate (phospholine iodide) is an irreversible cholinesterase inhibitor used in the treatment of glaucoma. Topical application leads to systemic absorption and an inhibition of plasma cholinesterase activity. Because succinylcholine is metabolized by this enzyme, echothiophate will prolong its duration of action. Paralysis usually will not exceed 20 to 30 min and postoperative apnea is unlikely. The inhibition of cholinesterase activity lasts for 3 to 7 weeks after discontinuation of echothiophate drops. Muscarinic side effects of echothiophate, such as bradycardia during induction, can be prevented with intravenous anticholinergic drugs (eg, atropine, glycopyrrolate).

Epinephrine eye drops can cause hypertension, tachycardia, and ventricular arrhythmias; the arrhythmogenic effects are potentiated by halothane. Direct instillation of epinephrine into the anterior chamber of the eye has not been associated with cardiovascular toxicity.

Timolol, a nonselective β-adrenergic antagonist, reduces intraocular pressure by decreasing production of aqueous humor. Topically applied timolol eye drops, commonly used to treat glaucoma, will often result in reduced heart rate. In rare cases, timolol has been associated with atropine-resistant bradycardia, hypotension, and bronchospasm during general anesthesia.

---

**General Anesthesia for Ophthalmic Surgery**
The choice between general and local anesthesia should be made jointly by the patient, anesthesiologist, and surgeon. Patients may refuse to consider local anesthesia due to fear of being awake during the operation, fear of the eye block procedure, or unpleasant recall of a previous eye block or local eye procedure. General anesthesia is indicated in children and uncooperative patients, as even small head movements can prove disastrous during microsurgery.

PREMEDICATION
Patients undergoing eye surgery may be apprehensive; however, premedication must be administered with caution and only after careful consideration of the patient’s medical status. Adult patients are often elderly, with systemic illnesses such as hypertension, diabetes mellitus, and coronary artery disease, and pediatric patients may have associated congenital disorders.

INDUCTION
The choice of induction technique for eye surgery usually depends more on the patient’s other medical problems than on the patient’s eye disease or the specific operation contemplated. One exception is the patient with a ruptured globe. The key to inducing anesthesia in a patient with an open eye injury is controlling intraocular pressure with a smooth induction. Specifically, coughing during intubation must be avoided by first achieving a deep level of anesthesia and profound paralysis. The intraocular pressure response to laryngoscopy and endotracheal intubation can be moderated by prior administration of intravenous lidocaine (1.5 mg/kg), an opioid (eg, remifentanil 0.5–1 mcg/kg or alfentanil 20 mcg/kg), or esmolol (0.5–1.5 mg/kg). A nondepolarizing muscle relaxant or succinylcholine may be used. Many patients with open globe injuries have full stomachs and require a rapid-sequence induction technique to avoid aspiration (see the later Case Discussion); despite theoretical concerns, succinylcholine does not increase the likelihood of vitreous loss with open eye injuries.

MONITORING & MAINTENANCE
Eye surgery often necessitates positioning the anesthesia provider away from the patient’s airway, making close monitoring of pulse oximetry and the capnograph particularly important. Endotracheal tube kinking, breathing circuit disconnection, and unintentional extubation may be more likely because of the surgeon working near the airway. Kinking and obstruction can be minimized by
using a preformed oral RAE (Ring-Adair-Elwyn) endotracheal tube (Figure 36–1). The possibility of arrhythmias caused by the oculocardiac reflex increases the importance of closely monitoring the electrocardiogram. In contrast to most other types of pediatric surgery, infant body temperature may rise during ophthalmic surgery because of head-to-toe draping and minimal body surface exposure. End-tidal CO₂ analysis helps to differentiate this situation from malignant hyperthermia.

FIGURE 36–1 An oral RAE endotracheal tube has a preformed right-angle bend at the level of the teeth so that it exits the mouth away from the surgical field during ophthalmic or nasal surgery.

The pain and stress evoked by eye surgery are considerably less than during a major surgical procedure. “Lighter” anesthesia might be attractive if the consequences of patient movement were not so potentially catastrophic. The lack of cardiovascular stimulation inherent in most eye procedures combined with the need for adequate anesthetic depth can result in hypotension in elderly individuals. This problem is usually avoided by ensuring adequate intravenous hydration and by administering small doses of intravenous vasoconstrictors. Administration of nondepolarizing muscle relaxants to avoid patient movement is often used in such circumstances in order to allow reduced depth of general anesthesia.

Emesis caused by vagal stimulation is a common postoperative problem following eye surgery, particularly with strabismus repair. The Valsalva effect and the increase in central venous pressure that accompany vomiting can be
detrimental to the surgical result. Intraoperative intravenous administration of drugs that prevent postoperative nausea and vomiting is strongly recommended.

**EXTUBATION & EMERGENCE**

A smooth emergence from general anesthesia is important in order to minimize the risk of postoperative wound dehiscence. Coughing or gagging due to stimulus from the endotracheal tube can be minimized by extubating the patient at a moderately deep level of anesthesia. As the time of extubation approaches intravenous lidocaine (1.5 mg/kg) may be given to blunt cough reflexes temporarily. Extubation proceeds 1 to 2 min after the lidocaine administration and during spontaneous respiration with 100% oxygen. Proper airway maintenance is crucial until the patient’s cough and swallowing reflexes return.

Severe discomfort is unusual following eye surgery. Scleral buckling procedures, enucleation, and ruptured globe repair are the most painful operations. Modest incremental doses of intravenous opioid usually provide sufficient analgesia. The surgeon should be alerted if severe pain is noted following emergence from general anesthesia, as it may signal intraocular hypertension, corneal abrasion, or other surgical complications.

---

**Regional Anesthesia for Ophthalmic Surgery**

Options for local anesthesia for eye surgery include topical application of local anesthetic or placement of a retrobulbar, peribulbar, or sub-Tenon (episcleral) block. All of these techniques are commonly combined with intravenous sedation. Local anesthesia is preferred to general anesthesia for eye surgery because local anesthesia involves less physiological trespass and is less likely to be associated with postoperative nausea and vomiting. However, eye block procedures have potential complications and may not provide adequate ophthalmic akinesia or analgesia. Some patients may be unable to lie perfectly still for the duration of the surgery. For these reasons, appropriate equipment and qualified personnel required to treat the complications of local anesthesia and to induce general anesthesia must be readily available.

**RETROBULBAR BLOCKADE**

In this technique, local anesthetic is injected behind the eye into the cone formed by the extraocular muscles (Figure 36–2), and a facial nerve block is utilized to
prevent blinking (Figure 36–3). A blunt-tipped 25-gauge needle penetrates the lower lid at the junction of the middle and lateral one-third of the orbit (usually 0.5 cm medial to the lateral canthus). Awake patients are instructed to stare supranasally as the needle is advanced toward the apex of the muscle cone. Commonly, patients undergoing such eye blocks will receive a brief period of deep sedation or general anesthesia during the block (using such agents as etomidate, propofol, or remifentanil). After aspiration to preclude intravascular injection, 2 to 5 mL of local anesthetic is injected, and the needle is removed. Choice of local anesthetic varies, but lidocaine 2% or bupivacaine (or ropivacaine) 0.75% are common. Addition of epinephrine may reduce bleeding and prolong the anesthesia. A successful retrobulbar block is accompanied by anesthesia, akinesia, and abolishment of the oculocephalic reflex (ie, a blocked eye does not move during head turning).

**FIGURE 36–2**  A: During administration of a retrobulbar block, the patient looks supranasally as a needle is advanced 1.5 cm along the inferotemporal wall of the orbit. B: The needle is then redirected upward and nasally toward the apex of the orbit and advanced until its tip penetrates the muscle cone.
Complications of retrobulbar injection of local anesthetics include retrobulbar hemorrhage, perforation of the globe, optic nerve injury, intravascular injection with resultant convulsions, oculocardiac reflex, trigeminal nerve block, respiratory arrest, and, rarely, acute neurogenic pulmonary edema. Forceful injection of local anesthetic into the ophthalmic artery causes retrograde flow toward the brain and may result in an instantaneous seizure. The postretrobulbar block apnea syndrome is probably due to injection of local anesthetic into the optic nerve sheath, with spread into the cerebrospinal fluid. The central nervous system is exposed to high concentrations of local anesthetic, leading to mental status changes that may include unconsciousness. Apnea occurs within 20 min and resolves within an hour. Treatment is supportive, with
positive-pressure ventilation to prevent hypoxia, bradycardia, and cardiac arrest. Adequacy of ventilation must be constantly monitored in patients who have received retrobulbar anesthesia.

The adjuvant *hyaluronidase* is frequently added to local anesthetic solutions used in eye blocks to enhance the spread and density of the block. Patients may rarely experience an allergic reaction to hyaluronidase. Retrobulbar hemorrhage, cellulitis, occult injury, and contact allergy to topical eye drops must be ruled out in the differential diagnosis. Retrobulbar injection is usually not performed in patients with bleeding disorders or receiving anticoagulation therapy because of the risk of retrobulbar hemorrhage, extreme myopia because the elongated globe increases the risk of perforation, or an open eye injury because the pressure from injecting fluid behind the eye may cause extrusion of intraocular contents through the wound.

**PERIBULBAR BLOCKADE**

In contrast to retrobulbar blockade, in the peribulbar blockade technique, the needle does not penetrate the cone formed by the extraocular muscles. Advantages of the peribulbar technique include less risk of penetration of the globe, optic nerve, and artery, and less pain on injection. Disadvantages include a slower onset and an increased likelihood of ecchymosis. Both techniques will have equal success at producing akinesia of the eye.

The peribulbar block is performed with the patient supine and looking directly ahead (or possibly under a brief period of deep sedation). After topical anesthesia of the conjunctiva, one or two transconjunctival injections are administered (Figure 36–4). As the eyelid is retracted, an inferotemporal injection is given halfway between the lateral canthus and the lateral limbus. The needle is advanced under the globe, parallel to the orbital floor; when it passes the equator of the eye, it is directed slightly medial (20°) and cephalad (10°), and 5 mL of local anesthetic is injected. To ensure akinesia, a second 5-mL injection may be given through the conjunctiva on the nasal side, medial to the caruncle, and directed straight back parallel to the medial orbital wall, pointing slightly cephalad (20°).
**FIGURE 36–4** Anatomic landmarks for the introduction of a needle or catheter in most frequently employed eye blocks: (1) medial canthus peribulbar anesthesia, (2) lacrimal caruncle, (3) semilunaris fold of the conjunctiva, (4) medial canthus episcleral anesthesia, and (5) inferior and temporal peribulbar anesthesia.

**Sub-Tenon (Episcleral) Block**

*Tenon’s fascia* surrounds the globe and extraocular muscles. Local anesthetic injected beneath it into the episcleral space spreads circularly around the sclera and to the extraocular muscle sheaths (*Figure 36–4*). A special blunt curved cannula is used for a sub-Tenon block. After topical anesthesia, the conjunctiva is lifted along with Tenon’s fascia in the inferonasal quadrant with forceps. A small nick is then made with blunt-tipped scissors, which are then slid underneath to create a path in Tenon’s fascia that follows the contour of the globe and extends past the equator. While the eye is still fixed with forceps, the cannula is inserted, and 3 to 4 mL of local anesthetic is injected. Complications with sub-Tenon blocks are significantly less than with retrobulbar and peribulbar techniques. Globe perforation, hemorrhage, cellulitis, permanent visual loss, and local anesthetic spread into cerebrospinal fluid have been reported.
FACIAL NERVE BLOCK
A facial nerve block prevents squinting of the eyelids during surgery and allows placement of a lid speculum. There are several techniques of facial nerve block: van Lint, Atkinson, and O’Brien (Figure 36–3). The major complication of these blocks is subcutaneous hemorrhage. The Nadbath technique blocks the facial nerve as it exits the stylomastoid foramen under the external auditory canal, in close proximity to the vagus and glossopharyngeal nerves. This block is not recommended because it has been associated with vocal cord paralysis, laryngospasm, dysphagia, and respiratory distress.

TOPICAL ANESTHESIA OF THE EYE
Simple topical local anesthetic techniques have been used for anterior chamber (eg, cataract) and glaucoma operations, and, increasingly, the trend has been to eliminate local anesthetic injections entirely. A typical regimen for topical local anesthesia consists of application of 0.5% proparacaine (also known as proxymetacaine) local anesthetic drops, repeated at 5-min intervals for five applications, followed by topical application of a local anesthetic gel (lidocaine plus 2% methyl-cellulose) with a cotton swab to the inferior and superior conjunctival sacs. Ophthalmic 0.5% tetracaine may also be utilized. Topical anesthesia is not appropriate for posterior chamber surgery (eg, retinal detachment repair with a buckle), and it works best for faster surgeons with a gentle surgical technique that does not require akinesia of the eye.

INTRAVENOUS SEDATION
Many techniques of intravenous sedation are available for eye surgery, and the particular drug used is less important than the dose. Deep sedation, although sometimes used during placement of ophthalmic nerve blocks, is almost never used intraoperatively because of the risks of apnea, aspiration, and unintentional patient movement during surgery. An intraoperative light sedation regimen that includes small doses of midazolam, with or without fentanyl or sufentanil, is recommended. Doses vary considerably among patients but should be administered in small increments.

Patients may find administration of eye blocks uncomfortable, and many anesthesia providers will administer small incremental doses of propofol to produce a brief state of unconsciousness during the regional block. Some will substitute a bolus of opioid (remifentanil 0.1–0.5 mcg/kg or alfentanil 375–500
mcg) to produce a brief period of intense analgesia during the eye block procedure.

Administration of an antiemetic should be considered if an opioid is used. Regardless of the anesthetic technique, American Society of Anesthesiologists standards for basic monitoring must be employed, and equipment and drugs necessary for airway management and resuscitation must be immediately available.

CASE DISCUSSION

An Approach to a Patient with an Open Eye & a Full Stomach

A 12-year-old boy is brought to the emergency department after being shot in the eye with a pellet gun. A brief examination by the ophthalmologist reveals intraocular contents presenting at the wound. The boy is scheduled for emergency repair of the ruptured globe.

What should be emphasized in the preoperative evaluation of this patient?

Aside from taking a medical history and performing a physical examination, the time of last oral intake before or after the injury should be established. The patient must be considered to have a full stomach if the injury occurred within 8 h after the last meal, even if the patient did not eat for several hours after the injury: Gastric emptying is delayed by the pain and anxiety that follow trauma.

What is the significance of a full stomach in a patient with an open globe injury?

Managing patients who have sustained penetrating eye injuries provides a challenge because of the need to deal with at least two conflicting objectives: (1) preventing further damage to the eye by avoiding increases in intraocular pressure, and (2) preventing pulmonary aspiration in a patient with a full stomach. However, many of the common strategies used to achieve these objectives are in conflict with one another (Tables 36–5 and 36–6). For example, although regional anesthesia (eg, retrobulbar block)
minimizes the risk of aspiration pneumonia, it is relatively contraindicated in patients with penetrating eye injuries because injecting local anesthetic behind the globe increases intraocular pressure and may lead to expulsion of intraocular contents. Therefore, these patients require general anesthesia—despite the increased risk of aspiration pneumonia.

**TABLE 36–5**  Strategies to prevent increases in intraocular pressure (IOP).

| Avoid direct pressure on the globe                                      |
| Patch eye with Fox shield                                               |
| No retrobulbar or peribulbar injections                                  |
| Careful face mask technique                                             |
| Avoid increases in central venous pressure                              |
| Prevent coughing during induction and intubation                        |
| Ensure a deep level of anesthesia and relaxation prior to laryngoscopy¹ |
| Avoid head-down positions                                               |
| Extubate under deep anesthesia¹                                         |
| Avoid pharmacological agents that increase IOP                          |

¹These strategies are not recommended in patients with full stomachs.

**TABLE 36–6**  Strategies to prevent aspiration pneumonia.

| Regional anesthesia with minimal sedation¹                              |
| Premedication                                                          |
| Metoclopramide                                                         |
| Histamine H₂-receptor antagonants                                      |
| Nonparticulate antacids                                                |
| Evacuation of gastric contents                                          |
| Nasogastric tube¹                                                      |
| Rapid-sequence induction                                               |
| Cricoid pressure                                                       |
| Rapid induction with rapid onset of paralysis                           |
| Avoidance of positive-pressure ventilation via mask                    |
| Intubation as soon as possible                                          |
These strategies are not recommended for patients with penetrating eye injuries.

**What preoperative preparation should be considered in this patient?**

One clearly will want to minimize the risk of aspiration pneumonia by decreasing gastric volume and acidity (see Case Discussion, Chapter 17). The risk of aspiration in patients with eye injuries is reduced by proper selection of drugs and anesthetic techniques. Evacuation of gastric contents with a nasogastric tube may lead to coughing, retching, and other responses that can dramatically increase intraocular pressure.

Metoclopramide increases lower esophageal sphincter tone, speeds gastric emptying, lowers gastric fluid volume, and exerts an antiemetic effect. It should be given intravenously (10 mg) as soon as possible and repeated every 2 to 4 h until surgery.

Ranitidine (50 mg intravenously), cimetidine (300 mg intravenously), and famotidine (20 mg intravenously) are \( \text{H}_2 \)-receptor antagonists that inhibit gastric acid secretion. Because they have no effect on the pH of gastric secretions present in the stomach prior to their administration, they have limited value in patients presenting for emergency surgery.

Unlike \( \text{H}_2 \)-receptor antagonists, antacids have an immediate effect. Unfortunately, they increase intragastric volume. Nonparticulate antacids (preparations of sodium citrate, potassium citrate, and citric acid) lose effectiveness within 30 to 60 min and should be given immediately prior to induction (15–30 mL orally).

**Which induction agents are recommended in patients with penetrating eye injuries?**

The ideal induction agent for patients with full stomachs would provide a rapid onset of action in order to minimize the risk of regurgitation. Propofol and etomidate have essentially equally rapid onsets of action and lower intraocular pressure. Although investigations of the effects of ketamine on intraocular pressure have provided conflicting results, ketamine is not recommended in penetrating eye injuries, owing to the increased risk of blepharospasm and nystagmus.

Although etomidate may prove valuable in some patients with cardiac disease, it is associated with an incidence of myoclonus ranging from 10%
An episode of severe myoclonus may have contributed to complete retinal detachment and vitreous prolapse in one patient with an open globe injury and limited cardiovascular reserve.

Propofol has a rapid onset of action and decreases intraocular pressure; however, it does not entirely prevent the hypertensive response to laryngoscopy and intubation or entirely prevent the increase in intraocular pressure that accompanies laryngoscopy and intubation. Prior administration of fentanyl (1–3 mcg/kg), remifentanil (0.5–1 mcg/kg), alfentanil (20 mcg/kg), esmolol (0.5–1.5 mg/kg), or lidocaine (1.5 mg/kg) attenuates this response with varying degrees of success.

**How does the choice of muscle relaxant differ between these patients and other patients at risk of aspiration?**

Succinylcholine moderately increases intraocular pressure, but that is a small price to pay for a rapid onset of action that decreases the risk of aspiration and profound muscle relaxation that decreases the chance of a Valsalva response during intubation. Advocates of succinylcholine point to the lack of evidence documenting further eye injury when succinylcholine has been used with open eye injuries.

Nondepolarizing muscle relaxants do not increase intraocular pressure, but the onset of deep muscle relaxation is much slower than with succinylcholine. Regardless of the muscle relaxant chosen, intubation should not be attempted until a level of paralysis is achieved that will reliably prevent coughing on the endotracheal tube.

**How do induction strategies vary in pediatric patients without an intravenous line?**

A hysterical child with a penetrating eye injury and a full stomach provides an anesthetic challenge for which there is no perfect solution. Once again, the dilemma is due to the need to avoid increases in intraocular pressure yet minimize the risk of aspiration. Screaming and crying can lead to tremendous increases in intraocular pressure. Attempting to sedate children with rectal suppositories or intramuscular injections often heightens their state of agitation and may worsen the eye injury. Similarly, although preoperative sedation may increase the risk of aspiration by obtunding airway reflexes, it is often necessary for establishing an intravenous line for a rapid-sequence induction. Although difficult to achieve, an ideal strategy would be to administer enough sedation
painless to allow the placement of an intravenous line, yet maintain a level of consciousness adequate to protect airway reflexes. However, the most prudent strategy is to do everything reasonable to avoid aspiration—even at the cost of further eye damage.

Are there special considerations during extubation and emergence?

Patients at risk of aspiration during induction are also at risk during extubation and emergence. Therefore, extubation must be delayed until the patient is awake and has intact airway reflexes (eg, spontaneous swallowing and coughing on the endotracheal tube). Deep extubation increases the risk of vomiting and aspiration. Intraoperative administration of antiemetic medication and nasogastric or orogastric tube suctioning may decrease the incidence of emesis during emergence, but they do not guarantee an empty stomach.

The anesthetic goals for laryngeal endoscopy include an immobile surgical field and adequate masseter muscle relaxation for introduction of the suspension laryngoscope (typically profound muscle paralysis will be sought), adequate oxygenation and ventilation, and cardiovascular stability despite periods of rapidly varying surgical stimulation.

During jet ventilation, chest wall motion must be monitored and sufficient exhalation time allowed in order to avoid air trapping and barotrauma.

The greatest concern during laser airway surgery is an airway tube fire. This risk can be moderated by minimizing the fraction of inspired oxygen ($\text{FiO}_2 < 30\%$ if tolerated by the patient) and can be eliminated when there is no combustible material (eg, flammable endotracheal tube, catheter, or dry cotton pledget) in the airway.

Techniques to minimize intraoperative blood loss include topical vasoconstriction with cocaine or an epinephrine-containing local anesthetic for vasoconstriction, maintaining a slightly head-up position, and providing a mild degree of controlled hypotension.

If there is serious preoperative concern regarding potential airway problems, intravenous induction may be avoided in favor of awake direct or fiberoptic laryngoscopy (cooperative patient) or direct or fiberoptic intubation following an inhalational induction, maintaining spontaneous ventilation (uncooperative patient). In any case, the appropriate equipment and qualified personnel required for emergent tracheostomy must be immediately available.
The surgeon may request the omission of neuromuscular blockers during neck dissection, thyroidectomy, or parotidectomy to allow nerve identification (e.g., spinal accessory, facial nerves) by direct nerve stimulation and thereby facilitate their preservation.

Manipulation of the carotid sinus and stellate ganglion during radical neck dissection has been associated with wide swings in blood pressure, bradycardia, arrhythmias, sinus arrest, and prolonged QT intervals. Infiltration of the carotid sheath with local anesthetic will usually moderate these problems. Bilateral neck dissection may result in postoperative hypertension and loss of hypoxic drive due to denervation of the carotid sinuses and bodies.

Patients undergoing maxillofacial reconstruction or orthognathic surgical procedures often pose airway challenges. If there are any anticipated signs of problems with mask ventilation or tracheal intubation, the airway should be secured prior to induction of general anesthesia.

If there is risk of postoperative edema involving structures that could obstruct the airway (e.g., tongue, pharynx), the patient should be closely observed and perhaps kept intubated.

Nitrous oxide is either entirely avoided during tympanoplasty or discontinued prior to graft placement.

Cooperation and communication between surgeon and anesthesia provider are critical elements of all surgery within or adjacent to the airway. Establishing, maintaining, and protecting an airway in the face of abnormal anatomy and simultaneous surgical intervention are demanding tasks. An understanding of airway anatomy (see Chapter 19) and an appreciation of common otorhinolaryngologic and maxillofacial procedures are invaluable in handling these anesthetic challenges.

ENDOSCOPY

Endoscopy includes laryngoscopy (diagnostic and operative) and microlaryngoscopy (laryngoscopy aided by an operating microscope) for conditions including vocal cord cysts and polyps and upper airway papillomatosis and malignancy, esophagoscopy, and bronchoscopy (discussed in Chapter 25). Endoscopic procedures may be accompanied by laser surgery.
**Preoperative Considerations**

Patients presenting for endoscopic surgery are often being evaluated for voice disorders (often presenting as hoarseness), stridor, or hemoptyisis. Possible diagnoses include foreign body aspiration, trauma to the aerodigestive tract, papillomas, tracheal stenosis, tumors, or vocal cord dysfunction. Thus, a preoperative medical history and physical examination, with particular attention to potential airway problems, must precede any decisions regarding the anesthetic plan. In some patients, flow–volume loop (see Chapter 6), radiographic, computed tomography, ultrasound, or magnetic resonance imaging studies may be available for review. Many patients will have undergone preoperative indirect laryngoscopy or fiberoptic nasopharyngoscopy, and the information gained from these procedures may be of critical importance.

Important initial questions that must be answered are whether adequate positive-pressure ventilation via face or laryngeal mask is feasible, and whether the patient can be intubated using conventional direct or video laryngoscopy. If the answer to either question is “no,” the patient’s airway should be secured prior to induction using an alternative technique such as fiberoptic bronchoscope or tracheostomy under local anesthesia (see Case Discussion, Chapter 19). However, even the initial securing of an airway with tracheostomy does not prevent intraoperative airway obstruction due to surgical manipulation, a foreign body, or hemorrhage.

Sedative premedication should be avoided in a patient with threatening upper airway obstruction. Glycopyrrolate (0.2–0.3 mg) works more effectively and persistently when given intramuscularly rather than intravenously 1 h before surgery and may prove helpful by minimizing secretions, thereby facilitating airway visualization.

**Intraoperative Management**

The anesthetic goals for laryngeal endoscopy include an immobile surgical field and adequate masseter muscle relaxation for introduction of the suspension laryngoscope (typically profound muscle paralysis will be sought), adequate oxygenation and ventilation, and cardiovascular stability despite rapidly varying levels of surgical stimulation.

A. **Muscle Relaxation**

Intraoperative muscle relaxation can be achieved by intermittent boluses or infusion of intermediate-duration nondepolarizing neuromuscular blocking
agents (NMBs) (eg, rocuronium, vecuronium, cisatracurium), or with a succinylcholine infusion. Rapid recovery is important, as endoscopy is often an outpatient procedure. Given that profound muscle relaxation is often needed until the very end of the operative procedure, endoscopy remains one of the few remaining indications for succinylcholine infusions. Use of sugammadex (Bridion) to reverse profound degrees of rocuronium or vecuronium neuromuscular blockade is an alternative approach.

B. Oxygenation & Ventilation
Several methods have successfully been used to provide oxygenation and ventilation during endoscopy, while simultaneously minimizing interference with the operative procedure. Most commonly, the patient is intubated with a small-diameter endotracheal tube through which conventional positive-pressure ventilation is administered. Standard endotracheal tubes of smaller diameters, however, are designed for pediatric patients, and therefore are too short for the adult trachea and have a low-volume cuff that will exert increased pressure against the tracheal mucosa. A 4.0-, 5.0-, or 6.0-mm specialized microlaryngeal endotracheal tube (Mallinckrodt MLT) is the same length as an adult tube, has a disproportionately large high-volume low-pressure cuff, and is stiffer and less prone to compression than is a conventional endotracheal tube of the same diameter. The advantages of intubation in endoscopy include protection against aspiration and the ability to administer inhalational anesthetics and to continuously monitor end-tidal CO₂.

In some cases (eg, those involving the posterior commissure or vocal cords), intubation with an endotracheal tube may interfere with the surgeon’s visualization or performance of the procedure. A simple alternative is insufflation of high flows of oxygen through a small catheter placed in the trachea. Although oxygenation may be maintained in patients with good lung function, ventilation will be inadequate for longer procedures unless the patient is allowed to breathe spontaneously.

Another option is the intermittent apnea technique, in which positive-pressure ventilation with oxygen by face mask or endotracheal tube is alternated with periods of apnea, during which the surgical procedure is performed. The duration of apnea, usually 2 to 3 min, is determined by how well the patient maintains oxygen saturation, as measured by pulse oximetry. Risks of this technique include hypoventilation with hypercarbia, failure to reestablish the airway, and pulmonary aspiration.

Another attractive alternative approach involves manual jet ventilation via
laryngoscope side port. During inspiration (1–2 s), a high-pressure (30–50 psi) jet of oxygen is directed through the glottic opening and entrains a mixture of oxygen and room air into the lungs (Venturi effect). Expiration (4–6 s duration) is passive. Chest wall motion must be monitored and sufficient exhalation time allowed in order to avoid air trapping and barotrauma. This technique requires total intravenous anesthesia. A variation of this technique is high-frequency jet ventilation, which utilizes a small cannula or tube in the trachea, through which gas is injected 80 to 300 times per minute (see Chapter 58). Capnography will not provide an accurate estimate of end-tidal CO₂ during jet ventilation due to constant and sizable dilution of alveolar gases.

C. Cardiovascular Stability
Blood pressure and heart rate often fluctuate markedly during endoscopic procedures for two reasons. First, some of the patients undergoing these procedures are elderly and have a long history of heavy tobacco and alcohol use that predisposes them to cardiovascular disease. In addition, the endoscopic procedure is, in essence, a series of physiologically stressful laryngoscopies and interventions, separated by varying periods of minimal surgical stimulation. Attempting to maintain a constant level of anesthesia invariably results in alternating intervals of hypertension and hypotension. Providing a modest baseline level of anesthesia allows supplementation with short-acting anesthetics (eg, propofol, remifentanil) or sympathetic antagonists (eg, esmolol), or both, as needed during periods of increased stimulation. Alternatively, some anesthesia providers utilize regional nerve block of the glossopharyngeal nerve and superior laryngeal nerve to help minimize intraoperative swings in blood pressure (see Case Discussion, Chapter 19).

Laser Precautions
Laser light differs from ordinary light in three ways: It is monochromatic (possesses one wavelength), coherent (oscillates in the same phase), and collimated (exists as a narrow parallel beam). These characteristics offer the surgeon excellent precision and hemostasis with minimal postoperative edema or pain. Unfortunately, lasers introduce several major hazards into the operating room environment.

The uses and side effects of a laser vary with its wavelength, which is determined by the medium in which the laser beam is generated. For example, a CO₂ laser produces a long wavelength (10,600 nm), whereas yttrium–
aluminum–garnet (YAG) lasers produce a shorter wavelength (1064 or 1320 nm). As the wavelength increases, absorption by water increases, and tissue penetration decreases. Thus, the effects of the CO₂ laser are much more localized and superficial than are those of the YAG laser.

General laser precautions include suction evacuation of toxic fumes (laser plume) from tissue vaporization because they have the potential to transmit microbial diseases. When a significant laser plume is generated, individually fitted respiratory filter masks compliant with U.S. Occupational Safety and Health Administration (OSHA) standards should be worn by all operating room personnel. In addition, during laser procedures, all operating room personnel should wear laser eye protection and the patient’s eyes should be taped shut. Operating room windows should be covered and appropriately placed signage should be used to alert those entering the room that a laser device is in use.

The greatest risk during laser airway surgery is an airway fire. This risk can be moderated by minimizing the fraction of inspired oxygen (Fio₂ <30% if tolerated by the patient) and can be eliminated when there is no combustible material (eg, flammable endotracheal tube, catheter, or dry cotton pledget) in the airway. If an endotracheal tube is used, it must be relatively resistant to laser ignition (Table 37–1). These tubes not only resist laser beam strikes, but they also possess double cuffs that should be inflated with saline instead of air in order to better absorb thermal energy and reduce the risk of ignition. If the proximal cuff is struck by the laser and the saline escapes, the distal cuff will continue to seal the airway. Alternatively, endotracheal tubes can be wrapped with a variety of metallic tapes; however, this is a suboptimal practice and should be avoided whenever use of a specialized, commercially available, flexible, stainless steel, laser-resistant endotracheal tube is possible (Table 37–2).

**TABLE 37–2 Disadvantages of wrapping a tracheal tube with metallic tape.**

- No cuff protection
- Adds thickness to tube
- Not a device approved by the US Food and Drug Administration
- Protection varies with type of metal foil
- Adhesive backing may ignite
- May reflect laser onto nontargeted tissue
- Rough edges may damage mucosal surfaces

Although specialized, laser-resistant endotracheal tubes may be used, it must be emphasized that no endotracheal tube or currently available endotracheal tube protection device is reliably laser-proof. Therefore, whenever laser airway surgery is being performed with an endotracheal tube in place, the following precautions should be observed:

- Inspired oxygen concentration should be as low as possible by utilizing air in
the inspired gas mixture (many patients tolerate an Fio\textsubscript{2} of 21%).

- Nitrous oxide supports combustion and must be avoided.
- The endotracheal tube cuffs should be filled with saline. Some practitioners add methylene blue to the saline to make cuff rupture more obvious. A well-sealed, cuffed endotracheal tube will minimize oxygen concentration in the pharynx.
- Laser intensity and duration should be limited as much as possible.
- Saline-saturated pledgets, although potentially flammable, should be placed in the airway to limit risk of endotracheal tube ignition and damage to adjacent tissue.
- A source of water (eg, water-filled 60-mL syringe and basin) should be immediately available in case of fire.

These precautions limit, but do not eliminate, the risk of an airway fire; anesthesia providers must proactively address the hazard of fire whenever laser or electrocautery is utilized near the airway (Table 37–3).

**TABLE 37–3 Airway fire protocol.**

If an airway fire should occur, all air/oxygen should immediately be turned off at the anesthesia gas machine, and burning combustible material (eg, an endotracheal tube) should be removed from the airway. The fire can be extinguished with saline, and the patient’s airway should be examined to be certain that all foreign body fragments have been removed.

**NASAL & SINUS SURGERY**
Common nasal and sinus surgeries include polypectomy, endoscopic sinus surgery, maxillary sinusotomy (Caldwell–Luc procedure), rhinoplasty, and septoplasty.

### Preoperative Considerations

Patients undergoing nasal or sinus surgery may have a considerable degree of preoperative nasal obstruction caused by polyps, a deviated septum, or mucosal congestion from infection. This may make face mask ventilation difficult, particularly if combined with other causes of difficult ventilation (eg, obesity, maxillofacial deformities).

Nasal polyps are often associated with allergic disorders, such as asthma. Patients who also have a history of allergic reactions to aspirin should not be given any nonsteroidal antiinflammatory drugs (including ketorolac) for postoperative analgesia. Nasal polyps are a common feature of cystic fibrosis.

Because of the rich vascular supply of the nasal mucosa, the preoperative interview should concentrate on questions concerning medication use (eg, aspirin, clopidogrel) and any history of bleeding problems.

### Intraoperative Management

Many nasal procedures can be satisfactorily performed under local anesthesia with sedation. The anterior ethmoidal nerve and sphenopalatine nerves (see Figure 19–3) provide sensory innervation to the nasal septum and lateral walls. Both can be blocked by packing the nose with gauze or cotton-tipped applicators soaked with local anesthetic. The topical anesthetic should be allowed to remain in place at least 10 min before instrumentation is attempted. Supplementation with submucosal injections of local anesthetic is often required. Use of an epinephrine-containing or cocaine solution will shrink the nasal mucosa and potentially decrease intraoperative blood loss. Intranasal cocaine (maximum dose, 3 mg/kg) is rapidly absorbed, reaching peak levels in 30 min, and may be associated with cardiovascular side effects (see Chapter 16).

General anesthesia is often preferred for nasal surgery because of the discomfort and incomplete block that may accompany topical anesthesia. Special considerations during and shortly following induction include using an oral airway during face mask ventilation to mitigate the effects of nasal obstruction, intubating with a reinforced or preformed Mallinckrodt oral RAE (Ring–Adair–Elwyn) endotracheal tube (Figure 36–1), and tucking the patient’s padded arms, with protection of the fingers, to the side. Because of the proximity of the
surgical field, it is important to tape the patient’s eyes closed to avoid a corneal abrasion. One exception to this occurs during dissection in endoscopic sinus surgery, when the surgeon may wish to periodically check for eye movement because of the close proximity of the sinuses and orbit (Figure 37–1); nonetheless, the eyes should remain protected until the surgeon is ready to observe them. NMBs are often utilized because of potential neurological or ophthalmic injury that may occur if the patient moves during sinus instrumentation.

**FIGURE 37–1** Orbital fracture is a risk of endoscopic sinus surgery because of the proximity of the sinuses to the orbit (A, frontal view; B, coronal section). (Modified with permission from Snell RS, Katz J. *Clinical Anatomy for Anesthesiologists*. New York, NY: Appleton & Lange; 1988.)

Techniques to minimize intraoperative blood loss include topical vasoconstriction with cocaine or an epinephrine-containing local anesthetic, maintaining a slightly head-up position, and providing a mild degree of controlled hypotension. A posterior pharyngeal pack is often placed to limit the risk of aspiration of blood. Despite these precautions, the anesthesiologist must be prepared for major blood loss, particularly during the resection of vascular tumors (eg, juvenile nasopharyngeal angiofibroma).

Coughing or straining during emergence from anesthesia and extubation should be avoided, as these events will increase venous pressure and increase postoperative bleeding. However, relatively deep extubation strategies that are commonly and appropriately utilized to accomplish this goal also may increase the risk of aspiration.

**HEAD & NECK CANCER SURGERY**
Surgery for cancer of the head and neck includes laryngectomy, glossectomy, pharyngectomy, parotidectomy, hemimandibulectomy, and radical neck dissection. An endoscopic examination following induction of anesthesia often precedes these surgical procedures. Timing of a tracheostomy, if planned, depends upon the patient’s preoperative airway compromise. Some procedures may include extensive reconstructive surgery, such as the transplantation of a free microvascular muscle flap, with long surgical time duration.

**Preoperative Considerations**

The typical patient presenting for head and neck cancer surgery is older and often has had many years of heavy tobacco and alcohol use. Common coexisting medical conditions include chronic obstructive pulmonary disease, coronary artery disease, hypertension, diabetes, alcoholism, and malnutrition. These patients often greatly benefit from an enhanced recovery after surgery program that includes preoperative nutritional repletion over the course of days and hydration with a carbohydrate–protein drink during the 24 h prior to surgery.

Airway management may be complicated by abnormal airway anatomy, an obstructing lesion, or by preoperative radiation therapy that has fibrosed, immobilized, and distorted the patient’s airway structures. If there is concern regarding potential airway problems, intravenous induction may be avoided in favor of awake direct or fiberoptic laryngoscopy (cooperative patient) or direct or fiberoptic intubation following an inhalational induction, maintaining spontaneous ventilation (uncooperative patient). Elective tracheostomy under local anesthesia prior to induction of general anesthesia is often a prudent option. In any case, the appropriate equipment and qualified personnel required for emergent tracheostomy must be *immediately* available.

**Intraoperative Management**

**A. Monitoring**

Because many of these procedures are lengthy and associated with substantial blood loss, and because of the prevalence of coexisting cardiopulmonary disease, arterial cannulation may be utilized for blood pressure monitoring and frequent laboratory analyses. If central venous access is deemed necessary, the surgeon should be consulted to ascertain that planned internal jugular or subclavian venous access will not interfere with the intended surgical procedures; antecubital or femoral veins are reasonable alternatives. Arterial lines and
intravenous cannulas should not be placed in the operative arm if a radial forearm flap is planned. A minimum of two large-bore intravenous lines and a urinary catheter (preferably with temperature-monitoring capability) should be placed. A forced-air warming blanket should be used to help maintain normal body temperature. Intraoperative hypothermia and consequent vasoconstriction can be detrimental to perfusion of a microvascular free flap.

Intraoperative nerve monitoring is increasingly utilized by surgeons in anterior neck operations to help preserve the superior laryngeal, recurrent laryngeal, and vagus nerves (Figure 37–2), and the anesthesia provider may be asked to place a specialized nerve integrity monitor endotracheal tube (Medtronic Xomed NIM endotracheal tube) to facilitate this process (Figure 37–3).

**FIGURE 37–2** The *vagus nerve* (cranial nerve X) originates in the medulla oblongata and then ramifies in the superior and inferior vagal ganglia in the neck. Its first major branch is the pharyngeal plexus of the vagus. The *superior*
laryngeal nerve divides into the external and internal laryngeal nerves. The internal branch supplies sensory innervation of the laryngeal mucosa above the vocal cords, and the external branch innervates the inferior pharyngeal constrictor muscles and the cricothyroid muscle of the larynx. Cricothyroid muscle contraction increases the voice pitch by lengthening, tensing, and adducting the vocal folds. The superior laryngeal nerve is at risk of damage during operations of the anterior neck, especially thyroid surgery, and injury to this nerve may result in hoarseness and loss of vocal volume. The next branch of the vagus is the recurrent laryngeal nerve, which innervates all of the muscles of the larynx except the cricothyroid, and is responsible for phonation and glottic opening. The recurrent laryngeal nerve runs immediately behind the thyroid gland and thus is the nerve of greatest risk for injury during thyroid surgery. Unilateral recurrent laryngeal nerve damage may result in vocal changes or hoarseness, and bilateral nerve damage may result in aphony and respiratory distress. Inferior to this nerve, the vagus nerve provides autonomic motor and sensory nerve fibers to the thoracic and abdominal viscera. (Reproduced with permission from Dillon FX. Electromyographic (EMG) neuromonitoring in otolaryngology-head and neck surgery. Anesthesiol Clin. 2010 Sep;28(3):423-442.)
FIGURE 37–3  A: The Medtronic Xomed NIM electromyographic (EMG) nerve integrity monitoring endotracheal tube. Succinylcholine (or no relaxant at all) should be used for intubation, and the endotracheal tube should be secured in the midline. If lubricant is used, it must not contain local anesthetics. B: A
slightly larger endotracheal tube size should be used to facilitate mucosal contact with the electrodes, and the blue band of the NIM tube must be positioned at the level of the vocal cords. C: Nerve integrity is continuously monitored via EMG activity (Medtronic Xomed NIM-Response 3.0 Nerve Integrity Monitor). Nondepolarizing muscle relaxants are contraindicated because they prevent EMG monitoring. (Used with permission from Medtronic Xomed.)

B. Tracheostomy

Head and neck cancer surgery often includes tracheostomy. Immediately prior to surgical entry into the trachea, the endotracheal tube and hypopharynx should be thoroughly suctioned to limit the risk of aspiration of blood and secretions. If electrocautery is used during the surgical dissection, the FiO₂ should be lowered to 30% or less, if possible, in order to minimize the risk of fire as the trachea is surgically entered. In any case, the easiest way to minimize airway fire risk in this circumstance is for the surgeon not to use the cautery to enter the trachea. After dissection down to the trachea, the tracheal tube cuff is deflated to avoid perforation by the scalpel. When the tracheal wall is transected, the endotracheal tube is withdrawn so that its tip is immediately cephalad to the incision. Ventilation during this period is difficult because of the large leak through the tracheal incision. A sterile, cuffed tracheostomy tube is placed in the trachea, the cuff is inflated, and the tube is connected to a sterile breathing circuit. As soon as correct position is confirmed by capnography and bilateral chest auscultation, the original endotracheal tube is removed. An increase in peak inspiratory pressure immediately after tracheostomy usually indicates a malpositioned endotracheal tube, bronchospasm, debris or secretions in the trachea, or, rarely, pneumothorax.

C. Maintenance of Anesthesia

The surgeon may request the omission of NMBs during neck dissection, thyroidectomy, or parotidectomy to allow nerve identification (eg, spinal accessory, facial nerves) by direct nerve stimulation and thereby facilitate their preservation. If a nerve integrity monitor endotracheal tube is utilized, succinylcholine (or propofol with no relaxant) may be used to facilitate intubation. Moderate controlled hypotension may be helpful in limiting blood loss; however, cerebral perfusion may be compromised with moderate hypotension when a tumor invades the carotid artery or jugular vein (the latter may increase cerebral venous pressure). If head-up tilt is utilized, it is important that the arterial blood pressure transducer be zeroed at the level of the brain.
(external auditory meatus) in order to most accurately determine cerebral perfusion pressure. In addition, head-up tilt increases the risk of venous air embolism.

Following reanastomosis of a microvascular free flap, blood pressure should be maintained at the patient’s baseline level. The use of vasoconstrictive agents (eg, phenylephrine) should be minimized because of potential decrease in flap perfusion due to vasoconstriction. Similarly, the use of vasodilators (eg, sodium nitroprusside or hydralazine) should be avoided in order to minimize any decrease in graft perfusion pressure.

D. Transfusion

Transfusion decisions must balance the patient’s immediate surgical risks with the possibility of an increased cancer recurrence rate resulting from transfusion-induced immune suppression. Rheological factors make a relatively low hematocrit (eg, 27–30%) desirable when microvascular free flaps are performed. Excessive diuresis should be avoided during microvascular free-flap surgery in order to optimize graft perfusion in the postoperative period.

E. Cardiovascular Instability

Manipulation of the carotid sinus and stellate ganglion during radical neck dissection has been associated with wide swings in blood pressure, bradycardia, arrhythmias, sinus arrest, and prolonged QT intervals. Infiltration of the carotid sheath with local anesthetic will usually moderate these problems. Bilateral neck dissection may result in postoperative hypertension and loss of hypoxic drive due to denervation of the carotid sinuses and carotid bodies.

Postoperative Management

The principal postoperative complications associated with head and neck cancer surgery include hypocalcemia secondary to acute hypoparathyroidism, and threats to airway integrity secondary to hemorrhage, hematoma formation, and bilateral vocal cord palsy with stridor resulting from bilateral recurrent laryngeal nerve injury (see Chapter 35). Postoperative hypoparathyroidism is a common condition, resulting from injury to the parathyroid glands or their blood supply during thyroidectomy or neck dissection, or from unintentional or intentional removal of all four parathyroid glands. It may be either symptomatic or asymptomatic, and occurs transiently in up to 49% of thyroidectomy patients, and is permanent in up to 33% of thyroidectomy patients. Symptoms and signs
depend upon the rate of onset and severity of hypocalcemia. Clinical signs of acute, severe hypocalcemia include laryngospasm, bronchospasm, QT prolongation-related arrhythmias, and congestive heart failure. Neurological symptoms and signs range from circumoral paresthesias, distal extremity numbness, and carpopedal spasm to confusion, delirium, and seizure activity. Symptomatic hypocalcemia is a medical emergency and should be treated with intravenous calcium salts, whereas asymptomatic hypocalcemia may be treated with oral calcium preparations (see Chapter 49).

MAXILLOFACIAL RECONSTRUCTION & ORTHOGNATHIC SURGERY

Maxillofacial reconstruction is often required to correct the effects of trauma (eg, fractures of the mandible or maxilla) or developmental malformations, or for radical cancer surgeries (eg, maxillectomy or mandibulectomy). Orthognathic procedures (eg, LeFort osteotomies, mandibular osteotomies) for skeletal malocclusion share many of the same surgical and anesthetic techniques.

Preoperative Considerations

Patients undergoing maxillofacial reconstruction or orthognathic surgical procedures often pose airway challenges. Particular attention should be focused on jaw opening, mask fit, neck mobility, micrognathia, retrognathia, maxillary protrusion (overbite), macroglossia, dental pathology, nasal patency, and the existence of any intraoral lesions or debris. If there are any anticipated signs of problems with mask ventilation or endotracheal intubation, the airway should be secured prior to induction of general anesthesia. This may involve fiberoptic nasal intubation, fiberoptic oral intubation, or tracheostomy with local anesthesia facilitated with cautious sedation. Nasal intubation with a straight tube with a flexible angle connector (Figure 37–4A) or a preformed nasal RAE (Figure 37–4B) tube is usually preferred in dental and oral surgery. The endotracheal tube can then be directed cephalad over the patient’s forehead. With any nasal intubation, care should be taken to prevent the endotracheal tube from putting pressure on the tissues of the nasal opening, as this situation may result in local tissue pressure necrosis in the setting of a lengthy surgical procedure. Nasal intubation should be considered with caution in LeFort II and III fractures because of the possibility of a coexisting basilar skull fracture (Figure 37–5).
FIGURE 37–4  A: A regular straight endotracheal tube can be cut at the level of the nares, and a flexible connector attached. B: Alternatively, a nasal RAE endotracheal tube has a preformed right-angle bend at the level of the nose so that the tube is directed over the forehead.
FIGURE 37–5 Diagrammatic representation of LeFort I, II, and III fractures. LeFort II and III fractures may coexist with a basilar skull fracture, a contraindication to nasal intubation.

**Intraoperative Management**

Maxillofacial reconstructive and orthognathic surgeries can be lengthy and involve substantial blood loss. An oropharyngeal (“throat”) pack is often placed to minimize the amount of blood and other debris reaching the larynx and trachea, and one must remember to remove the pack at the end of surgery before the jaws are wired shut! Strategies to minimize bleeding include a slight head-up position, controlled hypotension, and local infiltration with epinephrine solutions. Because the patient’s arms are typically tucked at the side, two intravenous lines may be established prior to surgery. An arterial line may be placed. As previously noted, if head-up tilt is utilized, it is important that the arterial blood pressure transducer be zeroed at the level of the brain (external auditory meatus) in order to most accurately determine cerebral perfusion pressure. In addition, the anesthesia provider must be alert to the increased risk of venous air embolism in the setting of head-up tilt.

Because of proximity of the airway to the surgical field, positioning of surgical team personnel, and positioning of the patient’s head often 90° or 180° away from the anesthesia provider, there is an increased risk of critical intraoperative airway problems, such as endotracheal tube kinking, disconnection, or perforation by a surgical instrument. Monitoring of end-tidal CO₂, peak inspiratory pressures, and breath sounds via an esophageal stethoscope assume greater importance in such cases. If the operative procedure is near the airway, the use of electrocautery or laser increases the risk of fire. At the end of surgery, the oropharyngeal pack must be removed and the pharynx suctioned. If there is risk of postoperative tissue edema involving structures that could potentially obstruct the airway (eg, tongue, pharynx), the patient should be
closely observed and perhaps kept intubated. In such uncertain situations, extubation may be performed over an endotracheal tube exchanger (eg, Cook Airway Exchange Catheter with Rapi-Fit Adapter, Cook Medical), which can facilitate reintubation and provide oxygenation in the setting of immediate postextubation respiratory obstruction. In addition, the operating team should be prepared for emergent tracheotomy or cricothyrotomy. Otherwise, extubation can be attempted once the patient is fully awake and there are no signs of continued bleeding. Patients with intermaxillary fixation (eg, maxillomandibular wiring) must have suction and appropriate wire cutting tools continuously at the bedside in case of vomiting or other airway emergencies. Extubating a patient whose jaws are wired shut and whose oropharyngeal pack has not been removed can lead to life-threatening airway obstruction. “Has the throat pack been removed?” should be asked before intermaxillary fixation is initiated and again before removing the endotracheal tube.

**EAR SURGERY**

Frequently performed ear surgeries include stapedectomy or stapedotomy, tympanoplasty, and mastoidectomy. Myringotomy with insertion of tympanostomy tubes is the most common pediatric surgical procedure and is discussed in Chapter 42.

**Intraoperative Management**

**A. Nitrous Oxide**

Nitrous oxide is not often used in anesthesia for ear surgery. Because nitrous oxide is more soluble than nitrogen in blood, it diffuses into air-containing cavities more rapidly than nitrogen (the major component of air) can be absorbed by the bloodstream (see Chapter 8). Normally, changes in middle ear pressures caused by nitrous oxide are well tolerated as a result of passive venting through the eustachian tube. However, patients with a history of chronic ear problems such as otitis media or sinusitis often suffer from obstructed eustachian tubes and may, on rare occasion, experience hearing loss or tympanic membrane rupture from administration of nitrous oxide anesthesia.

During tympanoplasty, the middle ear is open to the atmosphere, and there is no pressure buildup. However, once the surgeon has placed a tympanic membrane graft, the middle ear becomes a closed space, and if nitrous oxide is allowed to diffuse into any gas remaining in this space, middle ear pressure will
rise and the graft may be displaced. Conversely, discontinuing nitrous oxide after graft placement will create a negative middle ear pressure that could also cause graft dislodgment. Therefore, nitrous oxide is either entirely avoided during tympanoplasty or discontinued prior to graft placement. Obviously, the exact amount of time required to wash out the nitrous oxide depends on many factors, including alveolar ventilation and fresh gas flows (see Chapter 8), but 15 to 30 min is usually recommended.

**B. Hemostasis**
As with any form of microsurgery, even tiny amounts of blood can obscure the operating field. Techniques to minimize blood loss during ear surgery include mild (15°) head elevation, infiltration or topical application of epinephrine (1:50,000–1:200,000), and moderate controlled hypotension. Because coughing on the endotracheal tube during emergence (particularly during neck movement associated with head bandaging) will increase venous pressure and may cause bleeding and increased middle ear pressure, deep extubation is often utilized.

**C. Facial Nerve Identification**
Preservation of the facial nerve is an important consideration during some ear procedures, such as resection of a glomus tumor or acoustic neuroma. During such cases, intraoperative paralysis with NMBs will make identification of the facial nerve by direct nerve stimulation impossible. Thus, intraoperative paralysis should not be employed unless requested by the surgeon.

**D. Postoperative Vertigo, Nausea, & Vomiting**
Because the inner ear is intimately involved with the sense of balance, ear surgery may cause postoperative dizziness (vertigo) and postoperative nausea and vomiting (PONV). Induction and maintenance with propofol have been shown to decrease PONV in patients undergoing middle ear surgery. Prophylaxis with decadron prior to induction, and a 5-HT₃ blocker prior to emergence, should be considered. Patients undergoing ear surgery should be carefully assessed for vertigo postoperatively, and their ambulation closely monitored, in order to minimize the risk of falling.

**Oral Surgical Procedures**
Most minor oral surgical procedures are performed in a clinic or office setting utilizing local anesthesia, augmented with varying degrees of sedation. If
Intravenous sedation is employed, or if the procedure is complex, a qualified anesthesia provider should be present. A qualified anesthesia provider must be present to administer deep sedation or general anesthesia if either is utilized. Typically, a bite block and an oropharyngeal throat pack protect the airway. For light to moderate levels of sedation, the oropharyngeal pack prevents irrigating fluids and dental debris from entering the airway. Deep sedation and general anesthesia require an increased level of airway management by a qualified anesthesia provider. Regardless of whether deep sedation or general anesthesia is inadvertent or intended, appropriate equipment, supplies, and medications must be immediately available to help ensure that any anticipated or unexpected anesthesia-related problem occurring in an office or clinic environment can be safely addressed with the same standard of care that is required in the hospital or ambulatory surgery center setting.

Minor oral surgical procedures, such as dental extractions, typically last no longer than 1 h. Nerve block or local anesthetic infiltration is typically utilized. In adults, most oral surgeons use 2% lidocaine with 1:100,000 epinephrine or 0.5% bupivacaine with 1:200,000 epinephrine in quantities no greater than 12 mL and 8 mL, respectively. Articaine is commonly used in Europe. The anesthesia provider must be informed by the surgeon of the local anesthetic used and its concentration and volume injected so that the allowed dosage based on patient weight is not exceeded. Pediatric patients are particularly at risk of local anesthesia toxicity due to excess local anesthetic dose administration or accidental intravascular injection.

Intravenous sedation during oral surgical procedures greatly increases the patient’s comfort and facilitates surgery. Small doses of fentanyl and midazolam are usually adequate for adults prior to injection of the local anesthetic. The sedation can be further augmented by additional small dosages of fentanyl, midazolam, or propofol. Incremental doses of propofol, 20 to 30 mg for adults, are often used if the surgeon requires a brief episode of deep sedation or general anesthesia.

These techniques require a high level of cooperation and participation by both the surgeon and anesthesia provider. If there is the possibility of increased risk due to preexisting medical conditions, less than ideal airway, or extent of contemplated surgical procedure, it is safer to perform the procedure in a hospital or ambulatory surgery center setting with general endotracheal anesthesia.
Bleeding Following Sinus Surgery

A 50-year-old man has a paroxysm of coughing in the recovery room while awakening following uneventful endoscopic sinus surgery. Immediately afterward, his respirations seem labored with a loud inspiratory stridor.

What is the differential diagnosis of inspiratory stridor?

The acute onset of inspiratory stridor in a postoperative patient may be due to laryngospasm, laryngeal edema, foreign body aspiration, or vocal cord dysfunction. Laryngospasm, an involuntary spasm of the laryngeal musculature, may be triggered by blood or secretions stimulating the superior laryngeal nerve (see Chapter 19). Laryngeal edema may be caused by an allergic drug reaction, hereditary or iatrogenic angioedema, or a traumatic intubation. Vocal cord dysfunction could be due to residual muscle relaxant effect, hypocalcemic alkalotic tetany, intubation trauma, or paradoxical vocal cord motion.

Another paroxysm of coughing is accompanied by hemoptysis. What is your immediate management?

Bleeding after nose or throat surgery can be very serious. Patients who are not fully awake may continue to gag and cough on the secretions, increasing venous pressure and worsening the bleeding. Furthermore, they may aspirate blood and other secretions. Fortunately, because of its physiological pH, aspiration of blood is not as serious as aspiration of acidic gastric contents. Nonetheless, the airway should be immediately secured in the obtunded patient. This may be accomplished with an awake intubation or a rapid-sequence induction.

If the patient is awake and alert enough to cough and swallow and does not seem to be aspirating blood, the first priority should be to decrease the bleeding as quickly as possible. Immediate measures that should be considered include raising the head of the bed to decrease venous and arterial pressures at the site of bleeding and aggressively treating any degree of systolic hypertension with intravenous antihypertensive agents. Sedation should be avoided so that airway reflexes are not compromised.
Despite these measures, the bleeding continues, and surgical intervention seems to be necessary. Describe your strategy for induction of anesthesia in this patient.

Before induction of general anesthesia in a bleeding patient, hypovolemia should be corrected with isotonic crystalloid or with colloid. The degree of hypovolemia may be difficult to assess because much of the blood may be swallowed, but it can be estimated by changes in vital signs, postural hypotension, and hematocrit. Cross-matched blood should be readily available, and a second large-bore intravenous line secured. It must be appreciated that from an anesthetic standpoint, this is an entirely different patient than the one who presented for surgery initially: the patient now has a full stomach, is hypovolemic, and may be more difficult to intubate.

The preferred technique in this patient is a rapid-sequence induction. Induction drug choice (eg, ketamine, etomidate) and dosage should anticipate the possibility of hypotension from persistent hypovolemia. Qualified personnel and appropriate equipment for an emergency tracheostomy should be immediately available. An orogastric tube should be passed to decompress the stomach.

Which arteries supply blood to the nose?

The arterial supply of the nose is provided by the internal maxillary artery and the anterior ethmoid artery. These may have to be ligated in uncontrollable epistaxis.

Describe extubation.

Because this patient is still at risk of aspiration, extubation should not be attempted until the patient has fully awakened and regained airway reflexes. Although it is desirable to limit coughing and “bucking” on the endotracheal tube during emergence, this may be difficult to achieve in the awakening patient. Intravenous lidocaine or dexmedetomidine may be helpful in this situation.

SUGGESTED READINGS

Acharya K. Rigid bronchoscopy in airway foreign bodies: Value of the clinical
Hillman DR, Platt PR, Eastwood PR. Anesthesia, sleep and upper airway

Clinical manifestations of bone cement implantation syndrome include hypoxia (increased pulmonary shunt), hypotension, arrhythmias (including heart block and sinus arrest), pulmonary hypertension (increased pulmonary vascular resistance), and decreased cardiac output.

Use of a pneumatic tourniquet on an extremity creates a bloodless field that greatly facilitates surgery. However, tourniquets can produce potential problems of their own, including hemodynamic changes, pain, metabolic alterations, arterial thromboembolism, and pulmonary embolism.

Fat embolism syndrome classically presents within 72 h following long-bone or pelvic fracture, with the triad of dyspnea, confusion, and petechiae.

Deep vein thrombosis and pulmonary embolism can cause morbidity and mortality following orthopedic operations on the pelvis and lower extremities.

Neuraxial anesthesia alone or combined with general anesthesia may reduce thromboembolic complications by several mechanisms, including sympathectomy-induced increases in lower extremity venous blood flow, systemic antiinflammatory effects of local anesthetics, decreased platelet reactivity, attenuated postoperative increase in factor VIII and von Willebrand factor, attenuated postoperative decrease in antithrombin III, and alterations in stress hormone release.

For patients receiving prophylactic low-molecular-weight heparin once daily, neuraxial techniques may be performed (or neuraxial catheters
removed) 10 to 12 h after the previous dose, with a 4-h delay before administering the next dose.

7 Flexion and extension lateral radiographs of the cervical spine should be obtained preoperatively in patients with rheumatoid arthritis severe enough to require steroids, immune therapy, or methotrexate. If atlantoaxial instability is present, intubation should be performed with inline stabilization utilizing video or fiberoptic laryngoscopy.

8 Effective communication between the anesthesia provider and surgeon is essential during bilateral hip arthroplasty. If major hemodynamic instability occurs during the first hip replacement procedure, the second arthroplasty should be postponed.

9 Adjuvants such as opioids, clonidine, ketorolac, and neostigmine, when added to local anesthetic solutions for intraarticular injection, have been used in various combinations to extend the analgesia duration following knee arthroscopy.

10 Effective postoperative multimodal analgesia facilitates early physical rehabilitation to maximize postoperative range of motion and prevent joint adhesions following knee replacement.

11 Interscalene brachial plexus block with or without a perineural catheter is ideally suited for shoulder procedures. Even when general anesthesia is employed, a peripheral nerve or brachial plexus block can supplement anesthesia and provide effective postoperative analgesia.

Orthopedic surgery challenges the anesthesia provider. The comorbidities of these patients vary widely based on age group. Patients may present as neonates with congenital limb deformities, as teenagers with sports-related injuries, as adults for procedures ranging from excision of minor soft-tissue mass to joint replacement, or at any age with bone cancer. This chapter focuses on perioperative care issues specific to patients undergoing common orthopedic surgical procedures. For example, patients with long bone fractures are predisposed to fat embolism syndrome. Patients are at increased risk for venous thromboembolism following pelvic, hip, and knee operations. Use of bone cement during arthroplasties can cause hemodynamic instability. Limb tourniquets limit blood loss but introduce additional risks. Perioperative care of patients undergoing cervical, thoracic, and lumbar spine procedures is reviewed in Chapter 27.

Neuraxial and other regional anesthetic techniques play an important role in
decreasing the incidence of perioperative thromboembolic complications, providing postoperative analgesia, and facilitating early rehabilitation and hospital discharge. Advances in surgical techniques, such as minimally invasive approaches to knee and hip replacement, are necessitating modifications in anesthetic and perioperative management to facilitate overnight or even same-day discharge of patients who formerly required days of hospitalization. It is impossible to cover the anesthetic implications of diverse orthopedic operations in one chapter; hence, the focus here is on perioperative management considerations and strategies for the anesthetic management of patients undergoing select orthopedic surgical procedures. Anesthesia for surgery on the spine is discussed in Chapter 27.

PERIOPERATIVE MANAGEMENT CONSIDERATIONS IN ORTHOPEDIC SURGERY

Bone Cement

Bone cement, polymethylmethacrylate, is frequently required for joint arthroplasties. The cement interdigitates within the interstices of cancellous bone and strongly binds the prosthetic device to the patient’s bone. Mixing polymerized methylmethacrylate powder with liquid methylmethacrylate monomer causes polymerization and cross-linking of the polymer chains. This exothermic reaction leads to hardening of the cement and expansion against the prosthetic components. The resultant intramedullary hypertension (>500 mm Hg) can cause embolization of fat, bone marrow, cement, and air into venous channels. Systemic absorption of residual methylmethacrylate monomer can produce vasodilation and a decrease in systemic vascular resistance. The release of tissue thromboplastin may trigger platelet aggregation, microthrombus formation in the lungs, and cardiovascular instability as a result of the circulation of vasoactive substances. Nevertheless, most patients experience no adverse response to application of bone cement.

The clinical manifestations of bone cement implantation syndrome include hypoxia (increased pulmonary shunt), hypotension, arrhythmias (including heart block and sinus arrest), pulmonary hypertension (increased pulmonary vascular resistance), and decreased cardiac output. Emboli most frequently occur during insertion of a femoral prosthesis for hip arthroplasty. Treatment strategies for this complication include increasing inspired oxygen concentration prior to cementing, monitoring to maintain euvoolemia, creating a vent hole in the distal
femur to relieve intramedullary pressure, performing high-pressure lavage of the femoral shaft to remove debris (potential microemboli), or using a femoral component that does not require cement.

Another source of concern related to the use of cement is the potential for gradual loosening of the prosthesis over time. Newer cementless implants are made of a porous material that allows natural bone to grow into them. Cementless prostheses generally last longer and may be advantageous for younger, active patients; however, healthy active bone formation is required and recovery may be longer compared to cemented joint replacements. Therefore, cemented prostheses are preferred for older (>80 years) and less active patients who often have osteoporosis or thin cortical bone. Practices continue to evolve regarding selection of cemented versus cementless implants, depending on the joint affected, patient, and surgical technique.

**Pneumatic Tourniquets**

Use of a pneumatic tourniquet on an extremity creates a bloodless field that greatly facilitates surgery. However, tourniquets can produce potential problems of their own, including hemodynamic changes, pain, metabolic alterations, arterial thromboembolism, and pulmonary embolism. Inflation pressure is usually set approximately 100 mm Hg higher than the patient’s baseline systolic blood pressure. Prolonged inflation (>2 h) routinely leads to muscle ischemia and may produce rhabdomyolysis or permanent peripheral nerve damage. Tourniquet inflation has also been associated with increases in body temperature in pediatric patients undergoing lower extremity surgery.

Exsanguination of a lower extremity and tourniquet inflation cause a rapid shift of blood volume into the central circulation. Although not usually clinically important, bilateral lower extremity exsanguination can cause an increase in central venous pressure and arterial blood pressure that may not be well tolerated in patients with noncompliant ventricles and diastolic dysfunction.

Awake patients predictably experience tourniquet pain with inflation pressures of 100 mm Hg above systolic blood pressure for more than a few minutes. **During a regional block, tourniquet pain may gradually become so severe in some patients over time that they may require substantial supplemental intravenous analgesia, if not general anesthesia, despite the fact that the block is adequate for the surgical procedure.** Even during general anesthesia, noxious stimulus from tourniquet compression often manifests as a gradually increasing mean arterial blood pressure beginning
approximately 1 h after cuff inflation. Signs of progressive sympathetic activation include marked hypertension, tachycardia, and diaphoresis. The likelihood of tourniquet pain and its accompanying hypertension may be influenced by many factors, including anesthetic technique (regional anesthesia versus general anesthesia), extent of dermatomal spread or peripheral nerve coverage of the regional anesthetic block, choice of local anesthetic and dose (“density” of block), and supplementation with adjuvants either intravenously or in combination with local anesthetic solutions when applicable.

Cuff deflation invariably and immediately relieves tourniquet pain and associated hypertension. In fact, cuff deflation may be accompanied by a precipitous decrease in central venous and arterial blood pressure. Heart rate usually increases and core temperature decreases. Washout of accumulated metabolic wastes from the ischemic extremity increases carbon dioxide partial pressure in arterial blood (\( \text{PaCO}_2 \)), end-tidal carbon dioxide (\( \text{EtCO}_2 \)), and serum lactate and potassium levels. **These metabolic alterations can cause an increase in minute ventilation in the spontaneously breathing patient and, rarely, arrhythmias.** Tourniquet-induced ischemia of a lower extremity may lead to the development of deep venous thrombosis. Transesophageal echocardiography can detect subclinical pulmonary embolism (miliary emboli in the right atrium and ventricle) following tourniquet deflation even in minor cases such as diagnostic knee arthroscopy. Rare episodes of massive pulmonary embolism during total knee arthroplasty have been reported during leg exsanguination, after tourniquet inflation, and following tourniquet deflation. Tourniquets have been safely used in patients with sickle cell disease, although particular attention should be paid to maintaining oxygenation, normocarbia or hypocarbia, hydration, and normothermia.

**Fat Embolism Syndrome**

Some degree of fat embolism probably occurs with all long-bone fractures. *Fat embolism syndrome* is less frequent but potentially fatal (10–20% mortality). It classically presents within 72 h following long-bone or pelvic fracture, with the triad of dyspnea, confusion, and petechiae. This syndrome can also be seen following cardiopulmonary resuscitation, parental feeding with lipid infusion, and liposuction. The most popular theory for its pathogenesis holds that fat globules are released by the disruption of fat cells in the fractured bone and enter the circulation through tears in medullary vessels. An alternative theory proposes that the fat globules are chylomicrons resulting from the aggregation of
circulating free fatty acids caused by changes in fatty acid metabolism. Regardless of their source, the increased free fatty acid levels can have a toxic effect on the capillary–alveolar membrane leading to the release of vasoactive amines and prostaglandins and the development of acute respiratory distress syndrome (ARDS; see Chapter 58). Neurological manifestations (eg, agitation, confusion, stupor, or coma) are the probable result of capillary damage in the cerebral circulation and cerebral edema. These signs may be exacerbated by hypoxia.

The diagnosis of fat embolism syndrome is suggested by petechiae on the chest, upper extremities, axillae, and conjunctiva. Fat globules occasionally may be observed in the retina, urine, or sputum. Coagulation abnormalities such as thrombocytopenia or prolonged clotting times are occasionally present. Serum lipase activity may be elevated but does not predict disease severity. Pulmonary involvement typically progresses from mild hypoxia and a normal chest radiograph to severe hypoxia or respiratory failure with radiographic findings of diffuse pulmonary opacities. Most of the classic signs and symptoms of fat embolism syndrome occur 1 to 3 days after the precipitating event. During general anesthesia, signs may include a decline in $\text{ETCO}_2$ and arterial oxygen saturation and a rise in pulmonary artery pressures. Electrocardiography may show ischemic-appearing ST-segment changes and a pattern of right-sided heart strain.

Management of fat embolism syndrome involves preemption and support. Early stabilization of the fracture decreases the likelihood of fat embolism syndrome and, in particular, the risk of pulmonary complications. Supportive treatment consists of oxygen therapy with continuous positive airway pressure ventilation to prevent hypoxia and with specific ventilator strategies in the event of ARDS. Systemic hypotension will require appropriate pressor support, and vasodilators may aid the management of pulmonary hypertension. High-dose corticosteroid therapy is not supported by randomized clinical trials.

**Deep Venous Thrombosis & Thromboembolism**

Deep vein thrombosis (DVT) and pulmonary embolism (PE) can cause morbidity and mortality following orthopedic operations on the pelvis and lower extremities. Risk factors include obesity, age greater than 60 years, procedures lasting more than 30 min, use of a tourniquet, lower extremity fracture, and immobilization for more than 4 days. Patients at greatest risk include those undergoing hip surgery or knee replacement or major operations for lower
extremity trauma. Such patients will experience DVT rates of 40% to 80% without prophylaxis. The incidence of clinically important PE following hip surgery in some studies is reported to be as high as 20%, whereas that of fatal PE may be 1% to 3%. Underlying pathophysiological mechanisms include venous stasis with hypercoagulable state due to local and systemic inflammatory responses to surgery.

Pharmacological prophylaxis and the routine use of mechanical devices such as intermittent pneumatic compression (IPC) have been shown to decrease the incidence of DVT and PE. While mechanical thromboprophylaxis should be considered for every patient, the use of pharmacological anticoagulants must be balanced against the risk of bleeding. For patients at increased risk for DVT but having “normal” bleeding risk, low-dose subcutaneous unfractionated heparin (LUFH), warfarin, or low-molecular-weight heparin (LMWH) may be employed in addition to mechanical prophylaxis. Patients at significantly increased risk of bleeding may be managed with mechanical prophylaxis alone until bleeding risk decreases. In general, anticoagulants are started the day of surgery in patients without indwelling epidural catheters. Warfarin may be started the night before surgery depending on the particular orthopedic surgeon’s routine. Newer direct oral anticoagulants that inhibit factor Xa or thrombin have a fast onset of action, are renally excreted, and deserve special consideration in the context of regional anesthesia.

Neuraxial anesthesia alone or combined with general anesthesia may reduce thromboembolic complications by several mechanisms, including sympathetic-induced increases in lower extremity venous blood flow, systemic anti-inflammatory effects of local anesthetics, decreased platelet reactivity, attenuated postoperative increases in factor VIII and von Willebrand factor, attenuated postoperative decreases in antithrombin III, and alterations in stress hormone release.

According to the Third Edition of the American Society of Regional Anesthesia and Pain Medicine Evidence-Based Guidelines on regional anesthesia and anticoagulation, patients currently receiving antiplatelet agents (e.g., ticlopidine, clopidogrel, and intravenous glycoprotein IIb/IIIa inhibitors), thrombolytics, fondaparinux, direct thrombin inhibitors, or therapeutic regimens of LMWH present an unacceptable risk for spinal or epidural hematoma following neuraxial anesthesia. Performance of neuraxial block (or removal of a neuraxial catheter) is not contraindicated with subcutaneous LUFH when the total daily dose is 10,000 units or less; there are no data on the safety of neuraxial anesthesia when larger doses are given. For patients receiving
prophylactic LMWH, the guidelines vary based on regimen. With once-daily dosing, neuraxial techniques may be performed (or neuraxial catheters removed) 10 to 12 h after the previous dose, with a 4-h delay before administering the next dose. With twice-daily dosing, neuraxial catheters should not be left in situ and should be removed 2 or more hours before the first dose of LMWH. Patients on warfarin therapy should not receive a neuraxial block unless the international normalized ratio (INR) is normal, and catheters should be removed when the INR is 1.5 or lower. The Third Edition of these guidelines also suggests that these recommendations be applied to deep peripheral nerve and plexus blocks and catheters (see Suggested Reading). Revisions to these guidelines occur regularly.

**Hip Surgery**

Common hip procedures performed in adults include repair of hip fracture, total hip arthroplasty (THA), and closed reduction of hip dislocation.

**FRACTURE OF THE HIP**

**Preoperative Considerations**

Most patients presenting with femoral neck fractures are frail and elderly. An occasional young patient will have sustained major trauma to the femur or pelvis. Studies have reported mortality rates following hip fracture of up to 10% during the initial hospitalization and over 25% within 1 year. Many of these patients have concomitant diseases such as coronary artery disease, cerebrovascular disease, chronic obstructive pulmonary disease, or diabetes.

Patients presenting with hip fractures are frequently dehydrated from inadequate oral intake. Depending on the site of the hip fracture, occult blood loss may be significant, further compromising intravascular volume. In general, intracapsular (subcapital, transcervical) fractures are associated with less blood loss than extracapsular (base of the femoral neck, intertrochanteric, subtrochanteric) fractures (Figure 38–1). A normal or borderline-low preoperative hematocrit may be deceiving when hemoconcentration masks occult blood loss.
FIGURE 38–1 Blood loss from hip fracture depends on the location of the fracture (subtrochanteric, intertrochanteric > base of femoral neck > transcervical, subcapital) because the capsule restricts blood loss by acting like a tourniquet.

Another characteristic of hip fracture patients is the frequent presence of preoperative hypoxia that may, at least in part, be due to fat embolism; other factors can include bibasilar atelectasis from immobility, pulmonary congestion (and effusion) from congestive heart failure, or consolidation due to infection.

Intraoperative Management

The choice between regional (spinal or epidural) and general anesthesia has been extensively evaluated for hip fracture surgery. A meta-analysis of 15 randomized clinical trials showed a decrease in postoperative DVT and 1-month mortality with regional anesthesia, but these advantages do not persist beyond 3 months. A large database study involving over 50,000 patients treated for hip fracture in New York State also did not show a difference in 30-day mortality based on anesthetic technique but did show a slightly shorter length of stay for patients...
who received regional anesthesia. The incidence of postoperative delirium and cognitive dysfunction may be lower following regional anesthesia if intravenous sedation can be minimized. A large clinical trial addressing this important question is currently underway.

A neuraxial anesthetic technique, with or without concomitant general anesthesia, provides the additional advantage of postoperative pain control. If a spinal anesthetic is planned, hypobaric or isobaric local anesthesia facilitates positioning since the patient can remain in the same position for both block placement and surgery. Intrathecal opioids such as morphine can extend postoperative analgesia but require close postoperative monitoring for delayed respiratory depression.

Consideration should also be given to the type of reduction and fixation to be used. This is dependent on the fracture site, degree of displacement, preoperative functional status of the patient, and surgeon preference. Undisplaced fractures of the proximal femur may be treated with percutaneous pinning or cannulated screw fixation with the patient in the supine position. A hip compression screw and side plate are most often employed for intertrochanteric fractures. Displaced intracapsular fractures may require internal fixation, hemiarthroplasty, or THA (Figure 38–2). Surgical treatment of extracapsular hip fractures is accomplished with either an extramedullary implant (eg, sliding screw and plate) or intramedullary implant (eg, Gamma nail).
Hemiarthroplasty and THA are longer, more invasive operations than most other orthopedic procedures. They are usually performed with patients in the lateral decubitus position, are associated with greater blood loss, and, potentially, result in greater hemodynamic changes, particularly if cement is used. One should secure sufficient venous access to permit rapid transfusion.
Preoperative Considerations

Most patients undergoing THA suffer from osteoarthritis (degenerative joint disease), hip fracture, avascular necrosis, or autoimmune conditions such as rheumatoid arthritis (RA). Osteoarthritis is a degenerative disease affecting the articular surface of joints (commonly the hips and knees). The etiology of osteoarthritis appears to involve repetitive joint trauma. Because osteoarthritis may also involve the spine, neck manipulation during tracheal intubation should be minimized to avoid nerve root compression or disc protrusion.

RA is characterized by immune-mediated joint destruction with chronic and progressive inflammation of synovial membranes, as opposed to the articular wear-and-tear of osteoarthritis. RA is a systemic disease affecting multiple organ systems (Table 38–1). RA often affects the small joints of the hands, wrists, and feet causing severe deformity.

Extreme cases of RA involve almost all synovial membranes, including those in the cervical spine and temporomandibular joint. *Atlantoaxial subluxation,*
which can be diagnosed radiologically, may lead to protrusion of the odontoid process into the foramen magnum during intubation, compromising vertebral blood flow and compressing the spinal cord or brainstem (Figure 38–3). Flexion and extension lateral radiographs of the cervical spine should be obtained preoperatively in patients with RA severe enough to require steroids, immune therapy, or methotrexate. If atlantoaxial instability is present, intubation should be performed with inline stabilization utilizing video or fiberoptic laryngoscopy. Involvement of the temporomandibular joint can limit jaw mobility and range of motion to such a degree that conventional orotracheal intubation may be impossible. Hoarseness or inspiratory stridor may signal a narrowing of the glottic opening caused by cricoarytenoid arthritis. This condition may lead to postextubation airway obstruction even when a smaller diameter tracheal tube has been used.
FIGURE 38–3 Because instability of the cervical spine may be asymptomatic, lateral radiographs are mandatory in patients with severe rheumatoid arthritis. A: Radiograph of a normal lateral cervical spine. B: Lateral cervical spine of a patient with rheumatoid arthritis; note the severe C1–C2 instability.
Patients with RA or osteoarthritis commonly receive nonsteroidal antiinflammatory drugs (NSAIDs) for pain management. These drugs can have serious side effects such as gastrointestinal bleeding, kidney toxicity, and platelet dysfunction.

**Intraoperative Management**

THA involves several surgical steps, including positioning of the patient (usually in the lateral decubitus position), dislocation and removal of the femoral head, reaming of the acetabulum and insertion of a prosthetic acetabular cup (with or without cement), and reaming of the femur and insertion of a femoral component (femoral head and stem) into the femoral shaft with or without cement. THA is associated with three potentially life-threatening complications: bone cement implantation syndrome, intra- and postoperative hemorrhage, and venous thromboembolism. Thus, invasive arterial monitoring may be justified for select patients undergoing these procedures. General anesthesia, neuraxial anesthesia, or a combination of techniques can provide suitable operating conditions. The use of neuraxial anesthesia with or without general anesthesia may be associated with decreased incidence of postoperative complications such as all-cause infections, acute kidney injury, and need for mechanical ventilation. Neuraxial administration of opioids such as morphine in the perioperative period extends the duration of postoperative analgesia. Tranexamic acid may be administered intraoperatively to reduce blood loss.

**A. Hip Resurfacing Arthroplasty**

The increasing number of younger patients presenting for hip arthroplasty and of other patients who require revision of standard (metal-on-polyethylene) THA implants has led to redevelopment of hip resurfacing arthroplasty techniques. Compared with traditional hip arthroplasty implants, hip resurfacing maintains patients’ native bone to a greater degree. Metal-on-metal hybrid implants are usually employed. Surgical approaches can be anterior or posterior, with the posterior approach most commonly used due to better visualization. Since the femoral head remains intact, its dislocation and repositioning during surgery may theoretically compromise its own blood supply. With the posterior approach, patients are placed in the lateral decubitus position similar to traditional hip arthroplasty.

Outcomes data related to hip resurfacing versus traditional THA are controversial. Prospective studies have not shown a difference in gait or postural
balance at 3 months postoperatively. One meta-analysis favored resurfacing in terms of functional outcome and blood loss despite comparable results for postoperative pain scores and patient satisfaction. Of particular concern is the finding that patients who undergo resurfacing are nearly twice as likely to require revision surgery as those receiving traditional hip arthroplasty. There is a greater incidence of aseptic component loosening (possibly from metal hypersensitivity) and femoral neck fracture, particularly in women. Finally, the presence of metal debris in the joint space (from metal-on-metal contact) has led to a marked narrowing of indications for the prostheses and the procedure. Monitoring of serum cobalt and chromium levels has been suggested for these patients. Adverse local tissue reactions, including abnormal fluid collections and pseudotumors, may also occur as a result of metal debris and are best detected early to avoid permanent damage to muscle, bone, and soft tissues.

**B. Bilateral Arthroplasty**

Bilateral hip arthroplasty can be safely performed in fit patients as a combined procedure, assuming the absence of significant pulmonary embolization after insertion of the first femoral component. Monitoring may include echocardiography. Effective communication between the anesthesia provider and surgeon is essential. If major hemodynamic instability occurs during the first hip replacement procedure, the second arthroplasty should be postponed.

**C. Revision Arthroplasty**

Revision of a prior hip arthroplasty may be associated with much greater blood loss than in the initial procedure. Blood loss depends on many factors, including the experience and skill of the surgeon. Some studies suggest that blood loss may be decreased during hip surgery if a regional anesthesia technique is used (eg, spinal or epidural anesthesia) compared with general anesthesia even at similar mean arterial blood pressures. The mechanism is unclear. Because the likelihood of perioperative blood transfusion is increased, preoperative autologous blood donation and intraoperative blood salvage should be considered. Preoperative administration of vitamins B\textsubscript{12} and K and iron can treat mild forms of chronic anemia. Alternatively, intravenous iron infusion can be used. Finally, and most expensively, recombinant human erythropoietin (600 IU/kg subcutaneously weekly beginning 21 days before surgery and ending on the day of surgery) may also decrease the need for perioperative allogeneic blood transfusion. Erythropoietin increases red blood cell production by stimulating the division and differentiation of erythroid progenitors in the bone

**D. Minimally Invasive Arthroplasty**

Computer-assisted surgery (CAS) has been proposed to improve surgical outcomes and promote early rehabilitation through minimally invasive techniques employing cementless implants, although this approach is not considered mainstream. Computer software can accurately reconstruct three-dimensional images of bone and soft tissue based on radiographs, fluoroscopy, computed tomography, or magnetic resonance imaging data. The computer matches preoperative images or planning information to the position of the patient on the operating room table. Tracking devices are attached to target bones (Figure 38–4) and instruments used during surgery, and the navigation system utilizes optical cameras and infrared light-emitting diodes to sense their positions. CAS thus allows accurate placement of implants through small incisions, and the resulting reduction in tissue and muscle damage may lead to less pain and early rehabilitation. The lateral approach utilizes a single incision with the patient in the lateral decubitus position (Figure 38–4) while the anterior approach utilizes two small incisions (one for the acetabular component and another for the femoral component) with the patient supine. The evidence to date does not demonstrate outcome advantages of CAS.

![FIGURE 38–4](image)

**FIGURE 38–4** Minimally invasive total hip arthroplasty: lateral approach. Note the small 3-in. incision and tracking devices for the CAS navigation system.

**E. Hip Arthroscopy**
In recent years, hip arthroscopy has increased in popularity as a minimally invasive alternative to open arthrotomy for a variety of surgical indications such as femoroacetabular impingement (FAI), acetabular labral tears, loose bodies, and osteoarthritis. At present, there is some evidence in the published literature to support hip arthroscopy for FAI, but evidence is lacking for other indications.

**CLOSED REDUCTION OF HIP DISLOCATION**

There is a 3% incidence of hip dislocation following primary hip arthroplasty and a 20% incidence following total hip revision arthroplasty. Because less force is required to dislocate a prosthetic hip, patients with hip implants require special precautions during positioning for subsequent surgical procedures. Extremes of hip flexion, internal rotation, and adduction increase the risk of dislocation. Hip dislocations may be corrected with closed reduction facilitated by use of a brief intravenous general anesthetic, often performed in a monitored setting outside the operating room (eg, emergency department). Temporary paralysis can be provided by succinylcholine, if necessary, to facilitate the reduction when the hip musculature is severely contracted. Successful reduction should be confirmed radiologically.

**Knee Surgery**

The two most frequently performed knee surgeries are arthroscopy and total or partial arthroplasty.

**KNEE ARTHROSCOPY**

**Preoperative Considerations**

Arthroscopy has revolutionized surgery of many joints, including the hip, knee, shoulder, ankle, elbow, and wrist. Joint arthroscopies are usually performed as outpatient procedures. Although the typical patient undergoing knee arthroscopy is often thought of as being a healthy young athlete, knee arthroscopies may also be performed in elderly patients with multiple medical problems.

**Intraoperative Management**

A bloodless field facilitates arthroscopic surgery. Knee surgery lends itself to the
use of a pneumatic tourniquet, although its use is optional. The surgery is performed as an outpatient procedure. Alternative anesthetic techniques include general anesthesia, neuraxial anesthesia, peripheral nerve blocks, periarticular injections, or intraarticular injections employing local anesthetic solutions with or without adjuvants combined with intravenous sedation analgesia.

Comparing neuraxial anesthesia techniques, success and patient satisfaction appear to be equal between epidural and spinal anesthesia. However, for ambulatory surgery, time to discharge following neuraxial anesthesia may be prolonged compared with general anesthesia.

Postoperative Pain Management

Successful outpatient recovery depends on early ambulation, adequate analgesia, and minimal sedation and nausea and vomiting. Techniques that avoid large doses of systemic opioids have obvious appeal. Intraarticular bupivacaine or ropivacaine usually provide satisfactory analgesia for several hours postoperatively. Adjuvants such as opioids, clonidine, ketorolac, epinephrine, and neostigmine, when added to local anesthetic solutions for intraarticular injection, have been used in various combinations to extend analgesia duration. Other multimodal pain management strategies include systemic NSAIDs, gabapentinoids, and single or continuous peripheral nerve blocks for arthroscopic ligament reconstruction.

TOTAL KNEE ARTHROPLASTY

Preoperative Considerations

Patients presenting for total knee arthroplasty (TKA) (Figure 38–5) have similar comorbidities to those undergoing THA.
FIGURE 38–5 Total (A) and partial (B) knee replacement.

Intraoperative Management
During TKA, patients remain in a supine position, and intraoperative blood loss is limited by the use of a tourniquet. A neuraxial anesthetic technique is the preferred choice for cooperative patients as it is associated with decreased odds of developing all-cause infection and acute kidney injury, decreased odds of needing mechanical ventilation or blood transfusion, and decreased mortality at 30 days after surgery. Bone cement implantation syndrome following insertion of a femoral prosthesis is possible but is less likely than during THA. Subsequent release of emboli into the systemic circulation may exaggerate any tendency for hypotension following tourniquet release. Tranexamic acid is sometimes administered intraoperatively to reduce surgical bleeding.

Pain is typically more severe after TKA than following THA. Effective postoperative multimodal analgesia facilitates early physical rehabilitation to maximize postoperative range of motion and prevent joint adhesions following knee replacement. It is important to balance pain control with the need for an alert and cooperative patient during physical therapy. Epidural analgesia may be useful after bilateral TKA, depending on the choice of prophylactic anticoagulation in these high-risk cases. For unilateral knee replacement, lumbar epidural and femoral (or adductor canal) perineural catheters provide equivalent analgesia while perineural catheters produce fewer side effects (eg, pruritus, nausea and vomiting, urinary retention, or orthostatic lightheadedness) and are more likely to permit earlier ambulation. Preoperative epidural or perineural catheter placement in a “block room” or induction room can minimize operating room delays (Figure 38–6).
A “block room” can be located in a preoperative holding area, induction room, or postanesthesia care unit and should offer standard monitoring (as outlined by the American Society of Anesthesiologists) and ample storage for regional anesthesia supplies and equipment.

Unicompartmental or patellofemoral partial knee replacement and minimally invasive knee arthroplasty with muscle-sparing approaches have been described. With proper patient selection, these techniques may reduce quadriceps muscle damage, facilitating earlier achievement of range-of-motion and ambulation goals, and may allow for discharge within 24 h following surgery in select situations. Anesthetic management and postoperative analgesia should both accommodate and facilitate an accelerated, enhanced recovery program. Single or continuous peripheral nerve blocks, alone or in combination, can provide target-specific pain control and facilitate early rehabilitation. Continuous peripheral nerve block catheters with subsequent perineural local anesthetic infusions have been shown to decrease time to meet discharge criteria for TKA. The management of perineural catheters takes a hands-on team approach with 24/7/365 coverage. Among the complications of lower extremity perineural local anesthetic infusions, those involving patient falls are of greatest
concern, and comprehensive fall prevention programs need to be in place whenever these techniques are employed. Spinal anesthesia with intrathecal morphine or hydromorphone is also widely used and compatible with enhanced recovery programs. Finally, spinal anesthesia with postoperative analgesia using local injection in and around the knee joint of a “cocktail” containing ketorolac and dilute local anesthetic is increasingly popular and apparently very effective.

Surgery on the Upper Extremity

Procedures on the upper extremities include those for disorders of the shoulder (eg, subacromial impingement or rotator cuff tears), traumatic fractures, nerve entrapment syndromes (eg, carpal tunnel syndrome), and autoimmune or degenerative joint diseases.

SHOULDER SURGERY

Shoulder operations may be open or arthroscopic. These procedures are performed either in a sitting (“beach chair”) or, less commonly, the lateral decubitus position. The beach chair position may be associated with decreases in cerebral perfusion; blindness, stroke, and even brain death have been described, emphasizing the need to accurately measure blood pressure at the level of the brain. When using noninvasive blood pressure monitoring, the cuff should be applied on the upper arm because systolic blood pressure readings from the calf can be 40 mm Hg higher than brachial readings on the same patient. If the surgeon requests controlled hypotension, intraarterial blood pressure monitoring should be used, and the transducer should be positioned at the level of the brainstem (external meatus of the ear). Interscalene brachial plexus block with or without a perineural catheter is ideally suited for shoulder procedures. The supraclavicular block or a “shoulder block” (eg, suprascapular and axillary nerve blocks) may be used instead. Even when general anesthesia is employed, a peripheral nerve or brachial plexus block can supplement anesthesia and provide effective postoperative analgesia. Intense muscle relaxation is usually required for major shoulder surgery during general anesthesia, particularly when not combined with a brachial plexus block.

Preoperative insertion of an indwelling perineural catheter with subsequent infusion of a dilute local anesthetic infusion solution allows postoperative analgesia for 48 to 72 h with most fixed-reservoir disposable pumps following arthroscopic or open shoulder operations (see Chapter 46). Alternatively, the
surgeon may insert a subacromial catheter to provide continuous infusion of local anesthetic for postoperative analgesia. Direct placement of intraarticular catheters into the glenohumeral joint with infusion of bupivacaine has been associated with glenohumeral chondrolysis in human and animal studies and is not recommended. Multimodal analgesia, including systemic NSAIDs (if no contraindications) and local anesthetic infusions in the perioperative period, can help reduce postoperative opioid requirements.

**DISTAL UPPER EXTREMITY SURGERY**

Distal upper extremity surgical procedures generally take place on an outpatient basis. Minor soft tissue operations of the hand (eg, carpal tunnel release) of short duration may be performed with local infiltration or with intravenous regional anesthesia (IVRA, or Bier block). The limiting factor with IVRA is tourniquet tolerance.

For operations lasting more than 1 h or more invasive procedures involving bones or joints, a brachial plexus block is the preferred regional anesthetic technique. Multiple approaches can be used to anesthetize the brachial plexus for distal upper extremity surgery (see Chapter 46). Selection of brachial plexus block technique should take into account the planned surgical site and location of the pneumatic tourniquet, if applicable. Continuous peripheral nerve blocks may be appropriate for inpatient and select outpatient procedures to extend the duration of analgesia further into the postoperative period or facilitate physical therapy, or both. Brachial plexus blocks do not anesthetize the intercostobrachial nerve distribution (arising from the dorsal rami of T1 and sometimes T2); hence, subcutaneous infiltration of local anesthetic may be required for procedures involving the medial upper arm or cases in which a tourniquet is applied to the upper arm.

Anesthetic considerations for distal upper extremity surgery should include patient positioning and use of a pneumatic tourniquet. Most procedures can be performed with the patient supine; the operative arm abducted 90° and resting on a hand table; and the operating room table rotated 90° to position the operative arm in the center of the room. Exceptions to this rule often involve surgery around the elbow, and certain operations may require the patient be in lateral decubitus or even prone position. Because patients are often scheduled for same-day discharge, perioperative management should focus on ensuring rapid recovery without severe pain or nausea (see Chapter 44).
Managing Blood Loss in Jehovah’s Witnesses

A 58-year-old male patient who is a Jehovah’s Witness presents for hemipelvectomy to resect a malignant bone tumor (osteogenic sarcoma). The patient has received chemotherapy over the past 2 months with multiple drugs, including doxorubicin. He has no other medical problems, and the preoperative hematocrit is 47%.

How does the care of patients who are Jehovah’s Witnesses particularly challenge the anesthesiologist?

Jehovah’s Witnesses, a fellowship of more than 1 million Americans, object to the administration of blood for any indication. This objection stems from their interpretation of the Bible (“to keep abstaining from … blood,” Acts 15:28,29) and not for medical reasons (eg, the fear of hepatitis). Physicians should honor the principle of autonomy: Patients have final authority over what is done to them. Witnesses typically sign a waiver releasing physicians from liability for any consequences of blood refusal.

Which intravenous fluids will Witnesses accept?

Witnesses abstain from blood and blood products (eg, packed red blood cells, fresh frozen plasma, platelets) but not non–blood-containing solutions. They accept crystalloids, hetastarch, and dextran replacement solutions. Witnesses often view albumin, erythropoietin (because of the use of albumin), immune globulins, and hemophiliac preparations as a gray area that requires a personal decision by the believer.

Do they allow the use of autologous blood?

According to their religion, any blood that is removed from the body should be discarded (“You should pour it out upon the ground as water,” Deuteronomy 12:24) and not stored. Thus, the usual practice of autologous preoperative collection and storage would not be allowed. Techniques of acute normovolemic hemodilution and intraoperative blood salvage have been accepted by some Witnesses, however, as long as their blood maintains continuity with their circulatory systems at all times. For example, up to 4 units of blood could be drawn from the patient.
immediately before surgery and kept in anticoagulant-containing bags that maintain a constant link to the patient’s body. The blood could be replaced by an acceptable colloid or crystalloid solution then reinfused as needed during surgery.

**How would the inability to transfuse blood affect intraoperative monitoring decisions?**

Hemipelvectomy involves radical resection that can lead to massive blood loss. This is particularly true for large tumors removed using the more invasive internal approach. Intraarterial and central venous catheter placement would be indicated in most patients undergoing this procedure. Techniques that minimize intraoperative blood loss (eg, controlled hypotension, aprotinin) should be considered. In a Jehovah’s Witness patient, the management of life-threatening anemia (Hb <5 g/dL) may be improved by optimizing cardiac output, oxygen delivery, and oxygen consumption.

**What physiological effects result from severe anemia?**

Assuming the maintenance of normovolemia and the absence of preexisting major end-organ dysfunction, most patients tolerate severe anemia surprisingly well. Decreased blood viscosity and vasodilation lower systemic vascular resistance and increase blood flow. Augmentation of stroke volume increases cardiac output, allowing arterial blood pressure and heart rate to remain relatively unchanged. Coronary and cerebral blood flows increase in the absence of coronary artery disease and carotid artery stenosis. A decrease in venous oxygen saturation reflects an increase in tissue oxygen extraction. Oozing from surgical wounds as a result of dilutional coagulopathy may accompany extreme degrees of anemia.

**What are some of the anesthetic implications of preoperative doxorubicin therapy?**

This anthracycline chemotherapeutic agent has well-recognized cardiac side effects, ranging from transient arrhythmias and electrocardiographic changes (eg, ST-segment and T-wave abnormalities) to irreversible cardiomyopathy and congestive heart failure. The risk of cardiomyopathy appears to increase with a cumulative dose greater than 550 mg/m², prior radiotherapy, and concurrent cyclophosphamide treatment. Mild degrees of cardiomyopathy can be detected preoperatively with endomyocardial
biopsy, echocardiography, or exercise radionuclide angiography. The other important toxicity of doxorubicin is myelosuppression manifesting as thrombocytopenia, leukopenia, and anemia.

**Are there any special considerations regarding postoperative pain management in the Jehovah’s Witness patient?**

Witnesses generally refrain from any mind-altering drugs or medications, although opioids prescribed by a physician for severe pain are accepted by some believers. Insertion of an epidural catheter can provide acceptable analgesia with local anesthetics, with or without opioids.

**GUIDELINES**

**SUGGESTED READINGS**

2016;24:3482.
Anesthesia for Trauma & Emergency Surgery

Brian P. McGlinch, MD

KEY CONCEPTS

1. All trauma patients should be presumed to have a full stomach and thereby be at increased risk of pulmonary aspiration.

2. Cervical spine injury is presumed in any trauma patient presenting with neck pain or any suggestion of neurologic injury as well as those with loss of consciousness, significant head injury and/or intoxication.

3. In the patient with blunt or penetrating injury, providers should maintain a high level of suspicion for pulmonary injury that could evolve into a tension pneumothorax when mechanical ventilation is initiated. No trauma patient should die without having potential tension pneumothorax relieved.

4. In up to 25% of trauma patients, trauma-induced coagulopathy (TIC) is present shortly after injury and before any resuscitative efforts have been initiated.

5. Balanced administration of red blood cell, fresh frozen plasma, and platelet units (1:1:1) is termed damage control resuscitation (DCR). Administering blood products in equal ratios early in resuscitation has become an accepted approach for preventing or correcting TIC.

6. Transfusion-associated circulatory overload (TACO) is the greatest risk to trauma patients from DCR. The incidence of transfusion-related acute lung injury (TRALI) has decreased markedly with restriction of plasma and platelet donation to donors who are male, or who are female and who have either never been pregnant or who have been tested and found to be anti-HLA negative.
Damage control surgery is a surgical intervention intended to stop hemorrhage and limit gastrointestinal contamination of the abdominal compartment in severely injured and bleeding patients. An emergent exploratory laparotomy is performed in a start–stop fashion, attempting to discover and control bleeding injuries, while affording the anesthesia provider opportunities for resuscitation and preventing prolonged hypotension and hypothermia between surgical interventions.

Any trauma patient with an altered level of consciousness must be considered to have a traumatic brain injury (TBI) until proven otherwise. Presence or suspicion of TBI mandates attention to maintaining cerebral perfusion pressure and oxygenation during all aspects of care. The most reliable clinical assessment tool in determining the significance of TBI in a nonsedated, nonparalyzed patient is the Glasgow Coma Scale. Acute subdural hematoma is the most common brain injury warranting emergency neurosurgical intervention and is associated with the highest mortality.

Systemic hypotension (systolic blood pressures <90 mm Hg), hypoxia (Pao$_2$ <60 mm Hg), hypercapnia (Paco$_2$ >50 mm Hg), and hyperthermia (temperature >38.0°C) have a negative impact on morbidity and mortality following head injuries, likely because of their contributions to increasing cerebral edema and intracranial pressure (ICP).

Current Brain Trauma Foundation guidelines recommend maintaining cerebral perfusion pressure between 50 and 70 mm Hg and ICP at less than 20 mm Hg for patients with severe head injury.

Maintaining supranormal mean arterial blood pressure to help ensure adequate spinal cord perfusion in areas of otherwise reduced blood flow due to cord compression or vascular compromise is likely to be of more benefit than steroid administration.

Major burns (a second- or third-degree burn involving ≥20% total body surface area [TBSA]) induce a unique hemodynamic response. Cardiac output declines abruptly by up to 50% within 30 minutes of injury due to massive vasoconstriction, inducing a state of normovolemic hypoperfusion (burn shock).

In contrast to blunt and penetrating trauma, where crystalloid fluids are discouraged, burn fluid resuscitation emphasizes the use of balanced crystalloid fluids in preference to albumin, hydroxyethyl starch, normal or hypertonic saline, or blood.
The differential diagnosis for altered mental status following burn injury, smoke inhalation, or both, includes carbon monoxide and cyanide poisoning.

Beyond 48 h after significant burn injury, succinylcholine can produce lethal hyperkalemia.

The elderly represent the fastest-growing trauma population. A progressive decrease in trauma survivability is first seen beginning around age 50. Significant underlying medical conditions contribute to increased trauma-related morbidity and mortality after even modest injuries.

In situations of mass casualty incidents, point-of-care ultrasound technology may provide timely, critical information related to triaging patients for surgical and nonsurgical therapies using the CAVEAT (chest, abdomen, vena cava, and extremities) assessment.

Trauma is a leading cause of morbidity and mortality in all age groups and a leading cause of death in both the young (under 20 years old) and elderly (over 70 years old). All aspects of trauma care, from that provided at the scene, through transport, resuscitation, surgery, intensive care, and rehabilitation, must be coordinated if trauma patients are to have the greatest opportunity for full recovery. The Advanced Trauma Life Support (ATLS) program developed by the American College of Surgeons Committee on Trauma has provided training and recommendations leading to increasingly consistent approaches for trauma resuscitation. The development of criteria for Level 1 Trauma Centers has also improved trauma care by directing severely injured patients to facilities with appropriate trauma care resources. Although trauma anesthesia is sometimes thought of as a unique topic, many of the principles for managing trauma patients are relevant to any unstable or hemorrhaging patient. Thus, many common issues encountered in typical anesthesia practice are addressed in this chapter.

**PRIMARY SURVEY**

**Airway**

Emergency Medical Technician-Paramedics (EMT-P), Critical Care flight nurses and Emergency Medicine physicians have airway management training for the prehospital and hospital settings. As a result, the anesthesiologist’s role in
providing initial trauma airway interventions has declined significantly in North America. This trend also means that when called upon for assistance in airway management in the emergency department, anesthesia providers must expect a challenging airway since routine airway management techniques have likely proved unsuccessful.

There are three important aspects of airway management in the initial evaluation of a trauma patient: (1) the need for basic life support intervention; (2) the presumed presence of a cervical spinal cord injury until proven otherwise; and (3) the potential for failed endotracheal intubation. Effective basic life support, by improving oxygenation and reducing hypercarbia in the unresponsive trauma patient, may be sufficiently effective in improving a patient’s level of consciousness to remove the need for endotracheal intubation. In those with persistent unresponsiveness, effective basic life support skills improve preoxygenation and reduce the risk for hypoxia during airway management interventions. All trauma patients should be presumed to have a full stomach and thereby be at increased risk of pulmonary aspiration.

Cervical spine injury is presumed in any trauma patient presenting with neck pain or any suggestion of neurologic injury as well as those with loss of consciousness, significant head injury and/or intoxication. Cervical collar (“C-collar”) application before transport protects the cervical spinal cord by limiting cervical extension, and first-responders should utilize well-designed “hard” collars (eg, Aspen, Miami-J, Philadelphia) for cervical spine stabilization. Traditional “soft” cervical collars provide essentially no useful cervical spine stabilization. Hard collar cervical spine stabilization negatively impacts positioning for direct laryngoscopy and tracheal intubation, and alternative airway management devices (eg, video laryngoscope, fiberoptic bronchoscope) must be immediately available. If tracheal intubation is required, the front part of the C-collar can be removed as long as the head and neck are maintained in neutral position by a designated assistant maintaining manual in-line stabilization. This is usually performed with the assistant standing by the torso or kneeling at the head of the bed, holding the patient’s head at the level of the ears, allowing the patient’s mouth to open during laryngoscopy.

Alternative supraglottic devices for airway management (eg, King supralaryngeal device) may be used if direct laryngoscopy has failed in any environment (prehospital to intensive care unit). These devices, blindly placed into the airway, isolate the glottis opening between a large inflatable cuff positioned at the base of the tongue and the distal cuff that most likely rests in the proximal esophagus (Figure 39–1). The prolonged presence of supraglottic
devices in the airway has been associated with tongue engorgement resulting from the large, proximal cuff obstructing venous outflow from the tongue, and in some cases, tongue engorgement has been sufficiently severe to warrant tracheostomy prior to its removal.

**FIGURE 39–1** The King LT supralaryngeal device. The glottic opening lies between the large cuff positioned at the base of the tongue and the smaller balloon positioned in the proximal esophagus. The airway is not secured but rather isolated between the oropharynx and the proximal esophagus. (Reproduced with permission from King Systems Corporation, KLTD/KLTD Disposable Supralaryngeal Airways Inservice Program, August 23, 2006.)

Limited evidence exists that prehospital airway management in trauma patients improves outcomes. However, failed endotracheal intubation in the prehospital environment certainly exposes patients to significant morbidity. Failed intubation attempts often result in systemic hypoxemia, and repeated hypoxemic events after even modest neurological injury further exacerbate the initial neurological insult (the *second hit* phenomenon).

Airway management in trauma patients is uneventful in most circumstances. Cricothyroidotomies and tracheostomies are rarely required for securing trauma airways. However, when trauma significantly alters or distorts the facial or upper airway anatomy to the point of preventing effective mask ventilation, or when hemorrhage into the airway precludes the patient from lying supine, elective cricothyroidotomy or tracheostomy should be considered before any attempts are made at sedating or paralyzing the patient for oral intubation.

**Breathing**
Pulmonary injury may not be immediately apparent upon the trauma patient’s arrival to the hospital. In the patient with blunt or penetrating injury, providers should maintain a high level of suspicion for pulmonary injury that could evolve into a tension pneumothorax when mechanical ventilation is initiated. Peak inspiratory pressure and tidal volumes should be monitored throughout the initial resuscitation. Abrupt cardiovascular collapse shortly after instituting mechanical ventilation may signal the presence of a pneumothorax. Any trauma-related cardiovascular collapse is managed by disconnecting the patient from mechanical ventilation and performing bilateral needle thoracostomies. This intervention is accomplished by inserting a 14-gauge intravenous catheter into the second intercostal space in the midclavicular line followed by larger, more effective thoracostomy tube insertion placed in the midaxillary line. No trauma patient should die without having potential tension pneumothorax relieved.

**Circulation**

Signs of a pulse and blood pressure are sought during the primary trauma patient survey. Unless the trauma patient arrives at the hospital other than by ambulance, the resuscitation team will likely have received information about the patient’s vital signs from the prehospital first responders. The absence of a pulse following trauma is associated with dismal chances of survival. An emergent ultrasound evaluation of the chest and abdomen is indicated for any patient arriving after trauma in cardiac arrest, as is bilateral needle chest decompression. The ultrasound evaluation will focus on the presence of an empty heart or massive blood collections in the chest or abdomen, which are indications of lethal injury.

The American College of Surgeons Committee on Trauma no longer endorses the use of emergency thoracotomy in treating patients without blood pressure or palpable pulse following blunt trauma, given the lack of evidence supporting survival following this intervention. In victims of penetrating trauma without a palpable pulse or blood pressure, but with organized cardiac rhythm, a resuscitative thoracotomy may offer some survivability but mortality remains exceedingly high.

Tourniquet use remains underutilized for compressible hemorrhage. Any extremity with significant vascular injury should have a tourniquet applied at the earliest possible moment (“stop the bleed”). The fear of tourniquet-induced limb ischemia often distracts first responders from making prompt, effective interventions in controlling hemorrhage with a tourniquet. Hemorrhage, not limb ischemia and limb function, is the most pressing threat to life, and it
should be controlled by any effective measure at the earliest possible opportunity.

**Neurological Function**

Once the presence of circulation is confirmed, a brief neurological examination is conducted. Level of consciousness, pupillary size and reaction, lateralizing signs suggesting intracranial or extracranial injuries, and indications of potential spinal cord injury are quickly evaluated. As noted earlier, hypercarbia often causes depressed neurological responsiveness following trauma, and it is effectively corrected with basic life support airway interventions. Additional causes of depressed neurological function (eg, alcohol/drug intoxication, effects of illicit or prescribed medications, hypoglycemia, hypoperfusion, brain or spinal cord injury) must also be addressed. Mechanisms of injury must be considered as well as exclusion of other factors in determining the risk for central nervous system trauma. Persistently depressed levels of consciousness should be considered a result of central nervous system injury until disproved by emergent diagnostic studies (eg, computed tomography scan).

**Injury Assessment**

The patient must be fully exposed and examined in order to adequately assess the extent of injury. This physical exposure increases the risk of hypothermia, which is associated with increased bleeding in the trauma patient. The resuscitation bay and operating room must be maintained near body temperature (uncomfortably warm), all intravenous fluids and blood products (except platelets) should be warmed during administration, and under-body forced air patient warmers should be utilized. While these interventions are important in addressing hypothermia, trauma team efficiency in identifying life-threatening injuries is critical for patient survival. In most urban trauma centers, the initial major trauma evaluation is completed within 20 min of patient arrival.

**The FAST Examination**

The FAST (Focused Assessment with Sonography for Trauma) examination utilizes ultrasonography at the trauma victim’s bedside, performed by surgeons or emergency medicine physicians, for detecting the presence or absence of free fluid in the perihepatic and perisplenic spaces, pericardium, and pelvis. **Patients with free fluid in these areas, as well as two of the following—penetrating**
injury, systolic blood pressures less than 90 mm Hg, or heart rate over 120 beats per minute—are likely to have a high mortality, trauma-induced coagulopathy, and require a massive transfusion. These critical findings have been validated in numerous trauma studies and warrant immediate surgical intervention for hemorrhage control.

**RESUSCITATION**

**Hemorrhage**

Certain trauma terminology must be understood and utilized by the trauma care team in order to effectively communicate during trauma resuscitation or procedures in which blood loss is occurring. *Hemorrhage classifications I through IV, damage control resuscitation, and damage control surgery* are terms that quickly convey critical information, using a common understanding of the various interventions that may be required for resuscitating a trauma or surgical patient experiencing life-threatening bleeding. The American College of Surgeons identifies four classes of hemorrhage:

- **Class I hemorrhage** is the volume of blood that can be lost without hemodynamic consequence. The heart rate does not change and the blood pressure does not decrease with this volume of blood loss. In most circumstances, this amount of blood represents less than 15% of circulating blood volume. The typical adult has a blood volume equivalent of 70 mL/kg. For a 100-kg patient, the circulating blood volume is nearly 7 L. Children are considered to have 80 mL/kg blood volume and infants, 90 mL/kg. Intravenous resuscitation is not required if the bleeding is controlled promptly, as in minor elective surgical procedures.

- **Class II hemorrhage** is the volume of blood that, when lost, prompts sympathetic responses to maintain perfusion, and represents the loss of 15% to 30% of circulating blood volume. The diastolic blood pressure will increase due to vasoconstriction and the heart rate will increase to maintain cardiac output. Intravenous fluid replacement is indicated for blood loss of this volume. Transfusions may be required if the bleeding continues, suggesting a progression to class III hemorrhage.

- **Class III hemorrhage** represents loss of 30% to 40% of circulating blood volume, which consistently results in decreased blood pressure. Compensatory mechanisms of vasoconstriction and tachycardia are not
sufficient for maintaining tissue perfusion to meet metabolic demand, and metabolic acidosis will be detected on arterial blood gas analysis. Blood transfusion is necessary to restore adequate tissue perfusion and oxygenation. The other trauma team members must be notified when this pattern of fluid dependence develops, and discussion must be initiated regarding the possible need for damage control intervention (discussed later) for hemorrhage control.

- Life-threatening class IV hemorrhage represents more than 40% of circulating blood volume loss. The patient will be unresponsive and profoundly hypotensive, and rapid control of bleeding and aggressive blood-based resuscitation (damage control resuscitation) are required to prevent death. Patients experiencing this degree of hemorrhage will have some element of trauma-induced coagulopathy (TIC), require massive blood transfusion (more than 10 units of red blood cells in a 24-h period), and are at high risk of death. The response to hemorrhage of this consequence must be damage control resuscitation and damage control surgery (see later discussion).

**Trauma-Induced Coagulopathy**

Coagulation abnormalities are common following major trauma, and trauma-induced coagulopathy (TIC) coagulopathy is an independent risk factor for death. Recent prospective clinical studies suggest that in up to 25% of major trauma patients, TIC is present shortly after injury and before any resuscitative efforts have been initiated. This means that the coagulopathy cannot be attributed to dilutonal effects of resuscitative fluids. In one report, TIC was only related to the presence of a severe metabolic acidosis (base deficits >6 mEq/L) and appeared to have a dose-dependent relationship with the degree of tissue hypoperfusion; 2% of patients with base deficits less than 6 mEq/L developed coagulopathy compared with 20% of patients with base deficits greater than 6 mEq/L. Although injury severity scores were likely higher in the coagulopathic patients, only the presence of metabolic acidosis correlated to developing TIC.

Global tissue hypoperfusion appears to play a key role in the development of TIC. During hypoperfusion, the endothelium releases thrombomodulin and activated protein C which, at the microcirculation level, prevents thrombosis. Thrombomodulin binds thrombin, thereby preventing thrombin from cleaving fibrinogen to fibrin. The thrombomodulin–thrombin complex activates protein C, which then inhibits the extrinsic coagulation pathway through effects on
cofactors V and VIII (Figure 39–2). Activated protein C also inhibits plasminogen activator inhibitor-1 proteins, which increases tissue plasminogen activator, resulting in hyperfibrinolysis (Figure 39–3). One prospective clinical study found the following effects of hypoperfusion on coagulation parameters: (1) progressive coagulopathy as base deficit increases; (2) increasing plasma thrombomodulin and falling protein C (indicating activation of the protein levels with increasing base deficit), supporting the argument that the anticoagulant effects of these proteins in the presence of hypoperfusion are related to the prolongation of prothrombin and partial thromboplastin times; and (3) early-onset TIC and increased mortality.

**FIGURE 39–3** Mechanism of hyperfibrinolysis in tissue hypoperfusion. Tissue plasminogen activator (tPA) released from the endothelium during hypoperfusion states cleaves plasminogen to initiate fibrinolysis. Activated protein C (aPC) consumes plasminogen activator inhibitor-1 (PAI-1) when present in excess, and reduced PAI-1 leads to increased tPA activity and hyperfibrinolysis. FDPs, fibrin degradation products; PC, protein C; TM, thrombomodulin. (Reproduced with permission from Brohi K, Cohen MJ, Davenport RA. Acute coagulopathy of trauma: Mechanism, identification and effect. *Curr Opin Crit Care*. 2007 Dec;13(6):680-685.)

TIC is not solely related to impaired clot formation. As previously noted, fibrinolysis is an equally important component as a result of plasmin activity on an existing clot. Tranexamic acid administration is associated with decreased bleeding during cardiac and orthopedic surgeries, presumably because of its antifibrinolytic properties. A randomized control study involving 20,000 trauma patients with or at risk of significant bleeding found a significantly reduced risk for death from hemorrhage when tranexamic acid therapy (loading dose, 1 g over 10 min, followed by an infusion of 1 g over 8 h) was initiated within the first 3 h following major trauma (the CRASH-II study). **Figure 39–4** demonstrates the benefit of initiating this therapy in relation to the time of injury. Although this study resulted in widespread use of tranexamic acid in major trauma, its shortcomings (eg, a very small number of its 20,000 patients required transfusion or were transfused) have more recently resulted in reconsideration of tranexamic acid administration in trauma care.
FIGURE 39–4 Influence of tranexamic acid in preventing death from bleeding. Outcomes ratios (OR) of tranexamic acid with 95% confidence interval (green area) on the x-axis and time (h) to treatment on the y-axis demonstrate improved survival if tranexamic acid therapy is initiated within 3 h of injury. The area of the curve to the left of OR 1.0 demonstrates the benefits of therapy, while that to the right demonstrates harm from intervention. (Reproduced with permission from Roberts I, Shakur H, Afolabi A, et al. The importance of early treatment with tranexamic acid in bleeding trauma patients: An exploratory analysis of the CRASH-2 randomised controlled trial. Lancet. 2011 Mar 26;377(9771):1096-1101.)

Hemostatic Resuscitation

Early coagulopathy of trauma is associated with increased mortality. Military experience treating combat-wounded soldiers and civilians has provided great insight into trauma resuscitation and TIC. Battlefield resuscitation protocols have utilized whole blood for decades. Whole blood resuscitation is instituted in circumstances where casualty load exceeds available blood resources, usually in remote or forward bases near combat. The process requires about an hour to collect, process, and then deliver blood between soldiers. The blood is warm, and clotting factors and platelets are at optimum temperature and pH. The use of whole blood transfusions in these settings is lifesaving. However, in most circumstances, the U.S. Department of Defense utilizes more conventional blood banking techniques and utilization of blood products in combat theaters, making
the need for whole blood transfusions infrequent.

Military conflicts in the 2000s have provided ample opportunities for developing updated transfusion protocols. Retrospective analysis of severely wounded service members found improved survival when fresh frozen plasma was administered early in trauma resuscitations. In an attempt to recreate whole blood, balanced administration of red blood cell, fresh frozen plasma, and platelet units (1:1:1) became the standard trauma transfusion protocol in military settings, and was promptly adopted thereafter by major civilian trauma centers, which also noted improved patient survival. This approach to transfusion is termed *damage control resuscitation* (DCR).

Administering blood products in equal ratios early in resuscitation has become an accepted approach for preventing or correcting TIC. Although this combination of blood products attempts replication of whole blood, the resultant fluid is pancytopenic, with only a fraction of whole blood’s hematocrit and coagulation factor concentration. Red blood cells will improve oxygen delivery to hypoperfused, ischemic tissues. Fresh frozen plasma provides clotting factors V and VIII along with fibrinogen, which improves clotting, possibly due to overwhelming of the thrombin–thrombomodulin complex. Platelets and cryoprecipitate, although included in the 1:1:1 DCR protocol, are probably not necessary in the initial phase of resuscitation, given the normal platelet and fibrinogen levels noted in early coagulopathy. The use of crystalloid fluids in early trauma resuscitation has markedly decreased with the increased emphasis upon early blood product administration.

Most trauma centers have early-release type O-negative blood available for immediate transfusion to patients with severe hemorrhage. Depending on the urgency of transfusion need, blood product administration typically progresses from O-negative to type-specific, then to cross-matched units as the acute need decreases. Patients administered uncrossmatched, O-negative blood are those at high risk of requiring massive transfusion. As the amount of uncrossmatched blood administered increases beyond eight units, resuscitation should persist using O-negative blood without attempting to switch to the patient’s native blood type. Reverting to the patient’s native blood type in this situation risks transfusion reactions that will further complicate resuscitation and survival.

Most clinical studies evaluating DCR have been retrospective. However, a prospective, randomized, multi-institutional massive transfusion study from ten U.S. level 1 trauma centers (the PROMTT study) was conducted and published in 2013, confirming that the greater the injury and concomitant hemorrhagic shock, the greater the likelihood of TIC requiring massive transfusion, and the
greater the risk of death. The contribution of activated protein C to TIC and the benefits of blood-based, rather than crystalloid-based, resuscitation for hemorrhagic shock were also demonstrated.

Point-of-care functional clotting studies are extremely useful for guiding specific blood product use. Thromboelastography (TEG) and rotational elastometry (ROTEM) allow more specific use of blood components by addressing the specific deficiencies rather than relying solely on the 1:1:1 transfusion ratio DCR approach. Both TEG and ROTEM demonstrate the rate of clot formation and clot stability, reflecting the interactions between the coagulation cascades, platelets, and the fibrinolytic system. Figure 39–5 demonstrates the pattern seen with TEG. The end results of this technology in trauma resuscitations are reduced blood product use (with less exposure to potential infection and less expense) as well as recognition of fibrinolysis.

**FIGURE 39–5** Thromboelastograph (TEG). The graph begins as a straight line until clot formation begins (the enzymatic stage of clotting). As a clot forms, increasing resistance develops on the strain gauge, creating a splaying of the graph. The pattern of the graph suggests the status of fibrinogen stores (α angle) and platelet function (maximum amplitude, MA). Eventually, fibrinolysis will occur as demonstrated by decreasing MA. Deficiencies of various clotting components will affect each phase of the TEG, whereas increased fibrinolysis will be demonstrated by an earlier decline in the maximum amplitude. ACT, activated clotting time; EPL, Ly30, K, R, values related to rate of clot

Administration of blood products must be done with consideration for potential hazards that may result from aggressive administration during the resuscitation phase. Although blood-borne diseases such as acquired immunodeficiency syndrome, hepatitis B, and hepatitis C are usually cited as significant transfusion-related risks, modern blood bank donor screening has decreased the incidence of such infections by as much as 10,000-fold. The incidence of transfusion-related acute lung injury (TRALI), until recently the leading cause of transfusion-related death, has also markedly declined. With the recognition that the presence of HLA antibodies in donor plasma is the principal TRALI risk factor, most blood banks now accept plasma and platelet donations only from males, or from females who have either never been pregnant or who have been tested and found to be anti-HLA negative. The greatest transfusion risk patients now face during trauma resuscitation is transfusion-associated circulatory overload (TACO), which occurs when blood products are administered at a rate greater than the patient’s cardiac output. This is most likely to occur when the provider administering blood products has not recognized that the source of bleeding has been successfully controlled by the surgeon or proceduralist. Communication in this situation is critical between those team members resuscitating the patient with blood products those attempting to control the hemorrhage.

**Massive Transfusion Protocols**

Delay in obtaining blood products other than red blood cells is a potential problem for both military and civilian trauma resuscitations. Clinical evidence supports the need for, and benefit of, established massive transfusion protocols (MTPs), allowing the blood bank to assemble blood products in prescribed ratios in supporting blood-based trauma resuscitations. With MTPs in place, hemostatic resuscitation can continue until the demand for blood products stops. **An MTP-driven, blood-based resuscitation, rather than a crystalloid-based resuscitation, improves survival from trauma, reduces total blood product utilization in the first 24 h following injury, reduces acute infectious complications (severe sepsis, septic shock, and ventilator-associated pneumonia), and decreases postresuscitation organ dysfunction (an 80% decrease in odds of developing multisystem organ failure).**
MTPs benefit both the patient (improved survival and fewer complications) and the institution (more efficient and effective processes for utilizing critical blood bank resources). Most hospitals performing complex surgeries, transplants, or trauma resuscitations now have MTPs in place, although one must recognize that the transfusion needs of transplant, cancer, and cardiac patients may differ from those of trauma patients. Establishing which personnel are empowered to initiate MTP use during trauma resuscitation is of great importance, given the expense and implications for the blood bank in terms of blood product inventory, personnel training and availability, and disruption of routine blood bank duties. Annual reviews of MTPs are necessary for ensuring that the most current knowledge, technology, and medications are included in the protocols that will optimize utilization of blood products.

DEFINITIVE TRAUMA INTERVENTIONS

The initial history and physical examination, emergency procedures, and evaluations used to determine extent of injury, need for resuscitation, and need for surgical intervention all occur outside the operating room and at times before an anesthesia provider has been alerted. However, critical initial issues impacting anesthetic management of trauma patients include adequacy of airway and vascular access, ability of the patient to tolerate anesthesia, prevention of hypothermia, access to robust blood bank supplies, and avoidance of crystalloids and vasopressors until hemorrhage is controlled. Therefore, anesthesiologist participation in the earliest assessment of potentially severely injured trauma patients in the emergency room should be encouraged.

Anesthetic Induction & Maintenance

Severely injured, conscious, and oriented trauma patients arriving for emergency surgery should have an abbreviated interview and examination, including emphasis on consent for blood transfusions and advice that intraoperative awareness may occur during emergency surgery. As always, such discussions should be documented in the patient’s record.

The operating room should be as warm as practical. Intravenous fluid warmers and rapid infusion devices should be prepared and ready for use. As previously noted, all patients arriving for trauma surgery should be presumed to have full stomachs with increased risk for aspiration of gastric contents, and the presence of a C-collar for cervical spine stabilization may increase intubation difficulty. Alternative airway devices (eg, fiberoptic bronchoscope,
videolaryngoscope) and robust suction equipment must be immediately available and ready for use.

Intravenous access is usually established in the prehospital setting or emergency department. If the existing peripheral intravenous lines are of sufficient caliber and quality for infusing blood under pressure (eg, from a rapid infusion device), a central line may not be necessary for the initial surgical intervention. However, patients may arrive in the operating room so profoundly hypotensive and hypovolemic that peripheral intravenous line placement may be impossible. In these circumstances, a subclavian catheter or intraosseous device should be inserted and blood-based resuscitation initiated. The subclavian vein is often preferred for central venous access for profoundly hypotensive patients due to its position between the clavicle and first rib, which tends to stent the subclavian vein open even in profound hypovolemia. An intraosseous device placed with the use of a small bone drill in the proximal tibia or humerus provides direct access to venous complexes through the bone marrow. Use of interosseous access requires that the bone proximal and distal to the insertion site be intact, otherwise extravasation of infused fluids will occur due to the fluid taking the path of least resistance (the fracture site). Intraosseous infusions require pressure, not gravity, for infusions to overcome the resistance to flow originating in the bone marrow. Finally, the ubiquitous availability of point-of-care ultrasound devices in anesthesia practice may allow safe placement of large-bore or central venous catheters in jugular veins using ultrasound guidance, even in the presence of profound hypovolemia.

Major blood loss and hemodynamic instability create a dangerous situation for the conscious trauma patient and a challenging decision for the anesthesia provider planning the induction of general anesthesia. Trauma patients with severe injuries may experience profound hypotension following even modest doses (0.25–0.5 mg/kg intravenously) of propofol. Etomidate preserves sympathetic tone, which makes it a modestly safer choice than propofol. Ketamine is also a reasonable choice, particularly if given in 10-mg intravenous boluses until the patient becomes unresponsive. Scopolamine, 0.4 mg intravenously, should be considered as an amnestic agent for the profoundly hemodynamically unstable but conscious patient at high risk for hemodynamic collapse on induction of anesthesia arriving in the operating room for emergency surgery. What is most important is not the particular intravenous anesthetic induction agent chosen, but the recognition that the hemodynamically unstable trauma patient will tolerate significantly less medication for induction and maintenance of anesthesia than in normal circumstances.
Fluid management in major trauma resuscitations emphasizes blood products rather than crystalloid fluids, as previously noted. An MTP should be requested and followed, with the blood immediately available upon the arrival of the patient to the operating room. All fluids should be warmed, except for platelets. When blood products are rapidly infused, ionized calcium quickly declines and must be replaced. Vasopressors should not be used, if possible, until the source of bleeding is controlled. Studies suggest that raising the blood pressure with vasopressors during hemorrhage disrupts fresh clots, resulting in more bleeding.

An arterial line is helpful but not mandatory in the initial resuscitation of the trauma victim. Even with the assistance of ultrasonography, cannulating an artery in the presence of profound hypotension may prove difficult. Attempts at placing invasive monitors can continue as the patient is prepared for incision, to include gowning and gloving the person attempting arterial line placement on the surgical side of the drape, if necessary. Although arterial line placement may be a challenge, surgical incision cannot be delayed. Surgical control of bleeding and DCR are the top priorities in trauma resuscitation, not arterial line placement. Patients in this degree of hemodynamic compromise can be presumed to have TIC and be in need of massive transfusion. Attempts for arterial line placement can resume, and are more likely to be successful, as blood pressure improves from operative hemostasis and resuscitative transfusion.

**Damage Control Surgery**

If a trauma patient requires emergent laparotomy for intraabdominal hemorrhage, the trauma surgeon will perform an abbreviated procedure termed *damage control surgery* (DCS). This surgical intervention is intended to stop hemorrhage and limit gastrointestinal contamination of the abdominal compartment. After making a midline incision, the surgeon quickly searches for sources of bleeding through a quadrant-by-quadrant examination. Definitive repair of complex injuries is not part of DCS. Identification and control of injured blood vessels and solid organs, as well as inspection of injuries in areas relatively inaccessible to midline approaches but potentially addressed by interventional radiology techniques (eg, deep liver lacerations, retroperitoneal hemorrhage), occurs during DCS. Hollow viscus injuries are addressed with resection, stapling, or both. Leaving the intestines disconnected until the patient is more stable reduces intraabdominal contamination and operating time.

Communication among the entire trauma team is essential during DCS. The surgeon must know if the patient is becoming unstable, hypothermic, or coagulopathic. The anesthesia team must speak up when there is a need to pause
the surgical procedure to allow resuscitation. Pausing surgery results in the surgeon compressing or packing an area of bleeding during times of profound hypotension until transfusion restores acceptable systolic blood pressure (80–90 mm Hg). If this interruption of surgery is unsuccessful in improving blood pressure, the surgeon can directly compress the aorta. This intervention provides the surgeon direct feedback as to the effectiveness of transfusion—a soft aorta suggests profound hypovolemia, whereas the return of a firm, pulsatile aorta suggests a more acceptable circulating blood volume. A brief episode of bradycardia/asystole may accompany direct aortic compression. When transfusions are ineffective maintaining perfusion, the operation should be interrupted, the bleeding areas packed, and a decision should be made between the surgeon and anesthesia team as to whether the patient can be transferred to the interventional radiology suite to treat bleeding from surgically-inaccessible sites or to the intensive care unit where rewarming, correction of coagulopathy and hemodynamic stabilization may occur.

A key component of DCS is planned re-operation once the patient is more stable. At a later time, bowel continuity can be restored or a colostomy can be performed. The abdominal fascia is often not definitively closed after DCS. The wound may be covered with an occlusive dressing over a wound vacuum sponge. Bowel edema in the setting of a closed abdomen following massive transfusion risks abdominal compartment syndrome, respiratory compromise, and multisystem organ failure.

The interventional radiology suite is increasingly utilized as part of the DCS sequence. Interventional radiology techniques can reach essentially any bleeding vessel and deposit coils or foam that may control hemorrhage, most notably in liver, kidney, and retroperitoneal injuries. Hemorrhage from pelvic ring fractures or major thoracic or abdominal vascular injuries are also potentially controlled by such intravascular interventions. In addition, patients are often taken to interventional radiology following DCS to assess blood flow and hemostasis in organs either injured by the initial trauma or potentially compromised as part of the DCS.

**TRAUMATIC BRAIN INJURY**

任何 trauma patient with an altered level of consciousness must be considered to have a traumatic brain injury (TBI) until proven otherwise (see Chapter 27). Presence or suspicion of TBI mandates attention to maintaining cerebral perfusion pressure and oxygenation during all aspects of care. The most reliable clinical assessment tool in determining the significance
of TBI in a nonsedated, nonparalyzed patient is the Glasgow Coma Scale (GCS; see Table 27–2). A declining motor score is suggestive of progressing neurological deterioration, prompting urgent neurological evaluation and possible surgical intervention. Although trauma patients frequently have head injuries, few head injuries require emergent neurosurgical intervention. TBIs are categorized as either primary or secondary. Primary brain injuries are directly related to trauma. Four categories of primary brain injury are seen: (1) subdural hematoma; (2) epidural hematoma; (3) intraparenchymal hemorrhage; and (4) nonfocal, diffuse neuronal injury disrupting axons of the central nervous system. These injuries potentially compromise cerebral blood flow and elevate intracranial pressure (ICP). Death occurring soon after significant head trauma is usually the result of primary brain injury.

**Acute subdural hematoma is the most common brain injury warranting emergency neurosurgical intervention and is associated with the highest mortality.** Small bridging veins between the skull and brain are disrupted in deceleration or blunt force injuries, resulting in blood accumulation and compression of brain tissue. The accumulation of blood raises ICP and compromises cerebral blood flow. Morbidity and mortality are related to the size of the hematoma and magnitude of the midline shift of intracranial contents. Midline shifts of intracranial contents may exceed the size of the hematoma, suggesting a significant contribution of cerebral edema or underlying intracerebral hemorrhage.

**Epidural hematoma** occurs when the middle cerebral artery or other cranial vessels are disrupted, often in association with skull fracture. This injury accounts for less than 10% of neurosurgical trauma emergencies and has a better prognosis than acute subdural hematoma. The patient with an epidural hematoma may initially be conscious, followed by progressive unresponsiveness and coma. Emergent surgical decompression is indicated when supratentorial lesions occupy more than 30 mL volume and infratentorial lesions occupy more than 10 mL volume (brainstem compression may occur at much lower hematoma volumes). A small epidural hematoma may not require immediate evacuation if the patient is neurologically intact, if close observation and repeated neurological examinations are possible, and if neurosurgical resources are immediately available should emergent decompression become necessary.

**Intraparenchymal injuries** are caused by rapid deceleration of the brain within the skull, usually involving the tips of the frontal and temporal lobes, and represent nearly 20% of neurosurgical emergencies following trauma. Such injuries tend to be associated with significant edema, necrosis, and infarcts in
areas surrounding the damaged tissue. Intraparenchymal injury may coexist with a subdural hematoma. There is no consensus regarding the surgical interventions that should be performed for intraparenchymal hemorrhage, but surgical decompression may be necessary to reduce dangerously sustained elevated ICP.

Diffuse neuronal injury results from rapid deceleration or movement of brain tissue of sufficient force to disrupt neurons and axons, and is more common in children than in adults. The extent of injury may not be obvious in the period immediately following injury, but will become apparent with serial magnetic resonance imaging. The greater the extent of the diffuse neuronal injury following trauma, the higher the mortality and disability severity. Surgical intervention is not indicated for these injuries unless a decompressive craniectomy is required for relief of refractory elevated ICP.

Secondary brain injuries are considered potentially preventable injuries. Systemic hypotension (systolic blood pressures <90 mm Hg), hypoxia (PaO₂ <60 mm Hg), hypercapnia (PaCO₂ >50 mm Hg), and hyperthermia (temperature >38.0°C) have a negative impact on morbidity and mortality following head injuries, likely because of their contributions to increasing cerebral edema and ICP. Hypotension and hypoxemia are recognized as major contributors to poor neurological recovery from severe TBI. Hypoxemia is the single most important parameter correlating with poor neurological outcome following head trauma and should be corrected at the earliest possible opportunity. Hypotension (mean arterial blood pressure <60 mm Hg) should also be treated aggressively with fluids, vasopressors, or both, in the presence of isolated head injury.

Management of severe head trauma in the presence of other severe injuries and hemorrhage creates a difficult resuscitation dilemma. Simultaneous emergency neurosurgery and damage control laparotomy is nearly impossible to perform, and in most circumstances, control of life-threatening hemorrhage takes precedence over neurosurgical intervention. Attempts to increase cerebral perfusion pressure in the presence of life-threatening hemorrhage will exacerbate bleeding. Once non-neurosurgical hemorrhage is controlled, attention can be directed toward the neurosurgical emergency, specifically toward restoring cerebral perfusion pressure. The prolonged period of cerebral hypoperfusion in this situation is associated with significant, negative neurological outcome. At this time, no preventative interventions have been proven helpful in preserving neurological function in such a clinical scenario.
Management Considerations for Acute Traumatic Brain Injury

In the absence of an intracranial clot requiring surgical evacuation, medical interventions are the primary means of treating elevated ICP following head trauma. Normal cerebral perfusion pressure (CPP), the difference between mean arterial pressure (MAP) and ICP, is approximately 80 to 100 mm Hg (MAP – ICP = CPP; see Chapter 26). ICP monitoring is not required for conscious and alert patients. In addition, patients who are intentionally anticoagulated or who have bleeding diathesis in response to trauma should not have ICP monitoring. However, an ICP monitor should be placed when serial neurological examinations and additional clinical assessments reveal impairment, or when there is an increased risk for elevated ICP (Table 39–1). Interventions for reducing ICP are indicated when readings are higher than 20 to 25 mm Hg. Multiple studies have evaluated interventions aimed at improving CPP and managing ICP without finding obvious outcome benefits for any treatment scheme.

Current Brain Trauma Foundation guidelines recommend maintaining CPP between 50 and 70 mm Hg and ICP at less than 20 mm Hg for patients with severe head injury.

Cerebral blood flow (CBF) is directly related to arterial carbon dioxide concentration. As arterial carbon dioxide levels decrease, cerebral vasoconstriction occurs, reducing CBF and ICP. Conversely, as arterial carbon dioxide levels rise, cerebral vasodilation occurs, increasing CBF and ICP. Changes in arterial carbon dioxide levels exert a prompt CBF and ICP response, making hyperventilation an effective therapeutic intervention in cases of elevated ICP associated with TBI. However, hyperventilation in the presence of systemic hypotension, particularly in the hemodynamically unstable, hemorrhaging trauma patient, increases risk of neurological ischemia and should be avoided until normotension is restored.

Osmotic diuretic therapy is another commonly used and widely accepted intervention for reducing elevated ICP. Intravenous mannitol doses of 0.25 to 1.0 g/kg body weight are effective in drawing extravascular fluid from brain tissue into the vascular system, decreasing brain edema and ICP. Because this intervention also induces brisk diuresis, plasma osmolality and serum electrolytes must be monitored.

Barbiturate coma is an intervention to reduce cerebral metabolic rate, cerebral blood flow, and cerebral oxygen demand in order to reduce elevated ICP and suppress the metabolic rate of ischemic cells until cerebral perfusion improves. Hypotension is commonly associated with this therapy, which limits its use in hemodynamically unstable patients. Vasopressors may be used to maintain CPP between 50 and 70 mm Hg in such cases. The dose of pentobarbital (preferable to thiopental) is based upon electroencephalographic (EEG) evidence of burst suppression, the EEG threshold for maximally reduced cerebral metabolic rate for oxygen and glucose.

Crystalloid is preferable for fluid therapy in the presence of isolated TBI. Although the use of colloid might seem advantageous in preventing brain edema, in a recent study albumin-based resuscitation following TBI nearly doubled mortality. TBI is often associated with blood–brain barrier disruption, and albumin administration in this situation may result in greater brain tissue edema and higher ICP, contributing to higher morbidity and mortality.

**SPINAL CORD INJURY**
The normal spine structure comprises three columns: anterior, middle, and
posterior. The anterior column includes the anterior two-thirds of the vertebral body and the anterior longitudinal ligament. The middle column includes the posterior third of the vertebral body, the posterior longitudinal ligament, and the posterior component of the annulus fibrosus. The posterior column includes the laminae and facets, the spinous processes, and the interspinous ligaments. Spine instability results when two or more of the three columns are disrupted.

The trauma patient with a relevant mechanism of injury (typically blunt force involving acceleration–deceleration) must be approached with a high degree of suspicion for spinal cord injury unless it has been ruled out with imaging studies. **A lateral radiograph of the cervical spine demonstrating the entire cervical spine to the top of the T1 vertebrae will detect 85% to 90% of significant cervical spine abnormalities.** Cervical spine radiographs must be examined for structure and alignment of vertebral bodies, narrowing or widening of interspinous spaces and the central canal, alignment along the anterior and posterior ligament lines, and appearance of the spinolaminar line and posterior spinous processes of C2 through C7. The presence of one spinal fracture is associated with a 10% to 15% incidence of a second spinal fracture.

Thoracolumbar injuries most commonly involve the T11 through L3 vertebrae as a result of flexion forces. The presence of one thoracolumbar spinal injury is associated with a 40% chance of a second fracture caudal to the first, likely due to the force required to fracture the lower spine. Bilateral calcaneus fractures also warrant a thorough thoracolumbar spine evaluation due to the increased incidence of associated spinal fracture associated with this injury pattern.

Cervical spine injuries occurring above C2 are associated with apnea and death. (C3–C5 roots form the phrenic nerve). **High spinal injuries are often accompanied by neurogenic shock due to the loss of sympathetic tone.** Neurogenic shock may masquerade as hemorrhagic shock in the presence of major trauma because the source of bleeding may be presumed hemorrhagic, rather than neurological, in origin. The presence of profound bradycardia 24 to 48 h after a high thoracic spinal cord lesion likely represents compromise of the cardioaccelerator function found in the T1–T4 region.

The principal therapeutic objectives following spinal cord injury are to prevent exacerbation of primary structural disruption and to minimize risk of extending neurological injury from hypotension-related hypoperfusion of ischemic areas of the spinal cord. In patients with complete spinal cord transection, very few interventions will influence recovery. Patients with incomplete spinal cord lesions require careful management of hemodynamic
parameters (eg, avoiding hypotension) and surgical stabilization of the spine to prevent extension of existing injury and exacerbation of existing neurological deficits.

Surgical decompression and stabilization of spinal fractures is indicated when a vertebral body loses more than 50% of its normal height or the spinal canal is narrowed by more than 30% of its normal diameter. Methylprednisolone is often administered for spinal cord injury in this situation. The antiinflammatory properties of this steroid potentially reduce spinal cord edema within the tight confines of a compromised spinal canal. Despite outcome studies from animal models of traumatic spinal cord injury demonstrating benefit from early surgical intervention, steroid therapy, or both, current human studies have failed to demonstrate benefit from either intervention. The presence of a decompressible lesion in the area of an incomplete spinal cord transection is not an indication for early operative intervention unless other, more life-threatening, conditions are present.

- Maintaining supranormal mean arterial blood pressure to help ensure adequate spinal cord perfusion in areas of otherwise reduced blood flow due to cord compression or vascular compromise is likely to be of more benefit than steroid administration. Hypotension must be avoided during induction of anesthesia, throughout operative decompression and stabilization of the spine injury, and extending into the postoperative phase.

- The elderly are at greater risk for spinal cord injury due to decreased mobility and flexibility, greater incidence of spondylosis and osteophytes, and decreased space within the spinal canal to accommodate spinal cord edema following trauma. The incidence of spinal injury from falls in the elderly is rapidly approaching that of spinal cord injury from motor vehicle accidents in younger patients. Mortality following spinal cord injury in the elderly, particularly those over the age of 75 years, is greater than that in younger patients with similar injury.

- The unique injury pattern of penetrating spinal cord injury warrants separate consideration. Unlike blunt spinal trauma, penetrating trauma of the spinal cord due to bullets and shrapnel is unlikely to cause an unstable spine. As a result, C-collar or long-board immobilization may not be indicated in an isolated penetrating spinal cord injury. The C-collar placement in the presence of a cervical spine penetrating injury may actually hinder observation of soft tissue swelling, tracheal deviation, or other anatomic indications of imminent airway compromise. Unlike, blunt trauma, penetrating injuries of the spinal cord induce damage at the moment of injury without risk of subsequent exacerbation of the
injury. Like other spinal cord injuries, however, maintenance of spinal cord perfusion using supranormal mean arterial pressure is indicated until spinal cord function can be more thoroughly evaluated.

**BURNS**

Burns represent a unique but common traumatic injury that is second only to motor vehicle accidents as the leading source of accidental death. Temperature and duration of heat contact determine the extent of burn injury. Children, because of their high body surface area to body mass ratio, and the elderly, whose thinner skin allows deeper burns from similar thermal insult, are both at greater risk for major burn injury. The pathophysiological and hemodynamic responses to burn injuries are unique and warrant specialized burn care that can be optimally provided only at burn treatment centers, particularly when more than 20% of a patient’s total body surface area (TBSA) is involved in second- or third-degree burns. A basic understanding of burn pathophysiology and of resuscitation requirements, especially early initiation of therapies such as oxygen administration and aggressive fluid resuscitation, will improve patient survival.

Burns are classified as first, second, or third degree. *First-degree* burns are injuries that do not penetrate the epidermis (e.g., sunburns and superficial thermal injuries). Fluid replacement for these burns is not indicated, and the area of first-degree burns should not be included in calculating fluid replacement when more extensive or significant burns are also present. *Second-degree* burns are partial-thickness injuries (superficial or deep) that penetrate the epidermis, extend into the dermis for some depth, and are associated with blistering. Fluid replacement therapy is indicated for patients with second-degree burns when more than 20% of the TBSA is involved. Skin grafting also may be necessary in some cases of second-degree burns, depending upon wound size and location. *Third-degree* burns are those in which the thermal injury penetrates the full thickness of the dermis. Nerves, blood vessels, lymphatic channels, and other deep structures may have been destroyed, creating a severe, but insensate, wound, although healthy tissue surrounding the third-degree burn will be very painful. Debridement and skin grafting are almost always required for recovery from third-degree burns.

重大 burns (a second- or third-degree burn involving ≥20% TBSA) induce a unique hemodynamic response. Cardiac output declines by up to 50% within 30 min of the injury in response to a burn-induced massive vasoconstriction, inducing a state of normovolemic hypoperfusion (*burn shock*). Survival depends on restoration of circulating volume and infusion of crystalloid
fluids according to recommended protocols (see below). This intense hemodynamic response may be poorly tolerated by patients with significant underlying medical conditions. If adequate intravenous fluid therapy is provided, cardiac function returns to normal within 48 h of injury, then typically progresses to a hyperdynamic physiology as the metabolic challenge of healing begins. Plasma volume and urine output are reduced early on, after major burn injuries.

In contrast to fluid management of blunt and penetrating trauma, where crystalloid fluids are discouraged, burn fluid resuscitation emphasizes the use of balanced crystalloid fluids (see Chapter 51) in preference to albumin, hydroxylethyl starch, normal or hypertonic saline, or blood. Following burn injuries, acute kidney failure is more common when hypertonic saline is used during initial fluid resuscitation, death is more likely when blood is administered, and outcomes are unchanged when albumin (rather than crystalloid) is used in resuscitation.

Fluid resuscitation is continuous over the first 24 h following burn injury. Two formulas are commonly used in guiding burn injury fluid resuscitation; the Parkland and the modified Brooke. Both require an understanding of the Rule of Nines (Figure 39–6) to calculate resuscitation fluid volumes. The adult Parkland protocol recommends 4 mL/kg/% burned TBSA to be given in the first 24 h, with half the volume given in the first 8 h and the remaining volume over the following 16 h. The adult modified Brooke protocol recommends 2 mL/kg/% burned TBSA, with half the calculated volume beginning in the first 8 h and the remainder over the following 16 h. Both formulas use urine output as a reliable indicator of fluid resuscitation adequacy, targeting adult urine production of 0.5 to 1.0 mL/kg/h as indicators of adequate circulating volume. If adult urine output exceeds 1.0 mL/kg/h, the infusions are slowed. In both protocols, an amount equal to half the volume administered in the first 24 h is infused in the second 24-h period following injury. The goal of maintaining adult urine output at 0.5 to 1.0 mL/kg/h continues throughout the initial phase of resuscitation.
FIGURE 39–6 The Rule of Nines, utilized to estimate burned surface area as a percentage of total body surface area (TBSA). (Reproduced with permission from American College of Surgeons. ATLS: Advanced Trauma Life Support for Doctors (Student Course Manual). 9th ed. Chicago, IL: ACS; 2012.)
When pediatric burn patients are encountered, the fluid resuscitation protocols are the same as for adults. Children weighing less than 30 kg should receive 5% dextrose in their intravenous fluids and the target urine output is 1.0 mL/kg/h. The target urine output for infants younger than 1 year of age is 1 to 2 mL/kg/h.

**Burn Management Considerations**

**A. Fluid Creep**

The Parkland and modified Brooke protocols both use urine output as an indicator for adequate fluid resuscitation. However, circumstances may arise in which the volume of fluid administered exceeds the original volume goal. For example, initial fluid resuscitation volumes may be miscalculated if first-degree burns are mistakenly incorporated into the TBSA value. Prolonged use of sedation may result in hypotension, prompting administration of additional fluids rather than vasoconstrictors. The phenomenon of *fluid creep* occurs when intravenous fluid therapy volumes are increased beyond intended calculations in response to hemodynamic changes related to issues other than circulating volumes. Fluid creep is also associated with abdominal compartment syndrome and pulmonary complications, often leading to resuscitation-related morbidity.

**B. Abdominal Compartment Syndrome**

*Abdominal compartment syndrome* (ACS) is a risk for pediatric and adult patients with circumferential abdominal burns and patients receiving intravenous fluid volumes greater than 6 mL/kg/% burned TBSA. Intraabdominal pressure can be determined by measuring intraluminal bladder pressure using a Foley catheter connected to a pressure transducer. The transducer is connected to a three-way stopcock at the point where the Foley catheter connects to the drainage tube. After the transducer is zeroed at the pelvic brim, 20 mL of fluid is instilled into the bladder. Intraabdominal pressure readings are taken 60 s after infusing fluid into the bladder, which allows the bladder to relax. Intraabdominal pressures exceeding 20 mm Hg warrant abdominal cavity decompression. However, an abdominal surgical procedure places the burn patient at increased risk for intraabdominal *Pseudomonas* infection, particularly if the laparotomy incision is near burned tissue. Early and frequent assessment of intraabdominal pressure and consideration of potential etiologies of hypotension in the burn patient other than hypovolemia are important preventative measures for ACS.
C. Pulmonary Complications
Excessive fluid resuscitation volumes are associated with an increased incidence of pneumonia. Patients with severe burns frequently have pulmonary injury related to the burn. Decreased tracheal ciliary activity, the presence of resuscitation-induced pulmonary edema, reduced immunocompetence, and tracheal intubation predispose burn patients to pneumonia. ACS can have an adverse impact on pulmonary function. Intravenous fluid administration volumes must be monitored closely and documented to be consistent with American Burn Association recommendations (ie, the Parkland or modified Brooke protocol). Fluid administration that exceeds recommendations warrants careful review of the rationale.

D. Carbon Monoxide and Cyanide Poisoning
The differential diagnosis for altered mental status following burn injury and smoke inhalation includes carbon monoxide and cyanide poisoning (see Chapter 57). Endotracheal intubation and mechanical ventilation with high inspired oxygen concentration are indicated in this situation. Carbon monoxide binds hemoglobin with an affinity approximately 250 times that of oxygen. The resultant carboxyhemoglobin (HbCO) leaves less hemoglobin available for binding oxygen and shifts the $O_2$–Hb dissociation curve to the left, both causing impaired delivery of oxygen to tissues. Pulse oximetry provides a falsely elevated indication of oxygen saturation in the setting of carbon monoxide exposure because of its inability to distinguish oxygenated hemoglobin ($HbO_2$) from HbCO. Arterial or venous blood gas analysis can directly measure HbCO. Clinically significant carbon monoxide poisoning is seen when HbCO levels exceed 10% (those who regularly smoke tobacco have HbCO levels of up to 10%). If HbCO exceeds 20%, intubation and mechanical ventilation is indicated in order to improve local tissue oxygenation and accelerate carbon monoxide elimination. Death from carbon monoxide occurs when HbCO levels exceed 60%. Hyperbaric oxygen therapy is indicated for carbon monoxide poisonings from any etiology. Multiple hyperbaric oxygen sessions are required to reduce the long-term consequences of carbon monoxide poisoning.

Anesthetic Considerations for Burn Therapy
A primary characteristic of all burn patients is an inability to regulate temperature. The resuscitation environment must be maintained near body temperature through the use of radiant warming, forced air warming devices, and
fluid warming devices. All burn care environments must be maintained near 40°C.

Assessment of the burn patient begins with inspection of the airway. Although the face may be burned (singed facial hair, nasal vibrissae), facial burns are not an indication for tracheal intubation. The need for urgent airway management, mechanical ventilation, and oxygen therapy is indicated by hoarse voice, dyspnea, tachypnea, or altered level of consciousness. Arterial blood gas determination should be obtained early in the treatment process for assessment of HbCO level. Mechanical ventilation should be adjusted to achieve adequate oxygen saturation (based upon measured oxygen levels rather than pulse oximetry) at the lowest tidal volumes.

Tracheal intubation in the early period following burn injury (up to the first 48 h) can be facilitated with succinylcholine for muscle relaxation. In patients with significant burns (>20% TBSA), injury and disruption of neuromuscular end plates occurs, followed by upregulation of acetylcholine receptors. **Beyond 48 h after significant burn injury, succinylcholine can produce lethal hyperkalemia.** This risk for succinylcholine-induced hyperkalemia persists for up to 2 years following burn injury.

Analgesia for burn patients is challenging. Considerations and concerns regarding opioid tolerance and psychosocial complications of burn therapy are commonplace. Multimodal approaches are often advantageous. Regional analgesia may provide benefit, although in the early post-burn period this technique may mask the symptoms of compartment syndrome or other clinically significant signs and symptoms related to the primary burn injury.

**EMERGING TRENDS IN TRAUMA CARE**

**The Elderly**

The elderly represent the fastest-growing trauma population seen in trauma centers across the world. The aged are at greater risk for serious complications and death after even modest trauma. Preexisting, significant conditions that negatively impact physiological reserve and ability to recover from trauma contribute more to the higher complication and death rate after trauma than age itself. Although “geriatric” is not a specific age, with respect to “geriatric” trauma outcomes, several studies have observed increased morbidity and mortality after trauma beginning between the ages of 45 and 55 years, suggesting decreased physiological reserve following trauma may start at ages
far earlier than previously appreciated. With advancing age, several studies
found the risk for death after trauma doubled for trauma victims older than 65
years, when injury severity was matched for those younger than 65 years.

Falling from standing height is responsible for 90% of injuries in patients
over the age of 65 years. Fall-related intracranial hemorrhage, skeletal fractures,
and major thoracic or intraabdominal vascular injuries increase morbidity and
mortality in this patient population. Patients taking oral anticoagulants have
lower GCS scores and higher morbidity than elderly patients experiencing
similar injuries who do not use oral anticoagulants. Use of oral anticoagulants in
this patient population is an independent predictor of 30-day mortality after
falling. Preventing falls in the elderly is an emerging public health issue.

Mass Casualty Incidents

Preparing for *mass casualty incidents* has become a common annual exercise for
most hospitals, and such preparations must include the anesthesiology service.
While no specific number of casualties identifies an incident as a mass casualty
incident, there are themes of patterns that warrant some explanation and
understanding; nearly all relate to a facility’s usual emergency patient capacity.

Multiple injury incidents are those circumstances where more than one
patient arrives at the same facility from a traumatic event. In a small hospital,
this may overwhelm available resources. However, for most suburban and urban
trauma facilities, such an incident may simply redirect available resources away
from noncritical patients for a limited amount of time and the overall function of
the facility may not be significantly impacted.

Mass casualty incidents are events where the number of patients arriving from
the traumatic event overwhelm available hospital resources, prompting diversion
of noncritical patients to other facilities and interrupting normal hospital
functions, including elective surgery. Patient triage is critically necessary to
ensure limited resources are preserved for the highest-acuity patients. The use
of ultrasound technology has become integral in these situations where CAVEAT
(*chest, abdomen, vena cava, and extremities*) examinations quickly assess the
viability of critically injured patients.

Although mass casualty incidents are dreaded events, a few predictable
patterns have been well established and warrant mentioning. First, in most mass
casualty events, be it bus accidents, train crashes, civilian bombings in outdoor
settings, or terrorist attacks occurring where victims are not trapped in buildings,
10% of the victims die at the scene, another 10% will be critically wounded and
in need of emergency surgery, 20% will require urgent surgery within 8 h, and 30% will require nonemergent interventions. The key is identifying the nature and likely number of victims involved. Second, victims of mass casualty events often arrive at hospitals unannounced. Passers-by or law enforcement personnel begin transporting victims to the nearest hospital, even if the nearest hospital is not intended for trauma care, and may arrive without notice. This creates a need for transporting patients between facilities when emergency first-responder resources are likely already overwhelmed by the initial incident. Finally, resources must be reserved for salvageable victims in this setting. Only patients with pulses should be allowed access to surgical resources and intensive care beds in mass casualty incidents, and only those patients should be transfused.

**CASE DISCUSSION**

**Abdominal Trauma in a Previously Healthy Patient**

A 22-year-old, previously healthy, 70-kg man is brought to the emergency department (ED) at 9 am by his mother after fainting at home earlier that morning. The previous evening, he was involved in an altercation in a bar during which he was kicked repeatedly in the stomach. The patient is pale, tachycardic, and lethargic. His pulse is 140 beats/min and blood pressure is 60/34 mm Hg. A FAST (focused assessment with sonography for trauma) examination in the ED demonstrates free fluid in the abdomen. Two 18-gauge antecubital intravenous lines are placed and a blood sample is sent to the blood bank for type and cross-matching. A massive transfusion protocol (MTP) is initiated. The patient is brought to the operating room within 16 min of his arrival in the ED.

**What measures should be taken prior to induction of anesthesia?**

The patient has life-threatening injuries. Although surgical intervention is necessary, the interval between anesthetic induction and surgical incision must be as short as possible. Preparing the patient for incision for a major trauma surgical intervention warrants skin preparation extending from the patient’s chin to his toes, with warm skin preparation solution. The operating room should be as warm as possible until the patient is draped.
Avoiding hypothermia is of critical importance. The trauma surgeons should be prepared to operate immediately in case hemodynamic collapse occurs with anesthetic induction. This is why the skin must be prepared for incision prior to, or during, anesthetic induction. Delaying surgical incision for the placement of arterial line or central venous access is not indicated in this scenario. Red blood cells and other blood products should be available prior to anesthetic induction.

Warm intravenous fluids are infused quickly to prevent hemodynamic collapse upon anesthetic induction. While the fluids are infusing, standard ASA monitors are applied while the patient is preoxygenated. The surgical nurse is painting the patient from chin to toes with antiseptic solution. The surgeons are gowning and gloving. Immediate release, non–cross-matched O-negative packed red blood cells (RBCs) are brought to the room. The operating room temperature is uncomfortably warm. Invasive hemodynamic monitoring catheters and ultrasound devices are present and immediately available.

**What are the priorities of anesthetic induction and hemodynamic monitoring?**

The patient is lethargic. Cerebral hypoperfusion, traumatic brain injury, or intoxication cannot be ruled out. The mechanism of injury is that of blunt violence, obligating the need for cervical spinal cord immobilization until a more thorough neurological evaluation can occur. The choice of anesthetic induction agent must be chosen with appreciation for the need to prevent hemodynamic collapse. Benzodiazepines, opioids, and propofol each attenuate sympathetic tone, and their administration may be life-threatening in this scenario. Since all trauma patients should be considered to have full stomachs, rapid sequence anesthetic induction/intubation is indicated. If sufficient staff is available, someone from the anesthesia or surgical team should be gowned and gloved, working next to the operating surgeons to place arterial and central venous lines, using ultrasound technology, if needed, at the time of surgical incision.

With the patient draped, the surgeons ready for incision and arrival of the uncross-matched blood in the operating room. Scopolamine, 0.4 mg, is injected intravenously followed immediately by succinylcholine, 100 mg intravenously. With inline cervical spine immobilization maintained, the endotracheal tube is passed with the assistance of a video laryngoscope. Once endotracheal tube position is confirmed and secured, the surgeons
initiate the incision and proceed with damage control surgical intervention. The surgeons make a full laparotomy incision while an anesthesia colleague places a left subclavian central venous catheter. Hemodynamic collapse occurs as blood spills from the surgical site. The arterial line is not yet in place, but central venous access via the subclavian vein is now present. The first MTP blood products arrive in the operating room.

**What are the implications of damage control surgery (DCS) and damage control resuscitation (DCR)?**

When confronted with hemodynamic instability during life-threatening hemorrhage, the surgeons intervene to stop the hemorrhage until the hemodynamic status can be stabilized, and in a case of abdominal trauma, to limit gastrointestinal contamination of the abdominal compartment. This represents DCS. In this case, they pack off the abdomen until sufficient blood-based resuscitation restores systolic blood pressures to 80 to 90 mm Hg, which should allow the surgery to proceed.

DCR is an aggressive transfusion protocol utilized during life-threatening hemorrhage that seeks to mimic whole blood (ie, RBC, fresh frozen plasma [FFP], and platelet units in a ratio of 1:1:1). Emphasizing warmed blood product transfusion during hemorrhage reduces hypothermia and acidosis while attenuating trauma-induced coagulopathy (providing intravenous crystalloid administration is kept to a minimum). Blood products in this scenario, with the exception of platelets, must be infused through a fluid warmer capable of delivering large volumes of infusate for extended periods of time.

The surgeon packs the abdomen and compresses the aorta. Cardiopulmonary resuscitation (CPR) is not useful in blood loss scenarios; aortic compression is the most effective and prudent intervention in hemorrhage-related hemodynamic collapse. Blood is administered through a rapid infusion device in a 1:1:1 ratio. An increased end-tidal carbon dioxide tracing is now observed, and the surgeon notes the aorta is now more firm. The noninvasive blood pressure cuff shows a systolic pressure of 82 mm Hg. The surgeon removes an abdominal pack and begins exploring the abdomen. Although DCR continues, surgical exploration is repeatedly interrupted due to hemodynamic instability. Eventually, a brachial artery monitoring line is placed with ultrasound guidance.

**What technology is available for more closely tailoring blood
**component administration in this situation?**

DCR emphasizes blood product use during hemorrhage resuscitation. Experience with this lifesaving intervention suggests that blood product utilization can be more precise if functional coagulation tests (eg, thromboelastography [TEG] or rotational thromboelastometry [ROTEM]) are utilized. These technologies assess the functional status of clot formation, with results available within 5 min of sampling. Patterns of clot formation can guide the administration of platelets, fibrinogen, and plasma. Thrombolysis is also detected with this technology, providing evidence of the need for antithrombolytic therapies.

A blood gas sample demonstrates metabolic acidosis and hemoglobin of 7.0 g/dL. The functional coagulation study (TEG or ROTEM) demonstrates a hypercoagulable pattern. As a result, the anesthesiologist alters the transfusion ratios to 3 RBC:1 FFP:1 platelet units. The surgeon now indicates that the sources for bleeding—a ruptured spleen and lacerated kidney—are controlled. The anesthesiologist notifies the team that blood products will no longer need to be rapidly infused unless hemodynamic instability recurs.

**Are there guidelines for use of blood versus vasopressors?**

The question of when to initiate vasopressors during trauma resuscitation has not been defined. So-called permissive hypotension during active surgical hemostasis and damage control resuscitation is optimal to prevent disruption of clot formation. Systolic blood pressures in the 80 to 90 mm Hg range reduce blood loss and transfusion needs. However, once the source of blood loss is surgically controlled, no guidelines exist as to when vasopressors should be initiated, rather than continued transfusion of blood products. This is an active area of investigation in trauma practices.

As the surgeons continue assessing the abdominal cavity for any as yet undetected relevant trauma, the patient’s systolic blood pressure gradually declines to 70 mm Hg. The patient’s core temperature is 35.5°C, the blood gas shows an improvement of the metabolic acidosis, with a base excess of −4 mmol and hemoglobin of 10.0 g/dl. The TEG demonstrates normal coagulation patterns. Ionized calcium is within normal limits. The decision to initiate low-dose vasopressin and epinephrine infusions, rather than transfuse additional blood products, is made; the patient was otherwise healthy prior to this injury, and transfusion of additional blood products increases the risk of transfusion-associated circulatory overload (TACO).
The patient’s blood pressure and heart rate stabilize to within normal limits, the abdomen is temporarily closed, and he is transferred to the surgical intensive care unit while remaining intubated and sedated.

**Summary**

This typical trauma scenario broadly addresses the common resuscitation and management decisions required for major trauma resuscitation. At this time, applying these resuscitation concepts to intraoperative surgery-related hemorrhage is not supported. Unlike trauma, where the patient is typically hypotensive for an extended period of time (frequently more than an hour), intraoperative hemorrhage is typically recognized promptly and addressed rapidly. Such patients usually do not become profoundly acidotic prior to initiating resuscitation measures and transfusion. Unlike trauma coagulopathy, intraoperative coagulopathy in the setting of surgical hemorrhage is more likely dilutional, rather than endothelium-derived (thrombolytic), as in the trauma setting. However, the basic concepts of trauma resuscitation remain relevant: Allow lower systolic blood pressures until the source for bleeding is identified and controlled, limit administration of intravenous crystalloids during hemorrhage in deference to administration of blood products, and utilize TEG or ROTEM to provide functional assessment of clotting for guidance of blood product administration. These concepts are accepted and defendable interventions in nontrauma resuscitation, where research is ongoing to clarify best practices.

**SUGGESTED READINGS**

The minimum alveolar concentration (MAC) progressively decreases during pregnancy—at term, by as much as 40%—for all general anesthetic agents; MAC returns to normal by the third day after delivery.

Pregnant patients display enhanced sensitivity to local anesthetics during regional anesthesia and analgesia, and neural blockade occurs at reduced concentrations of local anesthetics; dose requirements may be reduced as much as 30%.

Obstruction of the inferior vena cava by the enlarging uterus distends the epidural venous plexus and increases epidural blood volume.

Approximately 5% of women at term develop the supine hypotension syndrome, which is characterized by hypotension associated with pallor, sweating, or nausea and vomiting.

The reduction in gastric motility and gastroesophageal sphincter tone place the parturient at high risk for regurgitation and pulmonary aspiration.

Ephedrine, which has considerable β-adrenergic activity, has traditionally been considered the vasopressor of choice for hypotension during pregnancy. However, clinical studies suggest that the α-adrenergic agonist phenylephrine is more effective in treating hypotension in pregnant patients and is associated with less fetal acidosis than ephedrine.

Volatile inhalational anesthetics decrease blood pressure and,
potentially, uteroplacental blood flow. In concentrations of less than 1 MAC, however, their effects are generally minor, consisting of dose-dependent uterine relaxation and minor reductions in uterine blood flow.

The greatest strain on the parturient’s heart occurs immediately after delivery, when intense uterine contraction and involution suddenly relieve inferior vena caval obstruction and increase cardiac output as much as 80% above late third-trimester values.

Current techniques employing dilute combinations of a local anesthetic (eg, bupivacaine, ≤0.125%) and an opioid (eg, fentanyl, ≤5 mcg/mL) for epidural or combined spinal–epidural (CSE) analgesia do not appear to prolong the first stage of labor or increase the likelihood of an operative delivery.

This chapter reviews the normal physiological changes associated with pregnancy, labor, and delivery. It concludes with a description of the physiological transition from fetal to neonatal life.

**PHYSIOLOGICAL CHANGES DURING PREGNANCY**

Pregnancy affects most organ systems (Table 40–1). Many of these physiological changes appear to be adaptive and useful to the mother in tolerating the stresses of pregnancy, labor, and delivery.

**Central Nervous System Effects**

1. The minimum alveolar concentration (MAC) progressively decreases during
pregnancy—at term, by as much as 40%—for all general anesthetic agents; MAC returns to normal by the third day after delivery. Progesterone, which is sedating when given in pharmacological doses, increases up to 20 times normal at term and is at least partly responsible for this phenomenon. A surge in β-endorphin levels during labor and delivery also likely plays a major role.

Pregnant patients display enhanced sensitivity to local anesthetics during regional anesthesia and analgesia, and neural blockade occurs at reduced concentrations of local anesthetics. The term *minimum local analgesic concentration* (MLAC) is used in obstetric anesthesia to compare the relative potencies of local anesthetics and the effects of additives; MLAC is defined as the local analgesic concentration leading to satisfactory analgesia in 50% of patients (EC₅₀). Local anesthetic dose requirements during epidural anesthesia may be reduced as much as 30%, a phenomenon that appears to be hormonally mediated but may also be related to engorgement of the epidural venous plexus. Obstruction of the inferior vena cava by the enlarging uterus distends the epidural venous plexus and increases epidural blood volume. The latter has three major effects: (1) decreased spinal cerebrospinal fluid volume, (2) decreased potential volume of the epidural space, and (3) increased epidural (space) pressure. The first two effects enhance the cephalad spread of local anesthetic solutions during spinal and epidural anesthesia (see Chapter 45). Bearing down during labor further accentuates all these effects. Positive (rather than the usual negative) epidural pressures have been recorded in parturients. Engorgement of the epidural veins also increases the likelihood of placing an epidural needle or catheter in a vein, resulting in an unintentional intravascular injection.

**Respiratory Effects**

Oxygen consumption and minute ventilation increase progressively during pregnancy. Tidal volume and, to a lesser extent, respiratory rate and inspiratory reserve volume also increase. By term, both oxygen consumption and minute ventilation have increased up to 50%. PaCO₂ decreases to 28 to 32 mm Hg; significant respiratory alkalosis is prevented by a compensatory decrease in plasma bicarbonate concentration. Hyperventilation may also increase PaO₂ slightly. Elevated levels of 2,3-diphosphoglycerate offset the effect of hyperventilation on hemoglobin’s affinity for oxygen (see Chapter 23). The P₅₀ for hemoglobin increases from 27 to 30 mm Hg; the combination of the latter with an increase in cardiac output (see next section on Cardiovascular Effects) enhances oxygen delivery to tissues.
The maternal respiratory pattern changes as the uterus enlarges. In the third trimester, elevation of the diaphragm is compensated by an increase in the anteroposterior diameter of the chest; diaphragmatic motion, however, is not restricted. Both vital capacity and closing capacity are minimally affected, but functional residual capacity (FRC) decreases up to 20% at term; FRC returns to normal within 48 h after delivery. This decrease is principally due to a reduction in expiratory reserve volume as a result of larger than normal tidal volumes. Flow–volume loops are unaffected, and airway resistance decreases. Physiological dead space decreases but intrapulmonary shunting increases toward term. A chest film may show prominent vascular markings due to increased pulmonary blood volume and an elevated diaphragm. Pulmonary vasodilation prevents pulmonary pressures from rising.

**The combination of decreased FRC and increased oxygen consumption promotes rapid oxygen desaturation during periods of apnea.** Preoxygenation (denitrogenation) prior to induction of general anesthesia is therefore mandatory to avoid hypoxemia in pregnant patients. Closing volume exceeds FRC in some pregnant women at term when they lie supine. Under these conditions, atelectasis and hypoxemia readily occur. The decrease in FRC coupled with the increase in minute ventilation accelerates the uptake of all inhalational anesthetics. The reduction in dead space narrows the arterial end-tidal CO₂ gradient.

Engorgement of the respiratory mucosa during pregnancy predisposes the upper airways to trauma, bleeding, and obstruction. Gentle laryngoscopy and smaller endotracheal tubes (6–6.5 mm) should be employed during general anesthesia.

**Cardiovascular Effects**

Cardiac output and blood volume increase to meet increased maternal and fetal metabolic demands. In the first trimester, there is a substantial decrease in peripheral vascular resistance with a nadir during the middle of the second trimester and a subsequent plateau or slight increase for the remainder of the pregnancy. An increase (55%) in plasma volume in excess of an increase in red cell mass (45%) produces dilutional anemia and reduces blood viscosity. Hemoglobin concentration usually remains greater than 11 g/dL. Moreover, the reduction in hemoglobin concentration is offset by the increase in cardiac output and the rightward shift of the hemoglobin dissociation curve (see the section on Respiratory Effects) to maintain oxygen delivery to tissues.
At term, blood volume has increased by 1000 to 1500 mL in most women, allowing them to easily tolerate the blood loss associated with delivery; total blood volume reaches 90 mL/kg. Average blood loss during vaginal delivery is 400 to 500 mL, compared with 800 to 1000 mL for a cesarean section. Blood volume does not return to normal until 1 to 2 weeks after delivery.

The increase in cardiac output (40% at term) is due to increases in both heart rate (20%) and stroke volume (30%). Cardiac chambers enlarge and myocardial hypertrophy is often noted on echocardiography. Pulmonary artery, central venous, and pulmonary artery occlusion pressures remain unchanged. Most of these effects are observed in the first and, to a lesser extent, the second trimester. In the third trimester, cardiac output does not appreciably rise, except during labor. The greatest increases in cardiac output are seen during labor and immediately after delivery (see the section on Effect of Labor on Maternal Physiology). Cardiac output often does not return to normal until 2 weeks after delivery.

Decreases in cardiac output can occur in the supine position after week 20 of pregnancy. Such decreases have been shown to be secondary to impeded venous return to the heart as the enlarging uterus compresses the inferior vena cava. Approximately 5% of women at term develop the supine hypotension syndrome (aortocaval compression), which is characterized by hypotension associated with pallor, sweating, or nausea and vomiting. The cause of this syndrome appears to be compression of the inferior vena cava by the gravid uterus. When combined with the hypotensive effects of regional or general anesthesia, aortocaval compression can readily produce fetal asphyxia. Turning the patient on her side typically restores venous return from the lower body and corrects the hypotension in such instances. This maneuver is conveniently accomplished by placing a wedge (>15°) under the right hip. The gravid uterus also compresses the aorta in most parturients when they are supine. This latter effect decreases blood flow to the lower extremities and, more importantly, to the uteroplacental circulation. Uterine contraction reduces caval compression but exacerbates aortic compression.

Chronic partial caval obstruction in the third trimester predisposes to venous stasis, phlebitis, and edema in the lower extremities. Moreover, compression of the inferior vena cava below the diaphragm distends and increases blood flow through the paravertebral venous plexus (including the epidural veins), and to a minor degree, the abdominal wall.

Lastly, elevation of the diaphragm shifts the heart’s position in the chest, resulting in the appearance of an enlarged heart on a plain chest film and in left
axis deviation and T wave changes on the electrocardiogram. Physical examination often reveals a systolic ejection flow murmur (grade I or II) and exaggerated splitting of the first heart sound ($S_1$); a third heart sound ($S_3$) may be audible. A few patients develop small, asymptomatic pericardial effusion.

**Renal & Gastrointestinal Effects**

Renal plasma flow and the glomerular filtration rate increase during pregnancy; as a result, serum creatinine and blood urea nitrogen may decrease to 0.5 to 0.6 mg/dL and 8 to 9 mg/dL, respectively. A decreased renal tubular threshold for glucose and amino acids is common and often results in mild glycosuria (1–10 g/d) or proteinuria (<300 mg/d), or both. Plasma osmolality decreases by 8 to 10 mOsm/kg.

Gastroesophageal reflux and esophagitis are common during pregnancy. Gastric motility is reduced, and upward and anterior displacement of the stomach by the uterus promotes incompetence of the gastroesophageal sphincter. These factors place the parturient at high risk for regurgitation and pulmonary aspiration. However, neither gastric acidity nor gastric volume changes significantly during pregnancy. Opioids and anticholinergics reduce lower esophageal sphincter pressure, may facilitate gastroesophageal reflux, and delay gastric emptying.

**Hepatic Effects**

Overall hepatic function and blood flow are unchanged; minor elevations in serum transaminases and lactic dehydrogenase levels may be observed in the third trimester. Mild elevations in serum alkaline phosphatase are due to its secretion by the placenta. A mild decrease in serum albumin is due to an expanded plasma volume, and as a result, colloid oncotic pressure is reduced. A 25% to 30% decrease in serum pseudocholinesterase activity is also present at term but rarely produces significant prolongation of paralysis by succinylcholine. The metabolism of ester local anesthetics is not appreciably altered. Pseudocholinesterase activity may not return to normal until up to 6 weeks postpartum. High progesterone levels appear to inhibit the release of cholecystokinin, resulting in incomplete emptying of the gallbladder. The latter, together with altered bile acid composition, can predispose to the formation of cholesterol gallstones during pregnancy.
**Hematological Effects**

Pregnancy is associated with a hypercoagulable state that may be beneficial in limiting blood loss at delivery. Fibrinogen and concentrations of factors VII, VIII, IX, X, and XII all increase; only factor XI levels may decrease. Accelerated fibrinolysis can be observed late in the third trimester. In addition to the dilutional anemia (see the section on Cardiovascular Effects), leukocytosis (up to 21,000/μL) and a 10% decrease in platelet count may be encountered during the third trimester. Because of fetal utilization, iron and folate deficiency anemias readily develop if supplements of these nutrients are not taken.

**Metabolic Effects**

Complex metabolic and hormonal changes occur during pregnancy. Altered carbohydrate, fat, and protein metabolism favors fetal growth and development. These changes resemble starvation, because blood glucose and amino acid levels are low whereas free fatty acid, ketone, and triglyceride levels are high. Nonetheless, pregnancy is a diabetogenic state; insulin levels steadily rise during pregnancy. Secretion of human placental lactogen, also called human chorionic somatomammotropin, by the placenta is probably responsible for the relative insulin resistance associated with pregnancy. Pancreatic beta cell hyperplasia occurs in response to an increased demand for insulin secretion.

Secretion of human chorionic gonadotropin and elevated levels of estrogens promote hypertrophy of the thyroid gland and increase thyroid-binding globulin; although thyroxine ($T_4$) and triiodothyronine ($T_3$) levels are elevated, free $T_4$, free $T_3$, and thyrotropin (thyroid-stimulating hormone) remain normal. Serum calcium levels decrease, but ionized calcium concentration remains normal.

**Musculoskeletal Effects**

Elevated levels of relaxin throughout pregnancy help prepare for delivery by softening the cervix, inhibiting uterine contractions, and relaxing the pubic symphysis and pelvic joints. Ligamentous laxity of the spine increases the risk of back injury. The latter may contribute to the relatively frequent occurrence of back pain during pregnancy.

**UteroPlacental Circulation**

A normal uteroplacental circulation (Figure 40–1) is critical in the development
and maintenance of a healthy fetus. Uteroplacental insufficiency is an important cause of intrauterine fetal growth retardation, and when severe, can result in fetal demise. The integrity of this circulation is, in turn, dependent on both adequate uterine blood flow and normal placental function.

**FIGURE 40–1** The uteroplacental circulation. (Reproduced with permission from Shnider S, Levinson G. Anesthesia for Obstetrics. 2nd ed. Philadelphia, PA: Williams & Wilkins; 1987.)

**Uterine Blood Flow**
At term, uterine blood flow represents about 10% of the cardiac output, or 600 to 700 mL/min (compared with 50 mL/min in the nonpregnant uterus). Eighty percent of uterine blood flow normally supplies the placenta; the remainder goes to the myometrium. Pregnancy maximally dilates the uterine vasculature, so that autoregulation is absent, but the uterine vasculature remains sensitive to α-adrenergic agonists. Uterine blood flow is not usually significantly affected by respiratory gas tensions, but extreme hypocapnia (PaCO₂ < 20 mm Hg) can reduce uterine blood flow and causes fetal hypoxemia and acidosis.

Blood flow is directly proportional to the difference between uterine arterial and venous pressures but inversely proportionate to uterine vascular resistance. Although not under appreciable neural control, the uterine vasculature has α-adrenergic and possibly some β-adrenergic receptors.

**Three major factors decrease uterine blood flow during pregnancy:** (1) **systemic hypotension**, (2) **uterine vasoconstriction**, and (3) **uterine contractions**. Common causes of hypotension during pregnancy include aortocaval compression, hypovolemia, and sympathetic blockade following regional anesthesia. Stress-induced release of endogenous catecholamines (sympathoadrenal activation) during labor causes uterine arterial vasoconstriction. Any drug with α-adrenergic activity (eg, phenylephrine) potentially is capable of decreasing uterine blood flow by vasoconstriction. Ephedrine, which has considerable β-adrenergic activity, has traditionally been considered the vasopressor of choice for hypotension during pregnancy. However, clinical studies suggest that the α-adrenergic agonist phenylephrine is more effective in treating hypotension in pregnant patients and is associated with less fetal acidosis than ephedrine.

Hypertensive disorders are often associated with decreased uterine blood flow due to generalized vasoconstriction. **Uterine contractions decrease uterine blood flow by elevating uterine venous pressure and compressing arterial vessels as they traverse the myometrium.** Hypertonic contractions during labor or during oxytocin infusions can critically compromise uterine blood flow.

**Placental Function**

The fetus is dependent on the placenta for respiratory gas exchange, nutrition, and waste elimination. The placenta is formed by both maternal and fetal tissues and derives a blood supply from each. The resulting exchange membrane has a functional area of about 1.8 m².
A. Physiological Anatomy
The placenta (Figure 40–2) is composed of projections of fetal tissue (villi) that lie in maternal vascular spaces (intervillous spaces). As a result of this arrangement, the fetal capillaries within villi readily exchange substances with the maternal blood that bathes them. Maternal blood in the intervillous spaces is derived from spiral branches of the uterine artery and drains into the uterine veins. Fetal blood within villi is derived from the umbilical cord via two umbilical arteries and returns to the fetus via a single umbilical vein.

![Diagram of the placenta](image)

**FIGURE 40–2** The placenta.

B. Placental Exchange
Placental exchange can occur by one of six mechanisms:

1. **Diffusion**—Respiratory gases and small ions are transported by diffusion. Most drugs used in anesthesia have molecular weights well under 1000 and consequently can readily diffuse across the placenta.

2. **Osmotic and hydrostatic pressure (bulk flow)**—Water moves across by osmotic and hydrostatic pressures. Water enters the fetal circulation in quantities
greater than any other substance.

3. **Facilitated diffusion**—Glucose enters the fetal circulation down the concentration gradient (no energy is consumed) facilitated by a specific transporter molecule.

4. **Active transport**—Amino acids, vitamin B\textsubscript{12}, fatty acids, and some ions (calcium and phosphate) utilize this mechanism.

5. **Vesicular transport**—Large molecules, such as immunoglobulins, are transported by pinocytosis. Iron also enters the fetal circulation in this way, facilitated by ferritin and transferrin.

6. **Breaks**—Breaks in the placental membrane may permit mixing of maternal and fetal blood. This probably underlies Rh sensitization (see Chapter 51). Rh sensitization occurs most commonly during delivery.

**Respiratory Gas Exchange**

At term, fetal oxygen consumption averages about 7 mL/min/kg of fetal body weight. Fortunately, because of multiple adaptive mechanisms, the normal fetus at term can survive 10 min or longer instead of the expected 2 min in a state of total oxygen deprivation. Partial or complete oxygen deprivation can result from umbilical cord compression, umbilical cord prolapse, placental abruption, severe maternal hypoxemia, or hypotension. Compensatory fetal mechanisms include redistribution of blood flow primarily to the brain, heart, placenta, and adrenal gland; decreased oxygen consumption; and anaerobic metabolism.

Transfer of oxygen across the placenta is dependent on the ratio of maternal uterine blood flow to fetal umbilical blood flow. The reserve for oxygen transfer is small even during normal pregnancy. Normal fetal blood from the placenta has a $\text{PaO}_2$ of only 30 to 35 mm Hg. To aid oxygen transfer, the fetal hemoglobin oxygen dissociation curve is shifted to the left such that fetal hemoglobin has greater affinity for oxygen than does maternal hemoglobin (whose curve is already shifted to the right; see the section on Respiratory Effects). In addition, fetal hemoglobin concentration is usually 15 g/dL (compared with approximately 12 g/dL in the mother).

Carbon dioxide readily diffuses across the placenta. Maternal hyperventilation (see the section on Respiratory Effects) increases the gradient for the transfer of carbon dioxide from the fetus into the maternal circulation.
Fetal hemoglobin has less affinity for carbon dioxide than do adult forms of hemoglobin. Carbon monoxide readily diffuses across the placenta, and fetal hemoglobin has greater affinity for carbon monoxide than do adult forms.

**Placental Transfer of Anesthetic Agents**

Transfer of a drug across the placenta is reflected by the ratio of its fetal umbilical vein to maternal venous concentrations (UV/MV), whereas its uptake by fetal tissues can be correlated with the ratio of its fetal umbilical artery to umbilical vein concentrations (UA/UV). Fetal effects of drugs administered to parturients depend on multiple factors, including route of administration (oral, intramuscular, intravenous, epidural, or intrathecal), dose, timing of administration (both relative to delivery as well as contractions), and maturity of the fetal organs (brain and liver). Thus, a drug given hours before delivery or as a single intravenous bolus during a uterine contraction just prior to delivery (when uterine blood flow is maximally reduced) is unlikely to produce high fetal levels. Fortunately, current-anesthetic techniques for labor and delivery generally have minimal fetal effects despite significant placental transfer of anesthetic agents and adjuncts.

*All inhalational agents and most intravenous agents freely cross the placenta.* Inhalational agents generally produce little fetal depression when they are given in limited doses (<1 MAC) and delivery occurs within 10 min of induction. Ketamine, propofol, and benzodiazepines readily cross the placenta and can be detected in the fetal circulation. Fortunately, when these agents (with the exception of benzodiazepines) are administered in usual induction doses, drug distribution, metabolism, and possibly placental uptake may limit fetal effects. Although most opiates readily cross the placenta, their effects on neonates at delivery vary considerably. Newborns appear to be more sensitive to the respiratory depressant effect of morphine compared with other opioids. Although meperidine produces respiratory depression, peaking 1 to 3 h after administration, it produces less than morphine; butorphanol and nalbuphine produce even less respiratory depression but still may have significant neurobehavioral depressant effects. Although fentanyl readily crosses the placenta, it appears to have minimal neonatal effects unless larger intravenous doses (>1 mcg/kg) are given immediately before delivery. Epidural or intrathecal fentanyl, sufentanil, and, to a lesser extent, morphine, generally produce minimal neonatal effects. Alfentanil causes neonatal depression similar to meperidine. Remifentanil also readily crosses the placenta and has the potential to produce respiratory depression in newborns. Fetal blood concentrations of remifentanil
are generally about half those of the mother just prior to delivery. The UA/UV ratio is about 30%, suggesting fairly rapid metabolism of remifentanil in the neonate. The highly ionized nature of muscle relaxants impedes placental transfer, resulting in minimal effects on the fetus.

Local anesthetics are weakly basic drugs that are principally bound to α₁-acid glycoprotein. Placental transfer depends on three factors: (1) pKₐ (see Chapter 16), (2) maternal and fetal pH, and (3) degree of protein binding. Except for chloroprocaine, fetal acidosis increases fetal-to-maternal drug ratios because binding of hydrogen ions to the nonionized form causes trapping of the local anesthetic in the fetal circulation. Highly protein-bound agents diffuse slowly across the placenta; thus, greater protein binding of bupivacaine and ropivacaine, compared with that of lidocaine, likely accounts for their lower fetal blood levels. Chloroprocaine has the least placental transfer because it is rapidly hydrolyzed by plasma cholinesterase in the maternal circulation.

Most commonly used anesthetic adjuncts also readily cross the placenta. Thus, maternally administered ephedrine, β-adrenergic blockers (such as labetalol and esmolol), vasodilators, phenothiazines, antihistamines (H₁ and H₂), and metoclopramide are transferred to the fetus. Atropine and scopolamine, but not glycopyrrolate, cross the placenta; the latter’s quaternary ammonium (ionized) structure results in only limited transfer.

**Effect of Anesthetic Agents on Uteroplacental Blood Flow**

Intravenous anesthetic agents have variable effects on uteroplacental blood flow. Propofol and barbiturates are typically associated with small reductions in uterine blood flow due to dose-dependent decreases in maternal blood pressure. A small induction dose, however, can produce greater reductions in blood flow as a result of sympathoadrenal activation (due to light anesthesia). Ketamine in doses of less than 1.5 mg/kg does not appreciably alter uteroplacental blood flow; its hypertensive effect typically counteracts any vasoconstriction. Uterine hypertonus may occur with ketamine at doses of more than 2 mg/kg. Etomidate likely has minimal effects, but its actions on uteroplacental circulation have not been well described.

Volatile inhalational anesthetics decrease blood pressure and, potentially, uteroplacental blood flow. In concentrations of less than 1 MAC, however, their effects are generally minor, consisting of dose-dependent uterine relaxation and minor reductions in uterine blood flow. Nitrous oxide has minimal effects on
uterine blood flow when administered with a volatile agent. In animal studies, nitrous oxide alone can vasoconstrict the uterine arteries.

High blood levels of local anesthetics—particularly lidocaine—cause uterine arterial vasoconstriction. Such levels are seen only with unintentional intravascular injections and occasionally following paracervical blocks (in which the injection site is in close proximity to the uterine arteries), and local absorption or injection into these vessels cannot be ruled out. Spinal and epidural anesthesia typically do not decrease uterine blood flow except when arterial hypotension occurs. Moreover, uterine blood flow during labor may actually improve in preeclamptic patients following epidural anesthesia; a reduction in circulating endogenous catecholamines likely decreases uterine vasoconstriction. The addition of dilute concentrations of epinephrine to local anesthetic solutions does not appreciably alter uterine blood flow. Intravascular uptake of the epinephrine from the epidural space may result in only minor systemic β-adrenergic effects.

PHYSIOLOGY OF NORMAL LABOR

On average, labor commences 40 ± 2 weeks following the last menstrual period. The factors involved in the initiation of labor likely involve distention of the uterus, enhanced myometrial sensitivity to oxytocin, and altered prostaglandin synthesis by fetal membranes and decidual tissues. Although circulating oxytocin levels often do not increase at the beginning of labor, the number of myometrial oxytocin receptors rapidly increases. Several prodromal events usually precede true labor approximately 2 to 4 weeks prior to delivery: the fetal presenting part settles into the pelvis (lightening); patients develop uterine (Braxton Hicks) contractions that are characteristically irregular in frequency, duration, and intensity; and the cervix softens and thins out (cervical effacement). Approximately 1 week to 1 h before true labor, the cervical mucous plug (which is often bloody) breaks free (bloody show).

True labor begins when the sporadic Braxton Hicks contractions increase in strength (25–60 mm Hg), coordination, and frequency (15–20 min apart). Amniotic membranes may rupture spontaneously prior or subsequent to the onset of true labor. Following progressive cervical dilation, the contractions propel first the fetus and then the placenta through the pelvis and perineum. By convention, labor is divided into three stages. The first stage is defined by the onset of true labor and ends with complete cervical dilation. The second stage begins with full cervical dilation, is characterized by fetal descent, and ends with complete delivery of the fetus. Finally, the third stage extends from the birth of
the baby to the delivery of the placenta.

Based on the rate of cervical dilation, the first stage is further divided into a slow \textit{latent phase} followed by a faster \textit{active phase} (Figure 40–3). The latent phase is characterized by progressive cervical effacement and minor dilation (2–4 cm). The subsequent active phase is characterized by more frequent contractions (3–5 min apart) and progressive cervical dilation up to 10 cm. The first stage usually lasts 8 to 12 h in nulliparous patients and about 5 to 8 h in multiparous patients.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure40-3.png}
\end{figure}

Contractions during the second stage occur 1.5 to 2 min apart and last 1 to 1.5 min. Although contraction intensity does not appreciably change, the parturient, by bearing down, can greatly augment intrauterine pressure and facilitate expulsion of the fetus. The second stage usually lasts 15 to 120 min and the third stage typically 15 to 30 min.

The course of labor is monitored by uterine activity, cervical dilation, and fetal descent. Uterine activity refers to the frequency and magnitude of uterine contractions. The latter may be measured directly, with a catheter inserted through the cervix, or indirectly, with a tocodynamometer applied externally around the abdomen. Cervical dilation and fetal descent are assessed by pelvic
examination. Fetal station refers to the level of descent (in centimeters) of the presenting part relative to the ischial spines (eg, –1 or +1).

**Effect of Labor on Maternal Physiology**

During intense painful contractions, maternal minute ventilation may increase up to 300%. Oxygen consumption also increases by an additional 60% above third-trimester values. With excessive hyperventilation, PaCO₂ may decrease below 20 mm Hg. Marked hypocapnia can cause periods of hypoventilation and transient maternal and fetal hypoxemia between contractions. Excessive maternal hyperventilation also reduces uterine blood flow and promotes fetal acidosis.

Each contraction places an additional burden on the heart by displacing 300 to 500 mL of blood from the uterus into the central circulation (analogous to an autotransfusion). Cardiac output rises 45% over third-trimester values. The greatest strain on the parturient’s heart, however, occurs immediately after delivery, when intense uterine contraction and involution suddenly relieve inferior vena caval obstruction and increase cardiac output as much as 80% above late third-trimester values.

**Effect of Anesthetic Agents on Uterine Activity & Labor**

A. **Inhalational Agents**

Sevoflurane, desflurane, isoflurane, and halothane depress uterine activity equally at equipotent doses; all cause dose-dependent uterine relaxation. Low doses (<0.75 MAC) of these agents, however, do not interfere with the effect of oxytocin on the uterus. Higher doses can result in uterine atony and increase blood loss at delivery. Nitrous oxide has minimal, if any, effects.

B. **Parenteral Agents**

Opioids minimally decrease the progression of labor; ketamine, in doses of less than 2 mg/kg, appears to have little effect.

C. **Regional Anesthesia**

The administration of epidural analgesia is usually based upon the patient’s choice, and it is often utilized for patients with maternal or fetal factors that increase the likelihood of prolonged labor or cesarean delivery (Table 40–2).
Current evidence indicates that dilute combinations of a local anesthetic (eg, bupivacaine, ≤0.125%) and an opioid (eg, fentanyl, ≤5 mcg/mL) for epidural or combined spinal–epidural (CSE) analgesia do not prolong labor or increase the likelihood of operative delivery.

**TABLE 40–2** Factors that prolong labor, increase the likelihood of cesarean section, and often cause patients to request an epidural.

When greater concentrations of local anesthetic (eg, bupivacaine, 0.25%) are used for continuous epidural analgesia, the second stage of labor may be prolonged by approximately 15 to 30 min. Intense regional analgesia/anesthesia can remove the urge to bear down during the second stage (*Ferguson reflex*), and motor weakness can impair expulsive efforts, often prolonging the second stage of delivery. Use of dilute local anesthetic–opioid mixtures can preserve motor function and allow effective pushing. Intravenous fluid loading (crystalloid boluses) is often used to reduce the severity of hypotension following an epidural or subarachnoid injection, and the prophylactic infusion of phenylephrine started at the time of intrathecal local anesthetic injection is effective in preventing post–spinal hypotension. Fluid loading before a block in a euvoletic patient does not reduce the incidence of hypotension and has been shown to reduce endogenous oxytocin secretion from the pituitary and transiently decrease uterine activity. Epinephrine-containing local anesthetic solutions could theoretically prolong the first stage of labor if absorption of epinephrine from the epidural space results in significant systemic β-adrenergic effects. Prolongation of labor is generally not clinically observed with very dilute (eg, 1:400,000) epinephrine-containing local anesthetics.

**D. Vasopressors**

Uterine muscle has both α and β receptors. α₁-Receptor stimulation causes
uterine contraction, whereas $\beta_2$-receptor stimulation produces relaxation.
Large doses of $\alpha$-adrenergic agents, such as phenylephrine, in addition to causing uterine arterial constriction, can produce tetanic uterine contractions. Small doses of phenylephrine (40 mcg) may increase uterine blood flow in normal parturients by raising arterial blood pressure. In contrast, ephedrine has little effect on uterine contractions.

E. Oxytocin
Oxytocin (Pitocin) is administered intravenously to induce or augment uterine contractions or to maintain uterine tone postpartum. It has a half-life of 3 to 5 min. Induction doses for labor are 0.5 to 8 mU/min. Complications include fetal distress due to hyperstimulation, uterine tetany, and, less commonly, maternal water retention (antidiuretic effect). Rapid intravenous infusion can cause transient systemic hypotension due to relaxation of vascular smooth muscle; reflex tachycardia may also occur.

Uterine atony is the most common cause of severe postpartum hemorrhage. Immediate administration of oxytocin after delivery is a standard measure to prevent this complication. Despite this practice, uterine atony complicates 4% to 6% of pregnancies. The concentration of volatile anesthetics should be reduced to 0.5 MAC in obstetric patients undergoing general anesthesia for cesarean delivery to avoid the uterine-relaxing effects of these drugs. Second-line oxytocics are methylergonovine (Methergine) and carboprost tromethamine (Hemabate).

F. Ergot Alkaloids
Methylergonovine causes intense and prolonged uterine contractions. It is therefore given only after delivery (postpartum) to treat uterine atony. Moreover, because it also constricts vascular smooth muscle and can cause severe hypertension if given as an intravenous bolus, it is usually administered only as a single 0.2 mg dose intramuscularly or in dilute form as an intravenous infusion over 10 minutes.

G. Prostaglandins
Carboprost tromethamine (Hemabate, prostaglandin $F_{2\alpha}$) is a synthetic analogue of prostaglandin $F_2$ that stimulates uterine contractions. It is often used to treat refractory postpartum hemorrhage. An initial dose of 0.25 mg intramuscularly may be repeated every 15 to 90 min to a maximum of 2 mg. Common side
effects include nausea, vomiting, bronchoconstriction, and diarrhea. It is contraindicated in patients with asthma. Prostaglandin E₁ (Cytotec, rectal suppository) or E₂ (Dinoprostone, vaginal suppository) is sometimes administered and has no bronchoconstricting effect.

**H. Magnesium**

Magnesium is used in obstetrics both to stop premature labor (*tocolysis*) and to prevent eclamptic seizures. It is usually administered as a 4 g intravenous loading dose (over 20 min) followed by a 2 g/h infusion. Therapeutic serum levels are considered to be 6 to 8 mg/dL. Serious side effects include hypotension, heart block, muscle weakness, and sedation. *Magnesium in these doses and concentrations intensifies neuromuscular blockade from nondepolarizing agents.*

**I. β₂ Agonists**

The β₂-adrenergic agonists ritodrine and terbutaline inhibit uterine contractions and are used to treat premature labor.

**FETAL PHYSIOLOGY**

The placenta, which receives nearly half the fetal cardiac output, is responsible for respiratory gas exchange. The fetal lungs receive little blood flow and the pulmonary and systemic circulations are parallel instead of in series, as in the adult (*Figures 40–4* and *40–5*). This arrangement is made possible by two cardiac shunts—the *foramen ovale* and the *ductus arteriosus*:

1. Well-oxygenated blood from the placenta (approximately 80% oxygen saturation) mixes with venous blood returning from the lower body (25% oxygen saturation) and flows via the inferior vena cava into the right atrium.
2. Right atrial anatomy preferentially directs blood flow from the inferior vena cava (67% oxygen saturation) through the foramen ovale into the left atrium.
3. Left atrial blood is then pumped by the left ventricle to the upper body (mainly the brain and the heart).
4. Poorly oxygenated blood from the upper body returns via the superior vena cava to the right atrium.
5. Right atrial anatomy preferentially directs flow from the superior vena cava
into the right ventricle.

6. Right ventricular blood is pumped into the pulmonary artery.

7. Because of high pulmonary vascular resistance, 95% of the blood ejected from the right ventricle (60% oxygen saturation) is shunted across the ductus arteriosus, into the descending aorta, and back to the placenta and lower body.
The parallel circulation results in unequal ventricular flows; the right
ventricle ejects two-thirds of the combined ventricular outputs, whereas the left ventricle ejects only one-third.

Up to 50% of the well-oxygenated blood in the umbilical vein can pass directly to the heart via the ductus venosus, bypassing the liver. The remainder of the blood flow from the placenta mixes with blood from the portal vein (via the portal sinus) and passes through the liver before reaching the heart. The latter may be important in allowing relatively rapid hepatic degradation of drugs (or toxins) that are absorbed from the maternal circulation.

In contrast to the fetal circulation, which is established very early during intrauterine life, maturation of the lungs lags behind. Extraterine survival is not possible until after 22 to 24 weeks of gestation, when pulmonary capillaries are formed and come to lie in close approximation to an immature alveolar epithelium. At 30 weeks, the cuboidal alveolar epithelium flattens out and begins to produce pulmonary surfactant. This substance provides alveolar stability and is necessary to maintain normal lung expansion after birth (see Chapter 23). Sufficient pulmonary surfactant is usually present after 34 weeks of gestation. Administration of glucocorticoids to the mother may accelerate fetal surfactant production.

**PHYSIOLOGICAL TRANSITION OF THE FETUS AT BIRTH**

The most profound adaptive changes at birth involve the circulatory and respiratory systems. Failure to make this transition successfully results in fetal death or permanent neurological damage.

At term, the fetal lungs are developed but contain about 90 mL of a plasma ultrafiltrate. During expulsion of the fetus at delivery, this fluid is normally squeezed from the lungs by the forces of the pelvic muscles and the vagina acting on the fetus (the vaginal squeeze). Any remaining fluid is reabsorbed by the pulmonary capillaries and lymphatics. Small (preterm) neonates and neonates delivered via cesarean section do not benefit from the vaginal squeeze and thus typically have greater difficulty in maintaining respirations (transient tachypnea of the newborn). Respiratory efforts are normally initiated within 30 s after birth and become sustained within 90 s. Mild hypoxia and acidosis as well as sensory stimulation—cord clamping, pain, touch, and noise—help initiate and sustain respirations, whereas the outward recoil of the chest at delivery aids in filling the lungs with air.

Lung expansion increases both alveolar and arterial oxygen tensions and
decreases pulmonary vascular resistance. The increase in oxygen tension is a potent stimulus for pulmonary arterial vasodilation. The resultant increase in pulmonary blood flow and augmented flow to the left heart elevates left atrial pressure and functionally closes the foramen ovale. The increase in arterial oxygen tension also causes the ductus arteriosus to contract and functionally close. Other chemical mediators that may play a role in ductal closure include acetylcholine, bradykinin, and prostaglandins. The overall result is elimination of right-to-left shunting and establishment of the adult circulation (Figure 40–5). Anatomic closure of the ductus arteriosus does not usually occur until about 2 to 3 weeks, whereas closure of the foramen ovale takes months if it occurs at all.

Hypoxia or acidosis during the first few days of life can prevent or reverse these physiological changes, resulting in persistence of (or return to) the fetal circulation, or persistent pulmonary hypertension of the newborn. The right-to-left shunting promotes hypoxemia and acidosis, which in turn promote more shunting (Figure 40–6). Right-to-left shunting may occur across the foramen ovale, the ductus arteriosus, or both.

**FIGURE 40–6** Pathophysiology of persistent pulmonary hypertension of the newborn (persistent fetal circulation).

**CASE DISCUSSION**

**Postpartum Tubal Ligation**

A 36-year-old woman is scheduled for bilateral tubal ligation 12 h after delivery of a healthy baby.

Is this patient still at increased risk for pulmonary aspiration?
Controversy exists over when the increased risk for pulmonary aspiration diminishes following pregnancy. Certainly, many factors contributing to delayed gastric emptying are alleviated shortly after delivery: mechanical distortion of the stomach is relieved, labor pains cease, and the circulating progesterone level rapidly declines. Gastric volume and acidity usually do not differ in pregnant compared with nonpregnant women, although 30% to 60% of pregnant patients have a gastric volume greater than 25 mL or a gastric fluid pH less than 2.5. In these parturients, gastric volume and gastric fluid pH (see the section on Renal & Gastrointestinal Effects) normalize within 24 h after delivery. Therefore, most clinicians still consider the immediate postpartum patient to be at increased risk for pulmonary aspiration and take appropriate precautions (see Chapters 17 and 41). It is not known when the risk returns to the level associated with elective surgical patients. Although some physiological changes associated with pregnancy may require up to 6 weeks for resolution, the increased risk of pulmonary aspiration probably returns to “normal” well before that time.

**Other than aspiration risk, what factors determine the “optimal” time for postpartum sterilization?**

The decision about when to perform postpartum tubal ligation (or laparoscopic fulguration) is complex and varies according to patient and obstetrician preferences as well as local practices. Factors influencing the decision include whether the patient had a vaginal or cesarean delivery and whether an anesthetic was administered for labor (epidural anesthesia) or delivery (epidural or general anesthesia).

Postpartum tubal ligation or fulguration may be (1) performed immediately following delivery of the baby and repair of the uterus during a cesarean section, (2) delayed 8 to 48 h following delivery to allow an elective fasting period, or (3) deferred until after the postpartum period (generally 6 weeks). Sterilization is technically easier to perform in the immediate postpartum period because of the enlargement of the uterus and tubes. Postpartum sterilizations following natural vaginal delivery are generally performed within 48 h of delivery.

**What factors determine selection of an anesthetic technique for postpartum sterilization?**

When continuous epidural anesthesia is administered for labor and
vaginal delivery, the epidural catheter may be left in place up to 48 h for subsequent tubal ligation. The delay allows a period of elective fasting. A T4–5 sensory level with regional anesthesia is usually necessary to ensure a pain-free anesthetic experience. Lower sensory levels (as low as T10) may be adequate but sometimes fail to prevent pain caused by surgical traction on viscera.

When the patient has not had anesthesia for delivery, postpartum sterilization may be performed under either regional or general anesthesia. Because of the increased risk of pulmonary aspiration, regional anesthesia usually is preferred for bilateral tubal ligation via a minilaparotomy. Many clinicians prefer spinal over epidural anesthesia in this setting because of its greater speed of onset and reliability (see Chapter 45). In addition, the incidence of postdural puncture headache is as low as 1% when a 25-gauge or smaller pencil-point needle is used. Dosage requirements for regional anesthesia generally return to normal within 24 to 36 h after delivery. Bupivacaine (8–12 mg) or lidocaine (60–75 mg) may be used for spinal anesthesia. For epidural anesthesia, 15 to 30 mL of lidocaine 1.5% to 2% or chloroprocaine 3% is most commonly used.

In contrast, when laparoscopic tubal fulguration is planned, general endotracheal anesthesia is preferred. Insufflation of gas during laparoscopy impairs pulmonary gas exchange and predisposes the patient to nausea, vomiting, and possibly pulmonary aspiration. Endotracheal intubation generally ensures adequate ventilation and protects the airway.

**What considerations are important for postpartum patients undergoing general anesthesia?**

Preoperative concerns include the persistent increased risk of pulmonary aspiration. Anemia is nearly always present as a result of the physiological effects of pregnancy combined with blood loss during and following delivery. Hemoglobin concentrations are usually greater than 9 g/dL, but levels as low as 7 g/dL are generally considered safe. Fortunately, sterilization procedures are rarely associated with significant blood loss.

The risk of pulmonary aspiration is diminished by a minimum of 8 h of fasting, premedication with an H₂ blocker (ranitidine), a clear antacid (sodium citrate), or metoclopramide (see Chapters 17 and 41). In addition, induction of anesthesia should employ a rapid-sequence technique prior to endotracheal intubation, and the patient should be extubated only when she is awake. Decreased plasma cholinesterase levels persist after delivery (see
the section on Hepatic Effects), modestly prolonging the effect of succinylcholine. The duration of vecuronium but not atracurium (or cisatracurium) has also been reported to be prolonged in postpartum women. Excessive concentrations of volatile agents should be avoided because of the at least theoretical risk of increasing uterine blood loss or inducing postpartum hemorrhage secondary to uterine relaxation. Intravenous opioids may be used to supplement inhalational agents. Intravenous drugs administered intraoperatively (other than meperidine and to a lesser extent morphine and hydromorphone) to mothers who are breastfeeding appear to have minimal if any effects on their neonates. There are no data regarding ketamine. With these few exceptions, current recommendations support immediate postanesthesia breastfeeding. The advice of some anesthetists to “pump and dump” breast milk for 24 h before resuming breastfeeding is outdated.

SUGGESTED READINGS

Obstetric Anesthesia

Michael A. Frölich, MD, MS

KEY CONCEPTS

1. The most common morbidities encountered in obstetrics are severe hemorrhage and severe preeclampsia.
2. Regardless of the time of last oral intake, all obstetric patients are considered to have a full stomach and to be at risk for pulmonary aspiration.
3. Nearly all parenteral opioid analgesics and sedatives readily cross the placenta and can affect the fetus. Regional anesthetic techniques are preferred for management of labor pain.
4. Using a local anesthetic–opioid mixture for lumbar epidural analgesia during labor significantly reduces drug requirements, compared with using either agent alone.
5. Analgesia during labor requires neural blockade at the T10–L1 sensory level in the first stage of labor and at the T10–S4 sensory level in the second stage.
6. Continuous lumbar epidural analgesia is the most versatile and most commonly employed technique, because it can be used for pain relief for the first stage of labor as well as analgesia/anesthesia for subsequent vaginal delivery or cesarean section.
7. Epidural analgesia does not increase the rate of operative delivery and has little, if any, effect on labor progress when dilute mixtures of a local anesthetic and an opioid are used.
8. Unintentional intravascular or intrathecal placement of an epidural needle or catheter is possible even when needle or catheter aspiration does not yield blood or cerebrospinal fluid.
9. Hypotension is a common side effect of regional anesthetic techniques.
and can be treated with intravenous boluses of phenylephrine (40–120 mcg), supplemental oxygen, left uterine displacement, and an intravenous fluid bolus to prevent fetal compromise.

Techniques using combined spinal–epidural (CSE) analgesia and anesthesia may especially benefit patients with severe pain early in labor and those who receive analgesia/anesthesia immediately prior to delivery.

Spinal or epidural anesthesia is preferred to general anesthesia for cesarean section because regional anesthesia is associated with less hemodynamic fluctuation, more gradual resolution of analgesia during anesthetic recovery, and lower maternal mortality.

Continuous epidural anesthesia allows better control over the sensory level than “single-shot” spinal anesthesia. Conversely, spinal anesthesia has a more rapid, predictable onset; may produce a more dense (more complete) block; and lacks the potential for serious systemic drug toxicity because of the smaller dose of local anesthetic employed.

Risk of systemic local anesthetic toxicity during epidural analgesia and anesthesia is minimized by slowly administering dilute solutions for labor pain and by fractionating the total dose administered for cesarean section into 5-mL increments.

Maternal hemorrhage is one of the most common and severe morbidities complicating obstetric anesthesia. Causes for antepartum hemorrhage include placenta previa, abruptio placentae, and uterine rupture. Common causes of postpartum hemorrhage include uterine atony, a retained placenta, obstetric lacerations, uterine inversion, and use of tocolytic agents prior to delivery.

Intrauterine asphyxia during labor is the most common cause of neonatal depression. The benefit of continuous fetal heart rate monitoring throughout labor is controversial, but it is routinely used in combination with other fetal surveillance methods to guide the clinical management of parturients.

This chapter focuses on the practice of obstetric anesthesia. Techniques for analgesia and anesthesia during labor, vaginal delivery, and cesarean section are presented. The chapter concludes with a review of neonatal resuscitation.
Although the majority of women of childbearing age would be considered to be at minimal operative risk, pregnancy, certain maternal–fetal factors, and preexisting medical conditions significantly increase surgical and obstetric risks.

**Maternal Mortality**

Maternal mortality is usually presented as the number of women who die while pregnant or within 42 days of pregnancy termination after excluding accidents and unrelated causes. This number is often indexed to the total number of live births. The maternal mortality index has decreased nearly 100-fold since 1900. Likely due to better reporting, it rose slightly in the United States to 21 deaths per 100,000 live births in 2010. The world average is 400 deaths per 100,000 live births. Of all maternal deaths worldwide, 99% occur in Africa, Asia, Latin America, and the Caribbean.

In the United States, overall mortality risk is greater for women older than 35 years of age, African-American women, and women who do not receive prenatal care. The leading causes of death associated with a live birth in 2010 were cardiovascular diseases (14%), cardiomyopathy (13%), hemorrhage (12%), noncardiovascular diseases (12%), hypertensive disorders of pregnancy (11%), infection/sepsis (11%), thrombotic pulmonary embolism (6%), amniotic fluid embolism (6%), cerebrovascular accidents (5%) and anesthesia-related complications (<1%). Of all maternal deaths, only 34% of patients die within 24 h of delivery, whereas 55% die between 1 and 42 days, and another 11% die between 43 days and 1 year. Direct causes of maternal deaths are more completely described in Canadian data, which show that, in addition to pulmonary embolism and preeclampsia/pregnancy-induced hypertension (PIH), amniotic fluid embolism and intracranial hemorrhage are also important additional causes of death.

Severe obstetric morbidity may be a more useful measure of peripartum outcome than maternal mortality. Data from the United Kingdom suggest that incidence of severe obstetric morbidity is 12 per 1000 deliveries, 100 times more common than mortality. Risk factors include age greater than 34 years, nonwhite ethnicity, multiple pregnancy, history of hypertension, previous postpartum hemorrhage, and emergency cesarean delivery. **Table 41–1** lists the estimated incidence of the most common causes of severe morbidity; thromboembolic disease was deliberately excluded because of the difficulty in making the diagnosis in nonfatal cases. By far the most common morbidities encountered in obstetrics are severe hemorrhage and severe preeclampsia.

\(^{3}\)HELLP syndrome consists of hemolysis, elevated liver enzymes, and low platelet count.

**Anesthetic Mortality**

Data collected between 1985 and 1990 suggested a maternal mortality of 32 deaths per 1,000,000 live births due to general anesthesia and 1.9 deaths per 1,000,000 live births due to regional anesthesia. More recent data between 2006 and 2010 suggest a lower overall maternal mortality from anesthesia (an estimated 0.9% of pregnancy-related deaths), possibly due to greater use of regional anesthesia for labor and cesarean delivery. Most deaths occur during or after cesarean section. Moreover, the risk of an adverse outcome is much greater with emergent than with elective cesarean sections.

**Obstetric Anesthesia Closed Claims**

Obstetric anesthesia care accounts for approximately 12% of the American Society of Anesthesiologists (ASA) Closed Claims database claims. A comparison of obstetric anesthesia claims from 1990 to 2003 with pre-1990 claims shows a decrease in maternal deaths, as well as a decrease in airway-related events (aspiration, difficult intubation, esophageal intubation, and inadequate oxygenation/ventilation). Although newborn deaths and brain
damage also decreased over this period, they remained a leading cause of obstetric anesthesia malpractice claims. Maternal nerve injury was more common in claims reported after 1990 compared with earlier years.

---

**General Approach to the Obstetric Patient**

All patients entering the obstetric suite potentially require anesthesia services. Patients requiring anesthetic care for labor or cesarean section should undergo a focused preanesthetic evaluation as early as possible, which should include maternal health history, anesthesia and anesthesia-related obstetric history, vital signs, airway assessment, and back examination for regional anesthesia.

Regardless of the time of last oral intake, all patients are considered to have a full stomach and to be at risk for pulmonary aspiration. Because the duration of labor is often prolonged, guidelines usually allow small amounts of oral clear liquid during uncomplicated labor. The minimum fasting period for elective cesarean section remains controversial but is typically recommended to be 6 h for light meals and 8 h for heavy meals. Prophylactic administration of a clear antacid (15–30 mL of 0.3 M sodium citrate orally) every 30 min prior to a cesarean section may help maintain gastric pH greater than 2.5 and may decrease the likelihood of severe aspiration pneumonitis. An H₂-blocking drug (eg, ranitidine, 100–150 mg orally or 50 mg intravenously) or metoclopramide, 10 mg orally or intravenously, should also be considered in high-risk patients and in those expected to receive general anesthesia. H₂ blockers reduce both gastric volume and pH but have no effect on the gastric contents already present. Metoclopramide accelerates gastric emptying, decreases gastric volume, and increases lower esophageal sphincter tone. The supine position should be avoided unless a left uterine displacement device (>15° wedge) is placed under the right hip.

---

**Anesthesia for Labor & Vaginal Delivery**

**PAIN PATHWAYS DURING LABOR**

The pain of labor arises from contraction of the myometrium against the resistance of the cervix and perineum, progressive dilation of the cervix and lower uterine segment, and stretching and compression of pelvic and perineal structures. Discomfort during the first stage of labor is primarily visceral pain
resulting from uterine contractions and cervical dilation. It is usually initially confined to the T11–T12 dermatomes during the latent phase, but eventually involves the T10–L1 dermatomes as labor enters the active phase. The visceral afferent fibers responsible for labor pain travel with sympathetic nerve fibers first to the uterovaginal plexus, then through the inferior hypogastric plexus, before entering the spinal cord with the T10–L1 nerve roots. The pain is initially perceived in the lower abdomen but may increasingly be referred to the lumbosacral area, gluteal region, and thighs as labor progresses. Pain intensity also increases with progressive cervical dilation and with increasing intensity and frequency of uterine contractions. Nulliparous women typically experience greater pain during the first stage of labor.

The onset of perineal pain at the end of the first stage signals the beginning of fetal descent and the second stage of labor. Stretching and compression of pelvic and perineal structures intensifies the pain. Sensory innervation of the perineum is provided by the pudendal nerves (S2–4), so pain during the second stage of labor involves the T10–S4 dermatomes.

PSYCHOLOGICAL & NONPHARMACOLOGICAL ANALGESIC TECHNIQUES

Psychological analgesic techniques include those of Bradley, Dick-Read, Lamaze, and LeBoyer. Patient education and positive conditioning about the birthing process are central to such techniques. Pain during labor tends to be accentuated by fear of the unknown or by previous unpleasant experiences. The Lamaze technique, one of the most popular, coaches the parturient to take a deep breath at the beginning of each contraction followed by rapid, shallow breathing for the duration of the contraction. The parturient also concentrates on an object in the room and attempts to focus her thoughts away from the pain. Less common nonpharmacological techniques include hypnosis, transcutaneous electrical nerve stimulation, biofeedback, and acupuncture. The success of all these techniques varies considerably from patient to patient, and many patients require additional forms of analgesia.

PARENTERAL AGENTS

Nearly all parenteral opioid analgesics and sedatives readily cross the placenta and can affect the fetus. Concern regarding fetal depression limits the use of these agents to the early stages of labor or to situations in which regional
anesthetic techniques are not available or appropriate. Central nervous system (CNS) depression in the neonate may be manifested by a prolonged time to sustained respirations, respiratory acidosis, or an abnormal neurobehavioral examination. Moreover, loss of beat-to-beat variability in the fetal heart rate (seen with most CNS depressants) and decreased fetal movements (due to sedation of the fetus) complicate the evaluation of fetal well-being during labor. Long-term fetal heart rate variability is affected more than short-term variability. The degree and significance of these effects depend on the specific agent, the dose, the time elapsed between its administration and delivery, and fetal maturity. Premature neonates exhibit the greatest sensitivity. In addition to maternal respiratory depression, opioids can also induce maternal nausea and vomiting and delay gastric emptying.

Meperidine, a commonly used opioid, can be given in doses of 10 to 25 mg intravenously or 25 to 50 mg intramuscularly, usually up to a total of 100 mg. Maximal maternal and fetal respiratory depression is seen in 10 to 20 min following intravenous administration and in 1 to 3 h following intramuscular administration. Consequently, meperidine is usually administered early in labor when delivery is not expected for at least 4 h. Intravenous fentanyl, 25 to 100 mcg/h, has also been used for labor. Fentanyl in 25 to 100 mcg doses has a 3- to 10-min analgesic onset that initially lasts about 60 min, and lasts longer following multiple doses. However, maternal respiratory depression outlasts the analgesia. Lower doses of fentanyl may be associated with little or no neonatal respiratory depression and are reported to have no effect on Apgar scores. A substantial body of evidence supports use of the ultra-short-acting opioid remifentanil for labor analgesia. Evidence suggests remifentanil is equally or more efficacious than other parenteral opioids or inhalational alternatives, although it does not provide the degree of pain relief offered by neuraxial analgesia. A popular patient-controlled analgesia setting is a 40-mcg bolus with a 2-min lockout. Careful one-on-one patient monitoring is mandatory. Agents with mixed agonist–antagonist activity (butorphanol, 1–2 mg, and nalbuphine, 10–20 mg intravenously or intramuscularly) are also effective and are associated with little or no cumulative respiratory depression, but excessive sedation with repeat doses can be problematic.

Promethazine (25–50 mg intramuscularly) and hydroxyzine (50–100 mg intramuscularly) can be useful alone or in combination with opioids. Both drugs reduce anxiety, opioid requirements, and the incidence of nausea, but do not add appreciably to neonatal depression. A significant disadvantage of hydroxyzine is pain at the injection site following intramuscular administration. Nonsteroidal
antiinflammatory agents, such as ketorolac, are not recommended as antepartum therapy because they suppress uterine contractions and promote closure of the fetal ductus arteriosus.

Small doses (up to 2 mg intravenously) of midazolam (Versed) may be administered in combination with a small dose of fentanyl (up to 100 mcg intravenously) in healthy parturients at term to facilitate the analgesic effect of neuraxial blockade. At this dose, maternal amnesia has not been observed. Chronic administration of the longer-acting benzodiazepine diazepam (Valium) has been associated with fetal depression.

Low-dose intravenous ketamine is a powerful analgesic. In doses of 10 to 15 mg intravenously, good analgesia can be obtained in 2 to 5 min without loss of consciousness. Large boluses of ketamine (>1 mg/kg) can be associated with hypertonic uterine contractions. Low-dose ketamine is most useful just prior to delivery or as an adjuvant to regional anesthesia (see Chapter 9).

In the past, reduced concentrations of volatile anesthetic agents (eg, methoxyflurane) in oxygen were sometimes used for relief of milder labor pain. Inhalation of nitrous oxide–oxygen remains in common use for relief of mild labor pain. As previously noted, nitrous oxide has minimal effects on uterine blood flow or uterine contractions.

**PUDENAL NERVE BLOCK**

Pudendal nerve blocks are often combined with perineal infiltration of local anesthetic to provide perineal anesthesia during the second stage of labor when other forms of anesthesia are not employed or prove to be inadequate. Paracervical plexus blocks are no longer used because of their association with a relatively high rate of fetal bradycardia; the close proximity of the injection site to the uterine artery may result in uterine arterial vasoconstriction, uteroplacental insufficiency, and increased levels of the local anesthetic in the fetal blood.

During a pudendal nerve block, a special needle (Koback) or guide (Iowa trumpet) is used to place the needle transvaginally underneath the ischial spine on each side; the needle is advanced 1 to 1.5 cm through the sacrospinous ligament, and 10 mL of 1% lidocaine or 2% chlorprocaine is injected following negative needle aspiration. The needle guide is used to limit the depth of injection and protect the fetus and vagina from the needle. Other potential complications include intravascular injection, retroperitoneal hematoma, and retropsoas or subgluteal abscess.
REGIONAL ANESTHETIC TECHNIQUES

Epidural or intrathecal techniques, alone or in combination, are currently the most popular methods of pain relief during labor and delivery. They can provide excellent analgesia while allowing the mother to be awake and cooperative during labor. Although spinal opioids or local anesthetics alone can provide adequate analgesia, techniques that combine the two have proved to be the most satisfactory in most parturients. Moreover, the synergy between opioids and local anesthetics decreases dose requirements and provides excellent analgesia with few maternal side effects and little or no neonatal depression.

1. Spinal Opioids Alone

Opioids may be given intrathecally as a single injection or intermittently via an epidural or intrathecal catheter (Table 41–2). Relatively large doses are required for analgesia during labor when epidural or intrathecal opioids are used alone. For example, the ED$_{50}$ during labor is 124 mcg for epidural fentanyl and 21 mcg for epidural sufentanil. The higher doses may be associated with a high risk of side effects, most importantly respiratory depression. For this reason, combinations of local anesthetics and opioids are most commonly used (see later discussion). Pure opioid techniques are most useful for high-risk patients who may not tolerate the functional sympathectomy associated with spinal or epidural anesthesia (see Chapter 45). This group includes patients with hypovolemia or significant cardiovascular disease such as moderate to severe aortic stenosis, tetralogy of Fallot, Eisenmenger syndrome, or pulmonary hypertension. With the exception of meperidine, which has local anesthetic properties, spinal opioids alone do not produce motor blockade or sympathectomy. Thus, they do not impair the ability of the parturient to “push.” Disadvantages include less complete analgesia, lack of perineal relaxation, and side effects such as pruritus, nausea, vomiting, sedation, and respiratory depression. Side effects may be ameliorated with low doses of naloxone (0.1–0.2 mg/h intravenously).

**TABLE 41–2** Spinal opioid dosages for labor and delivery.
Intrathecal Opioids

Intrathecal morphine in doses of 0.1 to 0.3 mg may produce satisfactory and prolonged (4–6 h) analgesia during the first stage of labor. Unfortunately, the onset of analgesia is slow (45–60 min), and these doses may not be sufficient in many patients. However, higher doses are associated with a relatively high incidence of side effects. Morphine is therefore rarely used alone. The combination of morphine, 0.1 to 0.25 mg, and fentanyl, 12.5 mcg (or sufentanil, 5 mcg), may result in a more rapid onset of analgesia (5 min). Intermittent boluses of 10 to 15 mg of meperidine, 12.5 to 25 mcg of fentanyl, or 3 to 10 mcg of sufentanil via an intrathecal catheter can also provide satisfactory analgesia for labor. Early reports of fetal bradycardia following intrathecal opioid injections (eg, sufentanil) have not been confirmed by subsequent studies. Hypotension following administration of intrathecal opioids for labor may be due to the resultant analgesia and decreased circulating catecholamine levels.

Epidural Opioids

Relatively large doses (≥7.5 mg) of epidural morphine are required for satisfactory labor analgesia but are not recommended because of the increased risk of delayed respiratory depression and because the resultant analgesia is effective only in the early first stage of labor. Onset may take 30 to 60 min but analgesia lasts up to 12 to 24 h (as does the risk of delayed respiratory depression). Epidural meperidine, 50 to 100 mg, provides good, but relatively brief, analgesia (1 to 3 h). Epidural fentanyl, 50 to 150 mcg, or sufentanil, 10 to 20 mcg, usually produces analgesia within 5 to 10 min with few side effects, but it has a short duration (1–2 h). Although “single-shot” epidural opioids do not appear to cause significant neonatal depression, caution should be exercised following repeated administrations. Combinations of a lower dose of morphine,
2.5 mg, with fentanyl, 25 to 50 mcg (or sufentanil, 7.5–10 mcg), may result in a more rapid onset and prolongation of analgesia (4–5 h) with fewer side effects.

### 2. Local Anesthetic/Local Anesthetic–Opioid Mixtures

Epidural and spinal (intrathecal) analgesia more commonly utilizes local anesthetics either alone or with opioids for labor and delivery. Analgesia during the first stage of labor requires neural blockade at the T10–L1 sensory level, whereas pain relief during the second stage of labor requires neural blockade at T10–S4. Continuous lumbar epidural analgesia is the most versatile and most commonly employed technique because it can be used for pain relief for the first stage of labor as well as analgesia/anesthesia for subsequent vaginal delivery or cesarean section, if necessary. “Single-shot” epidural, spinal, or combined spinal epidural analgesia may be appropriate when pain relief is initiated just prior to vaginal delivery (the second stage). Obstetric caudal injections have largely been abandoned because of less versatility; although effective for perineal analgesia/anesthesia, they require large volumes of local anesthetic to anesthetize upper lumbar and lower thoracic dermatomes. They have also been associated with early paralysis of the pelvic muscles that may interfere with normal rotation of the fetal head, and with a small risk of accidental puncture of the fetus.

Absolute contraindications to regional anesthesia include patient refusal, infection at the injection site, coagulopathy, marked hypovolemia, and true allergies to the chosen local anesthetic. The patient’s inability to cooperate may prevent successful regional anesthesia. Full anticoagulation markedly increases the risk of neuraxial anesthesia. Regional anesthesia should generally not be performed within 4 to 6 h of a subcutaneous minidose of unfractionated heparin or within 10 to 12 h of administration of low-molecular-weight heparin (LMWH). Thrombocytopenia or concomitant administration of an antiplatelet agent increases the risk of spinal hematoma. A vaginal birth after cesarean (VBAC) delivery is not a contraindication to regional anesthesia during labor. Concern that anesthesia may mask pain associated with uterine rupture during VBAC may not be justified, because not all dehiscences cause pain even without epidural anesthesia; moreover, changes in uterine tone and contraction pattern may be more reliable signs.

Before performing any regional block, appropriate equipment and supplies for resuscitation must be immediately available, including oxygen, suction, a mask with a positive-pressure device for ventilation, a functioning laryngoscope and blades, endotracheal tubes (6 or 6.5 mm), oral and nasal airways,
intravenous fluids, ephedrine, atropine, propofol, and succinylcholine. The ability to monitor blood pressure and heart rate is mandatory. A pulse oximeter and capnograph should be readily available, and ready availability of equipment such as a video laryngoscope or an intubating laryngeal mask airway device, for use with a difficult airway, is advisable.

**Lumbar Epidural Analgesia**

Epidural analgesia for labor may be administered in early labor after the patient has been evaluated by her obstetrician. Epidural analgesia does not increase the rate of operative delivery and has little if any effect on the progress of labor when dilute mixtures of a local anesthetic and an opioid are used. Concerns that regional analgesia will increase the likelihood of oxytocin augmentation, operative (eg, forceps) delivery, or cesarean section, are unjustified. It is often advantageous to place an epidural catheter early in labor, when the patient is less uncomfortable and can be positioned more easily. Moreover, should an urgent or emergent cesarean section become necessary, the presence of a functioning epidural catheter makes it possible to avoid general anesthesia.

**A. Technique**

Parturients may be positioned on their sides or in the sitting position for the procedure. The sitting position often makes it easier to identify the midline and spine, particularly in obese patients. When epidural anesthesia is being given for vaginal delivery (second stage of labor), the sitting position may promote sacral spread.

Identification of the epidural space can be difficult, and unintentional dural puncture will sometimes occur even in experienced hands; the incidence of “wet taps” in obstetric patients is 0.25% to 9%, depending on clinician experience. Many practitioners add a compressible air bubble to the saline syringe and bounce the plunger to ensure that it moves freely and does not stick to the syringe wall (Figure 41–1A and C). Most clinicians advocate the midline approach, whereas a minority favors the paramedian approach. For the placement of a lumbar epidural catheter in the obstetric patient, most anesthesiologists advance the epidural needle with the left hand, which is braced against the patient’s back, while applying continuous pressure to the plunger of a glass syringe filled with sterile saline (Figure 41–1A and C). Alternatively, some make use of the “wings” of the Weiss epidural needle by advancing it with both hands a few millimeters at a time (Figure 41–1B). A change of tissue
resistance is then tested continuously using tactile feedback when advancing the needle and by intermittently applying pressure to the air-filled loss-of-resistance syringe. The later technique allows for precise control of needle advancement and may allow a better distinction of various tissue densities. If air is used for detecting loss of resistance, the amount injected should be limited; injection of larger volumes of air (>2–3 mL) in the epidural space has been associated with patchy or unilateral analgesia and headache. The average depth of the lumbar epidural space in obstetric patients is 6 cm from the skin. Insertion of the epidural catheter at the L3–4 or L4–5 interspace is generally optimal for achieving a T10–S5 neural blockade. Ultrasound guidance has recently been offered as tool in assisting with the placement of an epidural catheter. This technique allows the practitioner to judge the depth of the epidural space and estimate the best angle of needle insertion. The potential benefit of this technique is most obvious in obese patients with poor anatomic landmarks. However, the technique is highly user-dependent, and few practitioners have adopted it.
FIGURE 41–1  A: One-handed needle advancement; continuous pressure technique. The operator applies continuous pressure to the plunger of a loss-of-resistance syringe filled with saline and an air bubble while advancing the needle with the left hand braced against the patient’s back. B: Bimanual needle advancement; intermittent pressure technique. The operator advances the loss-of-resistance syringe with both hands 2 to 3 mm at a time while appreciating the
resistance encountered by the needle. C: In between bimanual advancements of the needle, the operator tests the tissue resistance of the needle tip by bouncing the plunger of the air-filled loss-of-resistance syringe. Many practitioners add a compressible air bubble to a saline-filled syringe and bounce the plunger to ensure that the plunger is moving freely and not sticking to the syringe barrel wall.

If unintentional dural puncture occurs, the anesthetist has two choices: (1) place the epidural catheter in the subarachnoid space for continuous spinal (intrathecal) analgesia and anesthesia (see discussion that follows), or (2) remove the needle and attempt placement at another spinal level. The intrathecally placed epidural catheter may be used as continuous spinal anesthetic. If used in this fashion, an infusion of 0.0625% to 0.125% bupivacaine with fentanyl, 2 to 3 mcg/mL starting at 1–3 mL/h, is a typical choice.

B. Choice of Epidural Catheter
Many clinicians advocate use of a multi-orifice catheter instead of a single-orifice catheter for obstetric anesthesia. Use of a multi-orifice catheter may be associated with fewer unilateral blocks and greatly reduces the incidence of false-negative aspiration when assessing for intravascular or intrathecal catheter placement. Advancing a multi-orifice catheter 4 to 6 cm into the epidural space appears to be optimal for obtaining adequate sensory levels. A single-orifice catheter need only be advanced 3 to 5 cm into the epidural space. Shorter insertion lengths in the epidural space (<5 cm) may favor dislodgment of the catheter out of the epidural space in obese patients following flexion/extension movements of the spine. Longer epidural insertion lengths in the epidural space may increase the risk of unilateral analgesia or epidural vein insertion. Spiral wire-reinforced catheters are very resistant to kinking. A spiral or spring tip, particularly when used without a stylet, is associated with fewer, less intense paresthesias.

C. Choice of Local Anesthetic Solutions
The addition of opioids to local anesthetic solutions for epidural anesthesia has dramatically changed the practice of obstetric anesthesia. The synergy between epidural opioids and local anesthetic solutions reflects separate sites of action: opioid receptors and neuronal axons, respectively. When the two are combined, very low concentrations of both local anesthetic and opioid can be used with excellent effect. In addition, the incidence of adverse side effects, such as
hypotension and drug toxicity, is reduced. Although local anesthetics can be used alone, there is rarely a reason to do so. Moreover, when an opioid is omitted, the greater concentration of local anesthetic required (eg, bupivacaine, 0.25%, and ropivacaine, 0.2%) for adequate analgesia can impair the parturient’s ability to push effectively as labor progresses. The most common local anesthetic/opioid combination used for labor analgesia is bupivacaine or ropivacaine in concentrations of 0.0625% to 0.125% with either fentanyl, 2 to 3 mcg/mL, or sufentanil, 0.3 to 0.5 mcg/mL. In general, the lower the concentration of the local anesthetic the greater the concentration of opioid that is required. Very dilute local anesthetic mixtures (0.0625%) generally do not produce motor blockade and may allow some patients to ambulate (“walking” or “mobile” epidural). The long duration of action of bupivacaine makes it a popular agent for labor. Ropivacaine may be preferable because of its reduced potential for cardiotoxicity (see Chapter 16). At equi-analgesic doses, ropivacaine and bupivacaine appear to produce the same degree of motor block.

The effect of epinephrine-containing solutions on the course of labor is somewhat controversial. Many clinicians use epinephrine-containing solutions only for intravascular test doses because of concern that the solutions may slow the progression of labor or adversely affect the fetus; others use only very dilute concentrations of epinephrine such as 1:800,000 or 1:400,000. However, studies comparing these various agents have failed to find any differences in neonatal Apgar scores, acid–base status, or neurobehavioral evaluations.

D. Epidural Activation for the First Stage of Labor

Initial epidural injections may be done either before or after the catheter is placed. Administration through the needle can facilitate catheter placement, whereas administration through the catheter provides assurance that the catheter is functioning properly. The following sequence is suggested for epidural activation:

1. Test for unintentional subarachnoid or intravascular placement of the needle or catheter using a 3-mL test dose of a local anesthetic with 1:200,000 epinephrine Many clinicians test with lidocaine 1.5% because it results in less toxicity following unintentional intravascular injection and more rapid onset of spinal anesthesia following unintentional intrathecal injection than with bupivacaine or ropivacaine. The test dose should be injected between contractions to help reduce false-positive signs of an intravascular injection (ie, tachycardia due to a painful contraction).
2. If after 5 min signs of intravascular or intrathecal injection are absent, with the patient supine and left uterine displacement, administer 10 mL of the local anesthetic–opioid mixture in 5-mL increments, waiting 1 to 2 min between doses, to achieve a T10–L1 sensory level. The initial bolus is usually composed of 0.1% to 0.2% ropivacaine or 0.0625% to 0.125% bupivacaine combined with either 50 to 100 mcg of fentanyl or 10 to 20 mcg of sufentanil.

3. Monitor with frequent assessment of vital signs for 20 to 30 min, or until the patient is stable. Pulse oximetry should also be used. Oxygen is administered via face mask if significant decrease in blood pressure or oxygen saturation occurs.

4. Repeat steps 2 and 3 when pain recurs until the first stage of labor is completed. Alternatively, a continuous epidural infusion technique may be employed using bupivacaine or ropivacaine in concentrations of 0.0625% to 0.125% with either fentanyl, 1 to 5 mcg/mL, or sufentanil, 0.2 to 0.5 mcg/mL, at a rate of 10 mL/h, which subsequently is adjusted to the patient’s analgesic requirements (range: 5–15 mL/h). A third choice would be to use patient-controlled epidural analgesia (PCEA). Some studies suggest that total drug requirements may be less and patient satisfaction greater with PCEA when compared with other epidural analgesia techniques. Traditional PCEA settings are typically a 5-mL bolus dose with a 5 to 10 min lockout and 0 to 12 mL/h basal rate; a 1-h limit of 15 to 25 mL is typically used. Recent evidence also suggests that, compared with an epidural baseline infusion, programmed intermittent bolus techniques (eg, 6 mL bupivacaine 0.0625% every 30 min without baseline infusion) may improve patient satisfaction. Migration of the epidural catheter into a blood vessel during a continuous infusion technique may be heralded by loss of effective analgesia; a high index of suspicion is required because overt signs of systemic toxicity may be absent. Erosion of the catheter through the dura results in a slowly progressive motor blockade of the lower extremities and a rising sensory blockade level.

E. Epidural Administration During the Second Stage of Labor

Epidural analgesia administration for the second stage of labor should extend the block to include the S2–4 dermatomes. Whether a catheter is already in place or epidural anesthesia is just being initiated, the following steps should be undertaken:
1. If the patient does not already have a catheter in place, establish epidural space access while the patient is in a sitting position. A patient who already has an epidural catheter in place should be placed in a semiupright or sitting position prior to injection.

2. Give a 3-mL test dose of local anesthetic (eg, lidocaine 1.5%) with 1:200,000 epinephrine. As previously noted, the injection should be completed between contractions.

3. If, after 5 min, signs of intravascular or intrathecal injection are absent, administer 10 to 15 mL of additional local anesthetic–opioid mixture at a rate not faster than 5 mL every 1 to 2 min.

4. Lay the patient supine with left uterine displacement and monitor vital signs every 1 to 2 min for the first 15 min, then every 5 min thereafter.

F. Prevention of Unintentional Intravascular and Intrathecal Injections

Safe administration of epidural analgesia and anesthesia is dependent on avoiding unintentional intrathecal or intravascular injection. Unintentional intravascular or intrathecal placement of an epidural needle or catheter is possible even when aspiration fails to yield blood or cerebrospinal fluid (CSF). The incidence of unintentional intravascular or intrathecal placement of an epidural catheter is 5% to 15% and 0.5% to 2.5%, respectively. Even a properly placed catheter can subsequently erode into an epidural vein or an intrathecal position. This possibility should be considered each time local anesthetic is injected through an epidural catheter.

Test doses of lidocaine (45–60 mg), bupivacaine (7.5–10 mg), ropivacaine (6–8 mg), or chloroprocaine (100 mg) can be given to exclude unintentional intrathecal placement. Signs of sensory and motor blockade usually become apparent within 2 to 3 min and 3 to 5 min, respectively, if the injection is intrathecal.

In patients not receiving β-adrenergic antagonists, the intravascular injection of a local anesthetic solution with 15 to 20 mcg of epinephrine consistently increases the heart rate by 20 to 30 beats/min within 30 to 60 s if the epidural catheter or needle tip is intravascular. This technique is not always reliable in parturients because they often have marked spontaneous baseline variations in heart rate with contractions. Alternative methods of detecting unintentional intravascular catheter placement are based on eliciting signs of CNS toxicity, including tinnitus, dizziness, perioral numbness, or metallic taste. The use of
dilute local anesthetic solutions and slow injection rates of no more than 5 mL at a time may also enhance detection of unintentional intravascular injections before catastrophic complications develop.

G. Management of Complications

1. Hypotension—Generally defined as a greater than 20% decrease in the patient’s baseline systolic blood pressure, or a systolic blood pressure less than 100 mm Hg, hypotension is a common side effect of neuraxial anesthesia. It is primarily due to decreased sympathetic tone and is greatly accentuated by aortocaval compression and an upright or semiupright position. Treatment should consist of intravenous boluses of phenylephrine (40–120 mcg), supplemental oxygen, left uterine displacement, and an intravenous fluid bolus. Although the routine use of a crystalloid fluid bolus prior to dosing an epidural catheter is not effective in the prevention of hypotension, ensuring proper intravenous hydration of the pregnant patient is important. Use of the head-down (Trendelenburg) position is controversial because of its potentially detrimental effects on pulmonary gas exchange.

2. Unintentional intravascular injection—Early recognition of intravascular injection, facilitated by the use of small, repeated doses of local anesthetic instead of a large bolus, may prevent more serious local anesthetic toxicity, such as seizures or cardiovascular collapse. Intravascular injections of toxic doses of lidocaine or chloroprocaine usually present as seizures. Propofol, 20 to 50 mg, will terminate seizure activity. Maintenance of a patent airway and adequate oxygenation are critical; however, administration of succinylcholine and endotracheal intubation are rarely necessary. Intravascular injections of bupivacaine can cause rapid cardiovascular collapse as well as seizure activity. Cardiac resuscitation may be exceedingly difficult and is aggravated by acidosis and hypoxia. An immediate infusion of 20% Intralipid combined with incremental doses of epinephrine has shown efficacy in reversing bupivacaine-induced cardiac toxicity. Amiodarone is the agent of choice for treating local anesthetic–induced ventricular arrhythmias.

3. Unintentional intrathecal injection—Even when dural puncture is recognized immediately after injection of local anesthetic, attempted aspiration of the local anesthetic will usually be unsuccessful. The patient should be placed supine with left uterine displacement. Head elevation accentuates the adverse effects of hypotension on cerebral blood flow and should be avoided. Hypotension must be treated promptly with phenylephrine and intravenous
fluids. Moderate to profound hypotension may require the administration of epinephrine (10–50 mcg) or vasopressin (0.4–2.0 U intravenously). A high spinal level can also result in diaphragm and intercostal muscle paralysis, which necessitates intubation and ventilation with 100% oxygen. Delayed onset of a very high and often patchy or unilateral block may be due to unrecognized subdural injection (see Chapter 45), which is managed similarly.

4. **Postdural puncture headache (PDPH)**—There are many causes of headache after regional anesthesia in obstetrics. Caffeine-withdrawal and migraine headaches are not uncommon. Unintended dural puncture with a large epidural needle will commonly result in a PDPH, as a consequence of decreased intracranial pressure with compensatory cerebral vasodilation (see Chapter 45). Bed rest, hydration, oral analgesics, and caffeine sodium benzoate (5 00 mg added to 1000 mL intravenous fluids administered at 200 mL/h) may be effective in patients with mild headaches and as temporary treatment. Intravenous gabapentin, hydrocortisone, and oral theophylline have been shown to be successful in some studies. Patients with moderate to severe headaches usually require an epidural blood patch (10–20 mL; see Chapter 45). Prophylactic epidural blood patches are not recommended, as 25% to 50% of patients may not require a blood patch following dural puncture. Delaying a blood patch for 24 h increases its efficacy, although supine bed rest for a 24 h while awaiting the epidural blood patch is both inconvenient and impractical for the new mother. Intracranial subdural hematoma has been reported as a rare complication 1 to 6 weeks following unintentional dural puncture in obstetric patients.

5. **Maternal fever**—Maternal fever is often interpreted as chorioamnionitis and may trigger evaluation for neonatal sepsis. Contrary to reports by some authors, there is no clear evidence that epidural anesthesia affects maternal temperature or that neonatal sepsis is increased with epidural analgesia. An elevation in maternal temperature is associated with a high body mass index and with nulliparity in women and prolonged labor.

**Combined Spinal & Epidural (CSE) Analgesia**

Techniques using CSE analgesia and anesthesia may especially benefit patients with severe pain early in labor and those who receive analgesia/anesthesia immediately prior to delivery. Intrathecal opioid and local anesthetic are injected through the spinal needle, after which an epidural catheter is placed via the epidural needle. The intrathecal drugs provide essentially
immediate pain control and have minimal effects on the early progress of labor, whereas the epidural catheter provides a route for subsequent analgesia for labor and delivery or anesthesia for cesarean section. The addition of a small dose of local anesthetic agent to the intrathecal opioid injection greatly potentiates the opioid efficacy and can significantly reduce opioid requirement. Thus, many clinicians will inject preservative-free bupivacaine, 2.5 mg, or ropivacaine, 3 to 4 mg, with intrathecal opioid for analgesia in the first stage of labor. Typical intrathecal opioid doses for CSE are fentanyl, 10 to 12.5 mcg, or sufentanil, 5 mcg. Some studies suggest that CSE techniques may be associated with greater patient satisfaction and lower incidence of PDPH than epidural analgesia alone. A 24- to 27-gauge pencil-point spinal needle (Whitacre, Sprotte, or Gertie Marx) is used to minimize the incidence of PDPH.

For CSE techniques, the spinal and epidural needles may be placed at separate interspaces, but most clinicians use a needle-through-needle technique at the same interspace. Use of saline for identification of the epidural space may potentially cause confusion of saline for CSF. With the needle-through-needle technique, the epidural needle is placed in the epidural space and a long spinal needle is then introduced through it and advanced farther into the subarachnoid space. A distinct pop is felt as the needle penetrates the dura. The needle-beside-needle technique typically employs a specially designed epidural needle that has a channel for the spinal needle. After the intrathecal injection and withdrawal of the spinal needle, the epidural catheter is threaded into position and the epidural needle is withdrawn. The risk of advancing the epidural catheter through the dural hole created by the spinal needle is negligible when a 25-gauge or smaller spinal needle is used. The epidural catheter, however, should be aspirated carefully prior to use and local anesthetic should always be given slowly and in small increments to avoid unintentional intrathecal injections. Moreover, epidural drugs should be titrated carefully because the dural hole may facilitate entry of epidural drugs into intrathecal space and thereby potentiate their effects.

**Spinal Anesthesia**

Spinal anesthesia given just prior to delivery—also known as *saddle block*—provides profound anesthesia for operative vaginal delivery. Use of a 22-gauge or smaller, pencil-point spinal needle (Whitacre, Sprotte, or Gertie Marx) decreases the likelihood of PDPH. Hyperbaric tetracaine, 3–4 mg, bupivacaine, 2.5–5 mg, or lidocaine, 20–40 mg, usually provides excellent perineal anesthesia. Addition of fentanyl, 12.5–25 mcg, or sufentanil, 5–7.5 mcg, significantly potentiates the block. A T10 sensory level can be obtained with
slightly larger amounts of local anesthetic. Three minutes after intrathecal injection of the hyperbaric solution, the patient is placed in the lithotomy position with left uterine displacement.

**GENERAL ANESTHESIA**

Because of the increased risk of aspiration, general anesthesia for vaginal delivery is avoided except for a true emergency. If an epidural catheter is already in place and time permits, rapid-onset regional anesthesia can be obtained with alkalized lidocaine 2% or chloroprocaine 3%. Table 41–3 lists indications for general anesthesia during vaginal delivery. These indications are rare, and most include the need for urgent uterine relaxation.

**Anesthesia for Cesarean Section**

Common indications for cesarean section are listed in Table 41–4. The choice of anesthesia for cesarean section is determined by multiple factors, including the indication for operative delivery, its urgency, patient and obstetrician preferences, and the skills of the anesthetist. In a given country, cesarean section rates may vary as much as twofold between institutions. In some countries, cesarean delivery is seen as preferable to labor and rates are much greater than those in the United States, where rates vary between 15% and 35% from hospital to hospital. In the United States, most elective cesarean sections are performed under spinal anesthesia. Regional anesthesia has become the preferred technique because general anesthesia is associated with a greater risk of maternal morbidity and mortality, greater hemodynamic fluctuation during anesthetic induction, and the need for additional analgesia during anesthetic recovery. Deaths associated with general anesthesia are generally related to airway
problems, such as inability to intubate, inability to ventilate, or aspiration pneumonitis. However, most of the studies showing greater risk of general anesthesia were conducted before the arrival of video laryngoscopy and other advanced airway techniques. Deaths associated with regional anesthesia are generally related to excessive dermatomal spread of blockade or to local anesthetic toxicity.

Additional advantages of regional anesthesia include (1) less neonatal exposure to potentially depressant drugs, (2) a decreased risk of maternal pulmonary aspiration, (3) an awake mother who can experience the birth of her child, and (4) the option of using spinal opioids for postoperative pain relief.
Continuous epidural anesthesia allows better continuing control over the sensory level than “single-shot” spinal anesthesia techniques. Conversely, spinal anesthesia has a more rapid, predictable onset; may produce a denser (more complete) block; and lacks the potential for serious systemic drug toxicity because of the smaller local anesthetic dose employed. Regardless of the regional technique chosen, one must be prepared to administer a general anesthetic at any time during the procedure. Moreover, administration of a nonparticulate antacid within 30 min of surgery should be considered.

General anesthesia offers (1) a very rapid and reliable onset, (2) control over the airway and ventilation, (3) greater comfort for extremely anxious parturients, and (4) potentially less hypotension than regional anesthesia. General anesthesia also facilitates management in the event of severe hemorrhagic complications such as placenta accreta. Its principal disadvantages are the risk of pulmonary aspiration, the potential inability to intubate or ventilate the patient, and drug-induced fetal depression. Present anesthetic techniques, however, limit the dose of intravenous agents such that fetal depression is usually not clinically significant with general anesthesia when delivery occurs within 10 min of induction of anesthesia. Regardless of the type of anesthesia, neonates delivered more than 3 min after uterine incision have lower Apgar scores and pH values.

REGIONAL ANESTHESIA

Cesarean section requires that dermatomes up to and including T4 be anesthetized. Because of the associated sympathetic blockade, patients should receive an appropriate intravenous bolus of crystalloid such as lactated Ringer’s (typically 1000–1500 mL) solution at the time of neural blockade. Such boluses will not consistently prevent hypotension but can virtually eliminate preexisting hypovolemia. Concomitant with local anesthetic injection, phenylephrine may be titrated to maintain a blood pressure within 20% of baseline. An approximate 10% decrease in blood pressure is expected. Some studies suggest that phenylephrine produces less neonatal acidosis than ephedrine, although administration of ephedrine, 5 to 10 mg intravenously, may be necessary in the hypotensive patient with reduced heart rate.

After spinal anesthetic injection, the patient is placed supine with left uterine displacement; supplemental oxygen (40–50%) is given; and blood pressure is measured every 1 to 2 min until it stabilizes. Hypotension following epidural anesthesia administration typically has a slower onset. Slight Trendelenburg positioning facilitates achieving a T4 sensory level and may also help prevent severe hypotension. Extreme degrees of Trendelenburg may interfere with
pulmonary gas exchange.

**Spinal Anesthesia**

The patient is usually placed in the lateral decubitus or sitting position, and a hyperbaric solution of intrathecal lidocaine (50 to 60 mg) or bupivacaine (10 to 15 mg) is injected. Bupivacaine should be chosen if the obstetrician will not likely complete the surgery in 45 minutes or less. Use of a 22-gauge or smaller, pencil-point spinal needle (Whitacre, Sprotte, or Gertie Marx) decreases the incidence of PDPH. Adding fentanyl, 10 to 25 mcg, or sufentanil, 5 to 10 mcg, to the intrathecal local anesthetic solution enhances the intensity of the spinal block and prolongs its duration without adversely affecting neonatal outcome. Addition of preservative-free morphine, 0.1 to 0.3 mg, can prolong postoperative analgesia up to 24 h, but requires monitoring for delayed postadministration respiratory depression. Regardless of the anesthetic agents used, considerable variability in the maximal dermatomal extent of anesthesia should be expected (see Chapter 45). In obese patients, a standard 3.5-in. (9-cm) spinal needle may not be long enough to reach the subarachnoid space. In such cases, longer spinal needles of 4.75 in. (12 cm) to 6 in. (15.2 cm) may be required. To prevent these longer needles from bending, some anesthesiologists prefer larger diameter needles, such as the 22-gauge Sprotte needle. Alternatively, a 2.5-in. (6.3-cm) 20-gauge Quincke type spinal needle can be used as a long introducer and guide for a 25-gauge pencil-point spinal needle.

Continuous spinal anesthesia is also a reasonable option, especially for obese patients, following unintentional dural puncture sustained while attempting to place an epidural catheter for cesarean section. After the catheter is advanced 3 to 5 cm into the lumbar subarachnoid space and secured, it can be used to inject anesthetic agents; moreover, it allows later supplementation of anesthesia if necessary.

**Epidural Anesthesia**

Epidural anesthesia for cesarean section is typically performed using a catheter, which allows supplementation of anesthesia, if necessary, and provides an excellent route for postoperative opioid administration. After negative aspiration and a negative test dose, a total volume of 15 to 35 mL of local anesthetic is injected slowly in 5-mL increments in order to minimize the risk of systemic local anesthetic toxicity. Lidocaine 2% (typically with 1:200,000 epinephrine) or chlorprocaine 3% are most commonly used in the United
States. The addition of fentanyl, 50 to 100 mcg, or sufentanil, 10 to 20 mcg, greatly enhances analgesic intensity and prolongs its duration without adversely affecting neonatal outcome. Some practitioners also add sodium bicarbonate (7.5% or 8.4% solution) to local anesthetic solutions (1 mEq sodium bicarbonate/10 mL of lidocaine) to increase the concentration of the nonionized free base and produce faster onset and more rapid spread of epidural anesthesia. If pain develops as the sensory level recedes, additional local anesthetic is administered in 5-mL increments to maintain a T4 sensory level. “Patchy” anesthesia prior to delivery of the infant can be treated with 10 to 20 mg of intravenous ketamine in combination with 1 to 2 mg of midazolam or 30% nitrous oxide. After delivery, intravenous opioid supplementation may also be used, provided excessive sedation and loss of consciousness are avoided. Pain that remains intolerable in spite of a seemingly adequate sensory level and that proves unresponsive to these measures necessitates general anesthesia with endotracheal intubation. Nausea can be treated intravenously with a 5-HT₃-receptor antagonist, such as ondansetron, 4 mg.

Epidural morphine, 5 mg, at the end of surgery provides good to excellent pain relief postoperatively for 6 to 24 h. An increased incidence (3.5–30%) of recurrent herpes simplex labialis infection 2 to 5 days following epidural morphine administration has been reported. Postoperative analgesia can also be provided by continuous epidural infusions of fentanyl, 25 to 75 mcg/h, or sufentanil, 5 to 10 mcg/h, at a volume delivery rate of approximately 10 mL/h. Epidural butorphanol, 2 mg, can also provide effective postoperative pain relief, but marked somnolence is often a side effect.

**Combined Spinal & Epidural Anesthesia**

The technique for CSE is described in the earlier section on Combined Spinal & Epidural Analgesia for labor and vaginal delivery. For cesarean section, CSE combines the benefit of rapid, reliable, intense blockade of spinal anesthesia with the flexible utility of an epidural catheter. The catheter also allows supplementation of anesthesia and can be used for postoperative analgesia. As mentioned previously, drugs administered epidurally should be titrated carefully because the dural hole created by the spinal needle may facilitate movement of epidural drugs into CSF and thereby potentiate their effects.

**GENERAL ANESTHESIA**

Pulmonary aspiration of gastric contents and failed endotracheal intubation are
the major causes of maternal morbidity and mortality associated with general anesthesia. All patients should receive antacid prophylaxis against aspiration pneumonia with 0.3 M sodium citrate, 30 mL, 30 to 45 min prior to induction. Patients with additional risk factors predisposing them to aspiration should also receive intravenous ranitidine, 50 mg, or metoclopramide, 10 mg, or both, 1 to 2 h prior to induction of general anesthesia; such risk factors include morbid obesity, symptoms of gastroesophageal reflux, a potentially difficult airway, or emergent surgical delivery without an elective fasting period. Premedication with oral omeprazole, 40 mg, at night and in the morning, also appears to be highly effective in high-risk patients undergoing elective cesarean section. Although anticholinergics theoretically may reduce lower esophageal sphincter tone, premedication with glycopyrrolate, 0.1 mg, helps reduce airway secretions and should be considered in patients with a potentially difficult airway.

Anticipation of a difficult endotracheal intubation may help reduce the incidence of failed intubation. Examination of the neck, mandible, dentition, and oropharynx often helps predict which patients may have problems. Useful predictors of difficult intubation include Mallampati classification, short neck, receding mandible, prominent maxillary incisors, and history of difficult intubation (see Chapter 19). The higher incidence of failed intubation in pregnant relative to nonpregnant surgical patients may be due to airway edema, full dentition more likely found in young patients, or large breasts that can obstruct the handle of the laryngoscope in patients with short necks. Proper positioning of the head and neck may facilitate endotracheal intubation in obese patients: elevation of the shoulders, flexion of the cervical spine, and extension of the atlantooccipital joint (Figure 41–2). A variety of laryngoscope blades, a short laryngoscope handle, at least one extra stiletted endotracheal tube (6 mm), Magill forceps (for nasal intubation), a laryngeal mask airway (LMA), an intubating LMA (Fastrach), a fiberoptic bronchoscope, a video-assisted laryngoscope (GlideScope or Storz CMAC), the capability for transtracheal jet ventilation, and possibly an esophageal–tracheal Combitube should be readily available (see Chapter 19).
FIGURE 41–2 Optimal positioning for obese patients with a short neck. A: The normal supine position often prevents extension of the head and makes endotracheal intubation difficult. B: Elevation of the shoulder allows some neck flexion with more optimal extension of the head at the atlantooccipital joint, facilitating intubation.

When a difficult airway is suspected, alternatives to the standard rapid-sequence induction with conventional laryngoscopy, such as regional anesthesia or awake fiberoptic techniques, should be considered. We have found that video-assisted laryngoscopy has greatly reduced the likelihood of difficult or failed tracheal intubation at our institutions. Moreover, a clear plan should be formulated for a failed endotracheal intubation following induction of anesthesia.
(Figure 41–3). In the absence of fetal distress, the patient should be awakened, and an awake intubation with regional or topical local anesthesia should be initiated. In the presence of fetal distress, if spontaneous or positive-pressure ventilation by mask or LMA with cricoid pressure is possible, delivery of the fetus should be initiated. In such instances, a potent volatile agent with oxygen is employed for general anesthesia, but once the fetus is delivered, nitrous oxide may be added to reduce the concentration of the volatile agent; sevoflurane may be the best volatile agent because it may be least likely to depress ventilation. The inability to intubate the patient or ventilate the patient via mask or LMA will require transtracheal jet ventilation or immediate cricothyrotomy or tracheostomy.
FIGURE 41–3 An algorithm for a difficult intubation in obstetric patients.

**Suggested Technique for Cesarean Section**

1. The patient is placed supine with a wedge under the right hip for left uterine displacement.

2. Denitrogenation is accomplished with 100% oxygen for 3 to 5 min while monitors are applied.
3. The patient is prepared and draped for surgery.

4. When the surgeons are ready, a rapid-sequence induction with cricoid pressure is performed using propofol, 2 mg/kg, or ketamine, 1 to 2 mg/kg, and succinylcholine, 1.5 mg/kg. Ketamine is used instead of propofol in hypovolemic patients. Other agents, including methohexital and etomidate, offer little or no benefit in obstetric patients.

5. With few exceptions, surgery is begun only after proper placement of the endotracheal tube is confirmed. Excessive hyperventilation ($P_{a}CO_2 < 25$ mm Hg) should be avoided because it can reduce uterine blood flow and has been associated with fetal acidosis.

6. Fifty percent air in oxygen with up to 1 MAC expiratory volatile agent is used for maintenance of anesthesia until delivery of the infant. Thereafter, nitrous oxide up to 70% can be added with a concomitant reduction of the volatile agent to 0.75% MAC. The low dose of volatile agent helps ensure amnesia but is generally not enough to cause excessive uterine relaxation or prevent uterine contraction following oxytocin. A muscle relaxant of intermediate duration (cisatracurium, vecuronium, or rocuronium) is used for relaxation, but may exhibit prolonged neuromuscular blockade in patients who are receiving magnesium sulfate.

7. For elective caesarean section, a slow 0.3 to 1 IU intravenous bolus of oxytocin over 1 minute, followed by an intravenous infusion of 5 to 10 IU/h for 4 h, represents an evidence-based approach to dosing for women at low risk of postpartum hemorrhage. Additional intravenous agents, such as propofol, an opioid, or a benzodiazepine, can be given to ensure amnesia.

8. If the uterus does not contract readily, an opioid should be given, and the halogenated agent should be discontinued. Methylergonovine (Methergine), 0.2 mg in 100-mL normal saline as an intravenous infusion over 10 min, may also be given. 15-Methylprostaglandin F$_{2α}$ (Hemabate), 0.25 mg intramuscularly, may also be used.

9. An attempt to aspirate gastric contents via an oral gastric tube should be made prior to emergence from general anesthesia in order to decrease the likelihood of pulmonary aspiration.

10. At the end of surgery, the muscle relaxant is completely reversed, the gastric tube (if placed) is removed, and the patient is extubated while awake to reduce the risk of aspiration.
ANESTHESIA FOR EMERGENCY CESAREAN SECTION

Indications for emergency cesarean section include massive bleeding (placenta previa or accreta, abruptio placentae, or uterine rupture), umbilical cord prolapse, and severe fetal distress. A distinction must be made between a true emergency requiring immediate delivery (previously referred to as a “crash C-section”) and one in which some delay is possible. Close communication with the obstetrician is necessary to determine whether fetus, mother, or both are in immediate jeopardy.

The choice of anesthetic technique is determined by consideration for maternal safety (airway evaluation and aspiration risk), technical issues, and the anesthesiologist’s personal expertise. Criteria leading to the diagnosis of nonreassuring fetal status should be reviewed, as the fetal evaluation may be based on criteria with poor predictive accuracy and the fetal status may change. This information is required to choose the anesthetic technique that will produce the best outcome for both mother and fetus. Rapid institution of regional anesthesia is an option that is especially advocated for patients with presumed difficult airway, high risk of aspiration, or both. This choice may be problematic in severely hypovolemic or hypotensive patients. If general anesthesia is chosen, adequate denitrogenation may be achieved rapidly with four maximal breaths of 100% oxygen while monitors are being applied. Ketamine, 1 mg/kg, may be substituted for propofol in hypotensive or hypovolemic patients. Having a video laryngoscope and other alternative airway equipment immediately available is highly recommended.

Table 41–5 lists commonly accepted signs of fetal distress, an imprecise and poorly defined term. In most instances, the diagnosis is primarily based on monitoring of fetal heart rate. Because worrisome fetal heart rate patterns have a relatively high incidence of false-positive results, careful interpretation of other parameters, such as fetal scalp pH or fetal pulse oximetry, may also be necessary. Moreover, continuation of fetal monitoring in the operating room may help avoid unnecessary induction of general anesthesia for fetal distress when additional time for use of regional anesthesia is possible. In selected instances where immediate delivery is not absolutely mandatory, epidural anesthesia (with 3% chloroprocaine or alkalinized 2% lidocaine) or spinal anesthesia may be appropriate.

TABLE 41–5  Signs of fetal distress.
Nonreassuring fetal heart rate pattern
- Repetitive late decelerations
- Loss of fetal beat-to-beat variability associated with late or deep decelerations
- Sustained fetal heart rate <80 beats/min
- Fetal scalp pH <7.20
- Meconium-stained amniotic fluid
- Intrauterine growth restriction

Anesthesia for the Complicated Pregnancy

UMBILICAL CORD PROLAPSE

Prolapse of the umbilical cord complicates 0.2% to 0.6% of deliveries. Umbilical cord compression following prolapse can rapidly lead to fetal asphyxia. Predisposing factors include excessive cord length, malpresentation, low birth weight, grand parity (more than five pregnancies), multiple gestations, and artificial rupture of membranes. The diagnosis is suspected after sudden fetal bradycardia or profound decelerations and is confirmed by physical examination. Treatment includes immediate steep Trendelenburg or knee–chest position and manual pushing of the presenting fetal part back up into the pelvis until immediate cesarean section under general anesthesia can be performed. If the fetus is not viable, vaginal delivery is allowed to continue.

DYSTOCIA & ABNORMAL FETAL PRESENTATIONS & POSITIONS

Primary Dysfunctional Labor

A prolonged latent phase by definition exceeds 20 h in a nulliparous parturient and 14 h in a multiparous patient. The cervix usually remains at 4 cm or less but is completely effaced. The etiology is likely ineffective contractions without a dominant myometrial pacemaker. Arrest of dilation is present when the cervix undergoes no further change after 2 h in the active phase of labor. A protracted active phase refers to slower than normal cervical dilation, defined as less than
1.2 cm/h in a nulliparous patient and less than 1.5 cm/h in a multiparous parturient. A prolonged deceleration phase occurs when cervical dilation slows markedly after 8 cm. The cervix becomes very edematous and appears to lose effacement. A prolonged second stage (disorder of descent) is defined as a descent of less than 1 cm/h and 2 cm/h in nulliparous and multiparous parturients, respectively. Failure of the head to descend 1 cm in station after adequate pushing is referred to as arrest of descent.

Oxytocin is usually the treatment of choice for uterine contractile abnormalities. The drug is given intravenously at 1 to 6 mU/min and increased in increments of 1 to 6 mU/min every 15 to 40 min, depending on the protocol. Use of amniotomy is controversial. Treatment is usually expectant management, as long as the fetus and mother are tolerating the prolonged labor. Operative vaginal delivery or cesarean section is indicated when a trial of oxytocin is unsuccessful or when malpresentation or cephalopelvic disproportion is also present.

**Breech Presentation**

Breech presentations complicate 3% to 4% of deliveries and significantly increase both maternal and fetal morbidity and mortality rates. Breech presentations increase neonatal mortality and the incidence of cord prolapse more than tenfold. External cephalic version may be attempted after 34 weeks of gestation and prior to the onset of labor; however, the fetus may spontaneously return to the breech presentation before the onset of labor. Some obstetricians may administer a tocolytic agent at the same time. External version can be facilitated, and its success rate improved, by providing epidural analgesia with 2% lidocaine and fentanyl. Although an external version is successful in 75% of patients, it can cause placental abruption and umbilical cord compression necessitating immediate cesarean section.

Because the shoulders or head can become trapped after vaginal delivery of the body, some obstetricians employ cesarean section for all breech presentations. If vaginal delivery is elected, manual or forceps-assisted partial breech extraction is usually necessary. The need for breech extraction does not appear to be increased when epidural anesthesia is used for labor—if labor is well established prior to epidural activation. Moreover, epidural anesthesia may decrease the likelihood of a trapped head, because the former relaxes the perineum. Nonetheless, the fetal head can become trapped in the uterus even during cesarean section under regional anesthesia; rapid induction of general endotracheal anesthesia and administration of a volatile agent may be attempted.
in such instances to relax the uterus. Alternatively, nitroglycerin, 50 to 100 mcg intravenously, can be administered.

**Abnormal Vertex Presentations**

When the fetal occiput fails to spontaneously rotate anteriorly, a persistent *occiput posterior presentation* results in a more prolonged and painful labor. Manual, vacuum, or forceps rotation is usually necessary but increases the likelihood of maternal and fetal injuries. Regional anesthesia can be used to provide perineal analgesia and pelvic relaxation, facilitating manual or forceps rotation followed by forceps delivery.

A *face presentation* occurs when the fetal head is hyperextended and generally requires cesarean section. A *compound presentation* occurs when an extremity enters the pelvis along with either the head or the buttocks. Vaginal delivery is usually still possible because the extremity often withdraws as the labor progresses.

*Shoulder dystocia*, or impaction of a shoulder against the pubic symphysis, complicates 0.2% to 2% of deliveries and is one of the major causes of birth injuries. Shoulder dystocias are often difficult to predict, and the most important risk factor is fetal macrosomia. Several obstetric maneuvers can be used to relieve shoulder dystocia, but a prolonged delay in the delivery could result in fetal asphyxia. Induction of general anesthesia may be necessary if an epidural catheter is not already in place.

**MULTIPLE GESTATIONS**

Multiple gestations account for approximately 1 in 150 births and are commonly complicated by breech presentation, prematurity, or both. Anesthesia may be necessary for version, extraction, or cesarean section. The second infant (and any subsequent ones) is often more depressed and asphyxiated than the first. Regional anesthesia provides effective pain relief during labor, minimizes the need for sedative and analgesic medication, and may shorten the interval between the birth of the first and second infants. Some studies suggest that the acid–base status of the second twin is improved when epidural anesthesia is used. Patients with multiple gestations, are more prone to develop hypotension from aortocaval compression, particularly after regional anesthesia.

**ANTEPARTUM HEMORRHAGE**
Maternal hemorrhage is one of the most common severe morbidities complicating obstetric anesthesia. Causes include uterine atony, placenta previa, abruptio placentae, and uterine rupture.

**Placenta Previa**

A *placenta previa* is present if the placenta implants in advance of the fetal presenting part; this occurs in approximately 0.5% of pregnancies. It often occurs in patients who have had a previous cesarean section or uterine myomectomy. Other risk factors include multiparity, advanced maternal age, and a large placenta. An anterior-lying placenta previa increases the risk of excessive bleeding for cesarean section.

Placenta previa usually presents as painless vaginal bleeding, and although the bleeding often stops spontaneously, severe hemorrhage can occur at any time. The patient is usually treated with bed rest and observation when the gestation is less than 37 weeks in duration and the bleeding is mild to moderate. After 37 weeks of gestation, delivery is usually accomplished via cesarean section. Patients with low-lying placenta may rarely be allowed to deliver vaginally if the bleeding is mild.

Active bleeding or hemodynamic instability requires immediate cesarean section under general anesthesia. The patient should have two large-bore intravenous catheters in place; intravascular volume deficits must be replaced, and blood must be available for transfusion. The bleeding can continue after delivery because the placental implantation site in the lower uterine segment often does not contract well as does the rest of the uterus.

A history of a previous placenta previa or cesarean section increases the risk of abnormal placentation.

**Abruptio Placentae**

Premature separation of a normal placenta, *abruptio placentae*, complicates approximately 1% to 2% of pregnancies. Most abruptions are mild (grade I), but up to 25% are severe (grade III). Risk factors include hypertension, trauma, a short umbilical cord, multiparity, prolonged premature rupture of membranes, alcohol abuse, cocaine use, and an anatomically abnormal uterus. Patients usually experience painful vaginal bleeding and exhibit tenderness to palpation. Abdominal ultrasonography can help in the diagnosis. Factors in the choice between regional and general anesthesia include urgency for delivery, maternal hemodynamic stability, and presence of coagulopathy. Hemorrhage may remain
concealed inside the uterus, contributing to underestimation of blood loss. Severe abruptio placentae can cause coagulopathy, particularly following fetal demise. Fibrinogen levels are mildly reduced (150–250 mg/dL) with moderate abruptions, but are typically less than 150 mg/dL with fetal demise. The coagulopathy is thought to be due to activation of circulating plasminogen (fibrinolysis) and the release of tissue thromboplastins that precipitate disseminated intravascular coagulation (DIC). Platelet count and factors V and VIII are low, and fibrin split products are elevated. Severe abruption is a life-threatening emergency that necessitates an emergency cesarean section. The need for massive blood transfusion, including replacement of coagulation factors and platelets, should be considered.

**Uterine Rupture**

Uterine rupture is relatively uncommon (1:1000–3000 deliveries) but can occur during labor as a result of (1) dehiscence of a scar from a previous (usually classic) cesarean section (such a trial of labor is termed *vaginal birth after cesarian* [VBAC]); extensive myomectomy or uterine reconstruction; (2) intrauterine manipulations or use of forceps (iatrogenic); or (3) spontaneous rupture following prolonged labor in patients with hypertonic contractions (particularly with oxytocin infusions), fetopelvic disproportion, or a very large, thin, and weakened uterus. Uterine rupture can present as frank hemorrhage, fetal distress, loss of uterine tone, hypotension with occult bleeding into the abdomen, or a combination of these. Even when epidural anesthesia is employed for labor, uterine rupture is often heralded by the abrupt onset of continuous abdominal pain and hypotension. Treatment requires volume resuscitation and immediate laparotomy, usually under general anesthesia. Ligation of the internal iliac (hypogastric) arteries, with or without hysterectomy, may be necessary to control hemorrhage.

**PREMATURE RUPTURE OF MEMBRANES & CHORIOAMNIONITIS**

Premature rupture of membranes (PROM) is present when leakage of amniotic fluid occurs before the onset of labor. Confirmation of this diagnosis frequently involves the *nitrazine test*: The mildly alkaline pH of amniotic fluid (>7.1) causes nitrazine paper to change color from orange to blue in contrast to normal vaginal secretions, which are acidic pH <6). PROM complicates 10% of all
pregnancies and up to 35% of premature deliveries. Predisposing factors include a short cervix, prior history of PROM or preterm delivery, infection, multiple gestations, polyhydramnios, and smoking. Spontaneous labor commences within 24 h of ruptured membranes in 90% of patients. Management of PROM balances the risk of infection with the risk of fetal prematurity. Delivery is usually indicated sometime after 34 weeks of gestation. Preterm patients with a gestation of less than 34 weeks can be managed expectantly with prophylactic antibiotics, tocolytics, and two doses of glucocorticoid (to accelerate lung maturation) to await additional maturation of fetal organs. The longer the interval between rupture and the onset of labor, the greater the likelihood of chorioamnionitis. PROM also predisposes to placental abruption and postpartum endometritis.

*Chorioamnionitis* represents infection of the chorionic and amnionic membranes, and may involve the placenta, uterus, umbilical cord, and fetus. It complicates up to 1% to 2% of pregnancies and is usually, but not always, associated with ruptured membranes. The contents of the amniotic cavity are normally sterile but become vulnerable to ascending bacterial infection from the vagina when the cervix dilates or the membranes rupture. Intraamniotic infections are less commonly caused by hematogenous spread of bacteria or retrograde seeding through the fallopian tubes. The principal maternal complications of chorioamnionitis are premature or dysfunctional labor, often leading to cesarean section, intraabdominal infection, septicemia, and postpartum hemorrhage. Fetal complications include acidosis, hypoxia, and septicemia.

Clinical signs of chorioamnionitis include fever (>38°C), maternal and fetal tachycardia, uterine tenderness, and foul-smelling or purulent amniotic fluid. Blood leukocyte count is useful only if markedly elevated because it normally increases during labor (normal average 15,000/μL). C-reactive protein levels are usually elevated (>2 mg/dL). Gram stain of amniotic fluid obtained by amniocentesis is helpful in ruling out infection.

The use of regional anesthesia in patients with chorioamnionitis is controversial because of the theoretical risk of promoting the development of meningitis or epidural abscess. However, evidence suggests that this risk is very low and that these concerns may be unjustified. In the absence of overt signs of septicemia, thrombocytopenia, or coagulopathy, most clinicians offer regional anesthesia to patients with chorioamnionitis who have received antibiotic therapy.

**PRETERM LABOR**
**Preterm labor** by definition occurs between 20 and 37 weeks of gestation and is the most common complication of the third trimester. Approximately 8% of live-born infants in the United States are delivered before term. Important contributory maternal factors include extremes of age, inadequate prenatal care, unusual body habitus, increased physical activity, infections, prior preterm labor, multiple gestation, and other medical illnesses or complications during pregnancy.

Because of their small size and incomplete development, preterm infants—particularly those less than 30 weeks of gestational age or weighing less than 1500 g—experience a greater number of complications than term infants. PROM complicates one-third of premature deliveries; the combination of PROM and premature labor increases the likelihood of umbilical cord compression, resulting in fetal hypoxemia and asphyxia. Preterm infants with a breech presentation are particularly prone to prolapse of the umbilical cord during labor. Moreover, inadequate production of pulmonary surfactant frequently leads to idiopathic respiratory distress syndrome (hyaline membrane disease) after delivery since surfactant levels are generally adequate only after week 35 of gestation. Lastly, a soft, poorly calcified cranium predisposes these neonates to intracranial hemorrhage during vaginal delivery.

When preterm labor occurs before 35 weeks of gestation, bed rest and tocolytic therapy are usually initiated, with the goal of delaying birth to allow for the maternal administration of glucocorticoid (betamethasone) to enhance fetal lung maturity. The risk of respiratory distress syndrome is markedly reduced when the amniotic fluid *lecithin/sphingomyelin ratio* is greater than 2. Treatment successfully delays birth by 48 hours in 75% of patients; however, little evidence exists that the eventual preterm delivery is prevented. The most commonly used tocolytics are $\beta_2$-adrenergic agonists (ritodrine or terbutaline) and magnesium (6 g intravenously over 30 min followed by 2–4 g/h intravenously). Ritodrine, 100 to 350 mcg/min intravenously, and terbutaline, 2.5 to 5 mg orally every 4 to 6 h, also have some $\beta_1$-adrenergic receptor activity, which accounts for some of their side effects. Maternal side effects include tachycardia, arrhythmias, myocardial ischemia, mild hypotension, hyperglycemia, hypokalemia, and, rarely, pulmonary edema. Other tocolytic agents include calcium channel blockers (nifedipine), prostaglandin synthetase inhibitors, oxytocin antagonists (atosiban), and, possibly, nitric oxide. Fetal ductal constriction can occur after 32 weeks of gestation with administration of nonsteroidal antiinflammatory drugs (NSAIDs) such as indomethacin, but is usually transient and resolves after discontinuation of the drug; NSAID-associated acute kidney injury in the fetus may cause
oligohydramnios.

Anesthesia often becomes necessary when tocolytic therapy fails to arrest labor. The goal during vaginal delivery of a preterm fetus is a slow, controlled delivery with minimal pushing by the mother. An episiotomy and low forceps assistance are often employed. Spinal or epidural anesthesia promotes complete pelvic relaxation. Cesarean section is performed for fetal distress, breech presentation, intrauterine growth retardation, or failure of labor to progress. Residual effects from β-adrenergic agonists may complicate general anesthesia. The half-life of ritodrine may be as long as 3 h. Ketamine, ephedrine, and halothane should be used cautiously due to interaction with tocolytics. Hypokalemia is usually due to an intracellular uptake of potassium and rarely requires treatment; however, it may increase sensitivity to muscle relaxants. Magnesium therapy potentiates muscle relaxants and may predispose to hypotension secondary to vasodilation. Residual effects from tocolytics interfere with uterine contraction following delivery. Lastly, preterm newborns are often depressed at delivery and frequently need resuscitation; therefore, preparations for resuscitation should be completed prior to delivery.

HYPERTENSIVE DISORDERS

Hypertension during pregnancy can be classified as pregnancy-induced hypertension (PIH, often also referred to as preeclampsia), chronic hypertension that preceded pregnancy, or chronic hypertension with superimposed preeclampsia. Preeclampsia is usually defined as a systolic blood pressure greater than 140 mm Hg or diastolic pressure greater than 90 mm Hg on two occasions at least 4 h apart after the 20th week of gestation in a woman with previously normal blood pressure, accompanied by proteinuria (>300 mg/d) or protein/creatinine ratio greater than 0.3, and resolving within 48 h after delivery. When seizures occur, the syndrome is termed eclampsia. HELLP syndrome describes preeclampsia associated with hemolysis, elevated liver enzymes, and a low platelet count. In the United States, preeclampsia complicates approximately 7% to 10% of pregnancies; eclampsia is much less common, occurring in 1 of 10,000 to 15,000 pregnancies. Severe preeclampsia causes or contributes to 20% to 40% of maternal deaths and 20% of perinatal deaths. Maternal deaths are usually due to stroke, pulmonary edema, hepatic necrosis or rupture, or a combination of these complications.

Pathophysiology & Manifestations
The pathophysiology of preeclampsia is related to vascular dysfunction of the placenta, resulting in abnormal prostaglandin metabolism. Patients with preeclampsia have elevated production of thromboxane A₂ (TXA₂) and decreased production of prostacyclin (PGI₂). TXA₂ is a potent vasoconstrictor and promoter of platelet aggregation, whereas PGI₂ is a potent vasodilator and inhibitor of platelet aggregation. Endothelial dysfunction may reduce production of nitric oxide and increase production of endothelin-1. The latter is also a potent vasoconstrictor and activator of platelets. Marked vascular reactivity and endothelial injury reduce placental perfusion and can lead to widespread systemic manifestations.

Severe preeclampsia substantially increases both maternal and fetal morbidity and mortality. Features of severe preeclampsia include the standard features of preeclampsia in association with any of the following: blood pressure greater than 160/110 mm Hg, thrombocytopenia (<100,000/μL), proteinuria greater than 5 g/d, impaired liver function, progressive kidney insufficiency (serum creatinine concentration greater than 1.1 mg/dl oliguria, pulmonary edema, and CNS signs or symptoms (headache or visual disturbances; Table 41-6). Hepatic rupture may occur in patients with the HELLP syndrome.

Patients with severe preeclampsia or eclampsia have widely differing hemodynamic profiles. Most patients have low-normal cardiac filling pressures with increased systemic vascular resistance, but cardiac output may be reduced, normal, or increased.

Treatment

Treatment of preeclampsia consists of bed rest, sedation, repeated doses of antihypertensive drugs (usually labetalol, 5–10 mg, or hydralazine, 5 mg intravenously), and magnesium sulfate (4 g loading followed by 1–3 g/h intravenously) to treat hyperreflexia and prevent convulsions. Therapeutic magnesium levels are 4 to 6 mEq/L. It is recommended that corticosteroids be given if the fetus is viable and 33 weeks of gestation or less.

Invasive arterial and central venous monitoring are indicated in patients with severe hypertension, pulmonary edema, refractory oliguria, or a combination of these; in such patients an intravenous vasodilator infusion may be necessary. Definitive treatment of preeclampsia is delivery of the fetus and placenta.
Anesthetic Management

Standard anesthetic practices may be used for patients with mild preeclampsia. Spinal and epidural anesthesia are associated with similar decreases in arterial blood pressure in these patients. Patients with severe disease, however, are critically ill and require stabilization prior to administration of any anesthetic, including control of hypertension and correction of hypovolemia. In the absence of coagulopathy, continuous epidural anesthesia is the first choice for most patients with preeclampsia during labor and vaginal delivery. Moreover, continuous epidural anesthesia avoids the increased risk of a failed intubation due to severe edema of the upper airway.

A platelet count and coagulation profile should be checked prior to the institution of regional anesthesia in patients with severe preeclampsia. It has been recommended that regional anesthesia be avoided if the platelet count is less than 100,000/μL, but a platelet count as low as 50,000/μL may be acceptable in selected cases, particularly when the count has been stable and global coagulation, as measured by thrombelastography testing, is normal. Continuous epidural anesthesia decreases catecholamine secretion and improves uteroplacental perfusion by up to 75% in these patients, provided hypotension is avoided. Judicious fluid boluses may be required to correct hypovolemia. Goal-directed hemodynamic and fluid therapy utilizing arterial pulse wave contour analysis or other noninvasive cardiac function monitors such as echocardiography may be employed to guide fluid replacement. Use of an epinephrine-containing test dose for epidural anesthesia is controversial because of questionable reliability (see the earlier section, Prevention of Unintentional Intravascular and Intrathecal Injection) and the risk of exacerbating hypertension. Hypotension should be treated with smaller than usual doses of vasopressors because these patients tend to be very sensitive to these agents. Recent evidence suggests that spinal anesthesia does not, as previously thought, result in a more severe reduction of maternal blood pressure. Therefore, both spinal and epidural anesthetics are reasonable choices for cesarean section in a preeclamptic patient.

Intraarterial blood pressure monitoring is indicated in patients with severe hypertension during both general and regional anesthesia. Intravenous vasodilator infusions may be necessary to control blood pressure during general anesthesia. Intravenous labetalol (5–10-mg increments) can also be effective in controlling the hypertensive response to intubation and does not appear to alter placental blood flow. The short-term administration of intravenous nicardipine or clevipidine may be used to treat intraoperative hypertension. Because
magnesium potentiates muscle relaxants, doses of nondepolarizing muscle relaxants should be reduced in patients receiving magnesium therapy and should be guided by a peripheral nerve stimulator. The patient with suspected magnesium toxicity, manifested by hyporeflexia, excessive sedation, blurred vision, respiratory compromise, and cardiac depression, can be treated with intravenous administration of calcium gluconate (1 g over 10 min).

**HEART DISEASE**

The marked cardiovascular changes associated with pregnancy, labor, and delivery often cause the 2% of parturients with heart disease to decompensate during this period. Although most pregnant patients with cardiac disease have rheumatic heart disease, an increasing number of parturients are presenting with corrected or palliated congenital lesions. Anesthetic management is directed toward employing techniques that minimize the added stresses of labor and delivery, and specific management of the various lesions is discussed elsewhere. Most patients can be divided into one of two groups. Patients in the first group benefit from the reduced systemic vascular resistance caused by neuraxial analgesia and anesthesia techniques, but usually not from excessive fluid administration. These patients include those with mitral or aortic insufficiency, chronic heart failure, or congenital lesions with left-to-right shunting. The induced sympathectomy from spinal or epidural techniques reduces both preload and afterload, relieves pulmonary congestion, and in some cases, increases cardiac output.

Patients in the second group do not benefit from a decrease in systemic vascular resistance. These patients include those with aortic stenosis, congenital lesions with right-to-left or bidirectional shunting, or primary pulmonary hypertension. Reductions in venous return (preload) or afterload are usually poorly tolerated. These patients are better managed with intraspinal opioids alone, systemic medications, pudendal nerve blocks, and, if necessary, general anesthesia.

**AMNIOTIC FLUID EMBOLISM**

Amniotic fluid embolism is a rare (1:20,000 deliveries) but often lethal complication (86% mortality rate in some series) that can occur during labor, delivery, or cesarean section, or postpartum. Mortality may exceed 50% in the first hour. Entry of amniotic fluid into the maternal circulation can occur through any break in the uteroplacental membranes. Such breaks may occur during
normal delivery or cesarean section or following placental abruption, placenta previa, or uterine rupture. In addition to the mechanical effects of fetal debris, various prostaglandins and leukotrienes in amniotic fluid appear to play an important role in the genesis of this syndrome. The alternate term anaphylactoid syndrome of pregnancy has been suggested to emphasize the systemic role of chemical mediators.

Patients typically present with sudden tachypnea, cyanosis, shock, and generalized bleeding. Three major pathophysiological manifestations are responsible: (1) acute pulmonary embolism, (2) DIC, and (3) uterine atony. Mental status changes, including seizures, and pulmonary edema may develop; the latter has both cardiogenic and noncardiogenic components. Acute left ventricular dysfunction is common. Although the diagnosis can be firmly established only by demonstrating fetal elements in the maternal circulation (usually at autopsy or less commonly by aspirating amniotic fluid from a central venous catheter), amniotic fluid embolism should always be suggested by sudden respiratory distress and circulatory collapse. The presentation may initially mimic acute pulmonary thromboembolism, venous air embolism, overwhelming septicemia, or hepatic rupture or cerebral hemorrhage in a patient with toxemia.

Treatment consists of cardiopulmonary resuscitation and supportive care. When cardiac arrest occurs prior to delivery of the fetus, the efficacy of closed-chest compressions may be marginal at best. Aortocaval compression impairs resuscitation in the supine position, whereas chest compressions are less effective in a lateral tilt position. Expeditious delivery appears to improve maternal and fetal outcome, and immediate cesarean delivery should therefore be carried out. Once the patient is resuscitated, mechanical ventilation, fluid resuscitation, and inotropes are best provided under the guidance of invasive hemodynamic monitoring. Uterine atony is treated with oxytocin, methylergonovine, and prostaglandin F$_{2\alpha}$, whereas significant coagulopathies are treated with platelets and coagulation factors based on laboratory findings.

**POSTPARTUM HEMORRHAGE**

Postpartum hemorrhage is the leading cause of maternal mortality in developing countries, and it is diagnosed when postpartum blood loss exceeds 500 mL. Up to 4% of parturients may experience postpartum hemorrhage, which is often associated with a prolonged third stage of labor, preeclampsia, multiple gestations, and forceps delivery. Common causes include uterine atony, a
retained placenta, obstetric lacerations, uterine inversion, and use of tocolytic agents prior to delivery. Atony is often associated with uterine overdistention (multiple gestation and polyhydramnios). Less commonly, a clotting defect may be responsible.

The anesthesiologist may be consulted to assist in venous access or fluid and blood resuscitation, as well as to provide anesthesia for careful examination of the vagina, cervix, and uterus. Perineal lacerations can usually be repaired with local anesthetic infiltration or pudendal nerve blocks. Residual anesthesia from prior epidural or spinal anesthesia facilitates examination of the patient; however, supplementation with an opioid, nitrous oxide, or both may be required. Induction of spinal or epidural anesthesia should be avoided in the presence of marked hypovolemia. **General anesthesia is usually required for manual extraction of a retained placenta, reversion of an inverted uterus, or repair of a major laceration.** Uterine atony should be treated with oxytocin (a slow 0.3–1 IU intravenous bolus of oxytocin over 1 min, followed by an infusion of 5–10 IU/h), methylergonovine (0.2 mg in 100 mL of normal saline administered over 10 min intravenously), and prostaglandin F$_2$α (0.25 mg intramuscularly). Emergency laparotomy and hysterectomy may be necessary in rare instances. Early ligation of the internal iliac (hypogastric) arteries may help avoid hysterectomy and reduce blood loss.

---

**Fetal & Neonatal Resuscitation**

**FETAL RESUSCITATION**

Resuscitation of the neonate starts during labor. Any compromise of the uteroplacental circulation readily produces fetal asphyxia. **Intrauterine asphyxia during labor is the most common cause of neonatal depression.** Fetal monitoring throughout labor is helpful in identifying which fetuses may be at risk, detecting fetal distress, and evaluating the effect of acute interventions. These include correcting maternal hypotension with fluids or vasopressors, providing supplemental oxygen, and decreasing uterine contraction (stopping oxytocin or administering tocolytics). Some studies suggest that the normal fetus can compensate for up to 45 min of relative hypoxia, a period termed *fetal stress*; the latter is associated with a marked redistribution of blood flow primarily to the heart, brain, and adrenal glands. With time, however, progressive lactic acidosis and asphyxia produce increasing fetal distress that necessitates
immediate delivery.

1. Fetal Heart Rate Monitoring

Monitoring of fetal heart rate (FHR) is presently the most useful technique in assessing fetal well-being, although alone it has a 35% to 50% false-positive rate of predicting fetal compromise. Because of this, the term *fetal distress* in the context of FHR monitoring has been largely replaced with *nonreassuring* FHR. Correct interpretation of heart rate patterns is crucial. Three parameters are evaluated: baseline heart rate, baseline variability, and the relationship to uterine contractions (deceleration patterns). Monitoring of heart rate is most accurate when fetal scalp electrodes are used, but this may require rupture of the membranes and is not without complications (eg, amnionitis or fetal injury). Based on concerns about a lack of consistency in interpretation and management of FHR, a three-tier FHR system was developed. **Category I** tracings are normal. **Category II** tracings are indeterminate and do not predict abnormal fetal acid base status. **Category III** tracings are abnormal and include either absent baseline variability with recurrent late or variable decelerations or bradycardia, or the presence of a sinusoidal pattern. They predict abnormal fetal acid–base status.

**Baseline Heart Rate**

The mature fetus normally has a baseline heart rate of 110 to 160 beats/min. An increased baseline heart rate may be due to prematurity, mild fetal hypoxia, chorioamnionitis, maternal fever, maternally administered drugs (anticholinergics or β-agonists), or, rarely, hyperthyroidism. A decreased baseline heart rate may be due to a postterm pregnancy, fetal heart block, or fetal asphyxia.

**Baseline Variability**

The healthy mature fetus normally displays a baseline beat-to-beat (R-wave to R-wave) variability that can be classified as *minimal* (<5 beats/min), *moderate* (6–25 beats/min), or *marked* (>25 beats/min). Baseline variability, which is best assessed with scalp electrodes, has become an important sign of fetal well-being and represents a normally functioning autonomic system. *Sustained decreased baseline variability is a prominent sign of fetal asphyxia.* CNS depressants (opioids, barbiturates, volatile anesthetics, benzodiazepines, or magnesium
sulfate) and parasympatholytics (atropine) also decrease baseline variability, as do prematurity, fetal arrhythmias, and anencephaly. A sinusoidal pattern that resembles a smooth sine wave is associated with fetal depression (hypoxia, drugs, and anemia secondary to Rh isoimmunization).

**Accelerations**

Accelerations of FHR are defined as increases of 15 beats/min or more lasting for more than 15 s. Periodic accelerations in FHR reflect normal oxygenation and are usually related to fetal movements and to responses to uterine pressure. Such accelerations are generally considered reassuring. By 32 weeks, fetuses display periodic increases in baseline heart rate that are associated with fetal movements. Normal fetuses have 15 to 40 accelerations/h, and the mechanism is thought to involve increases in catecholamine secretion with decreases in vagal tone. Accelerations diminish with fetal sleep, some drugs (opiods, magnesium, and atropine), as well as fetal hypoxia. Accelerations to fetal scalp or vibroacoustic stimulation are considered a reassuring sign of fetal well-being. *The absence of both baseline variability and accelerations is nonreassuring and may be an important sign of fetal compromise.*

**Deceleration Patterns**

**A. Early (Type I) Decelerations**

Early deceleration (usually 10–40 beats/min) ([Figure 41–4A](#)) is thought to be a vagal response to compression of the fetal head or stretching of the neck during uterine contractions. The heart rate forms a smooth mirror image of the contraction. Early decelerations are generally not associated with fetal distress and occur during descent of the head.
Figure 41–4 Periodic changes in fetal heart rate related to uterine contraction. 

A: Early (type I) decelerations. B: Late (type II) decelerations. C: Variable (type III) decelerations. (Reproduced with permission from Danforth DN, Scott JR. Obstetrics and Gynecology. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1986.)

B. Late (Type II) Decelerations

Late decelerations (Figure 41–4B) are associated with placental insufficiency and fetal compromise and are characterized by a decrease in heart rate at or following the peak of uterine contractions. Late decelerations may be subtle (as few as 5 beats/min) and are thought to represent the impact of decreased arterial oxygen tension on atrial chemoreceptors. Late decelerations with normal variability may be observed following acute insults (maternal hypotension or hypoxemia) and are usually reversible with treatment. Late decelerations with
decreased variability are associated with prolonged asphyxia and may be an indication for fetal scalp sampling (see section on Other Monitoring). *Complete abolition of variability in this setting is an ominous sign signifying severe decompensation and the need for immediate delivery.*

C. Variable (Type III) Decelerations

The most common type of deceleration is variable (Figure 41–4C). These decelerations are variable in onset, duration, and magnitude (often >30 beats/min). They are typically abrupt in onset and are thought to be related to umbilical cord compression and acute intermittent decreases in umbilical blood flow. Variable decelerations are typically associated with fetal asphyxia when fetal heart rate declines to less than 60 beats/min, fetal bradycardia lasts more than 60 s, or recurrent bradycardia occurs in a pattern that persists for more than 30 min.

2. Other Monitoring

Other less commonly used monitors include fetal scalp pH measurements, scalp lactate concentration, fetal pulse oximetry, and fetal ST-segment analysis. Clinical experience is limited with all of these modalities except fetal scalp pH measurements. Unfortunately, fetal scalp pH measurement is associated with a small but significant incidence of false negatives and false positives. Fetal blood can be obtained and analyzed via a small scalp puncture once the membranes are ruptured. A fetal scalp pH higher than 7.20 is usually associated with a vigorous neonate, whereas a pH less than 7.20 is often, but not always, associated with a depressed neonate and necessitates prompt (typically operative) delivery. Because of wide overlap, fetal blood sampling can be interpreted correctly only in conjunction with heart rate monitoring.

3. Treatment of the Fetus

Treatment of intrauterine fetal asphyxia is aimed at preventing fetal demise or permanent neurological damage. All interventions are directed at restoring an adequate uteroplacental circulation. Aortocaval compression, maternal hypoxemia or hypotension, or excessive uterine activity (during oxytocin infusions) must be corrected. Changes in maternal position, supplemental oxygen, and intravenous ephedrine or fluid, or adjustments in an oxytocin infusion often correct the problem. *Failure to relieve fetal stress, as well as progressive fetal acidosis and asphyxia, necessitate immediate delivery.*
1. General Care of the Neonate

One health care provider whose sole responsibility is to care for the neonate and who is capable of providing resuscitation should attend every delivery. As the head is delivered, the nose, mouth, and pharynx are suctioned with a bulb syringe. After the remainder of the body is delivered, the skin is dried with a sterile towel. Once the umbilical cord stops pulsating or neonatal breathing is initiated, the cord is clamped and the neonate is placed in a radiant warmer with the bed tilted in a slight Trendelenburg position.

Neonatal evaluation and treatment are carried out simultaneously (Figure 41–5). If the neonate is obviously depressed, the cord is clamped early and resuscitation is initiated immediately. Breathing normally begins within 30 s and is sustained within 90 s. Respirations should be 30 to 60 breaths/min and the heart rate 120 to 160 beats/min. Respirations are assessed by auscultation of the chest, whereas heart rate is determined by palpation of the pulse at the base of the umbilical cord or auscultation of the precordium. The neonate must be kept warm.
FIGURE 41–5 An algorithm for resuscitation of the newly born infant.
In addition to respirations and heart rate, color, tone, and reflex irritability should be evaluated. The Apgar score (Table 41–7), recorded at 1 min and again at 5 min after delivery, remains the most valuable assessment of the neonate. The 1-min score correlates with survival, whereas the 5-min score has limited relationship to neurological outcome.

Neonates with Apgar scores of 8 to 10 are vigorous and may require only gentle stimulation (flicking the foot, rubbing the back, and additional drying). A catheter should first be gently passed through each nostril to rule out choanal atresia, and then through the mouth to suction the stomach and rule out esophageal atresia.

### 2. Meconium-Stained Neonates

The presence or absence of meconium in the amniotic fluid (approximately 10% to 12% of deliveries) changes the immediate management of the neonate at birth.
Fetal distress, particularly after 42 weeks of gestation, is often associated with release of thick meconium into the amniotic fluid. Fetal gasping during stress results in entry of a large amount of meconium-containing amniotic fluid into the lungs. When the neonate initiates respiration at birth, the meconium moves from the trachea and large airways down toward the periphery of the lung. Thick or particulate meconium may obstruct small airways and cause severe respiratory distress in 15% of meconium-stained neonates. Moreover, these infants can develop persistent fetal circulation.

Unless the neonate has absent or depressed respirations, thin watery meconium does not require suctioning beyond careful bulb suctioning of the oropharynx when the head emerges from the perineum (or from the uterus at cesarean section). When thick meconium is present in the amniotic fluid, however, some clinicians intubate and suction the trachea immediately after delivery but before the first breath is taken. However, recent evidence has challenged the benefit of tracheal suctioning even in the depressed infant. Tracheal suctioning of the thick meconium is accomplished by a special suctioning device attached to the endotracheal tube as the tube is withdrawn. If meconium is aspirated from the trachea, the procedure should be repeated until no meconium is obtained—but no more than three times, after which it is usually of no further benefit. The infant should then be given supplemental oxygen by face mask and observed closely. The stomach should also be suctioned to prevent passive regurgitation of any meconium. Newborns with meconium aspiration have an increased incidence of pneumothorax (10% compared with 1% for all vaginal deliveries).

3. Care of the Depressed Neonate

Approximately 6% of newborns require some form of advanced life support. Resuscitation of these depressed neonates, most of whom weigh less than 1500 g, requires two or more caregivers—one to manage the airway and ventilation and another to perform chest compressions, if necessary. A third caregiver greatly facilitates placement of intravascular catheters and administration of fluids or drugs, or both. The anesthesiologist caring for the mother can render only brief assistance and only when it does not jeopardize the mother; other personnel are, therefore, usually responsible for neonatal resuscitation.

Because the most common cause of neonatal depression is intrauterine asphyxia, the emphasis in resuscitation is on respiration and oxygenation. Hypovolemia is also a contributing factor in a significant number of neonates. Factors associated with hypovolemia include early clamping of the umbilical
cord, holding the neonate above the introitus prior to clamping, prematurity, maternal hemorrhage, placental transection during cesarean section, sepsis, and twin-to-twin transfusion.

Failure of the neonate to quickly respond to respiratory resuscitative efforts mandates vascular access and blood gas analysis; pneumothorax (1% incidence) and congenital anomalies of the airway, including tracheoesophageal fistula (1:3000–5000 live births), and congenital diaphragmatic hernia (1:2000–4000 live births) should be considered.

Grouping by the 1-min Apgar score greatly facilitates resuscitation: (1) mildly asphyxiated neonates (Apgar score of 5–7) usually need only stimulation while 100% oxygen is blown across the face; (2) moderately asphyxiated neonates (Apgar score of 3–4) require temporary assisted positive-pressure ventilation with mask and bag; and (3) severely depressed neonates (Apgar score of 0–2) should be immediately intubated, and chest compressions may be required.

**Guidelines for Ventilation**

Indications for positive-pressure ventilation of the neonate include (1) apnea, (2) gasping respirations, (3) persistent central cyanosis with 100% oxygen, and (4) a persistent heart rate less than 100 beats/min. Excessive flexion or extension of the neck can cause airway obstruction. A 1-inch-high towel under the shoulders may be helpful in maintaining proper head position. Assisted ventilation by bag and mask should be at a rate of 30 to 60 breaths/min with 100% oxygen. Initial breaths may require peak pressures of up to 40 cm H₂O, but pressures should not exceed 30 cm H₂O thereafter. Adequacy of ventilation should be checked by auscultation and chest excursions. Gastric decompression with an 8F tube often facilitates ventilation. If after 30 s the heart rate is greater than 100 beats/min and spontaneous ventilations become adequate, assisted ventilation is no longer necessary. If the heart rate remains less than 60 beats/min or 60 to 80 beats/min without an increase in response to resuscitation, the neonate is intubated and chest compressions are started. If the heart rate is 60 to 80 beats/min and increasing, assisted ventilation is continued and the neonate is observed. Failure of the heart rate to rise above 80 beats/min is an indication for chest compressions. Indications for endotracheal intubation also include ineffective or prolonged mask ventilation and the need to administer medications.

Intubation (Figure 41–6) is performed with a Miller 00, 0, or 1 laryngoscope blade, using a 2.5-, 3-, or 3.5-mm endotracheal tube (for neonates <1 kg, 1–2 kg,
Correct endotracheal tube size is indicated by a small leak with 20 cm H$_2$O pressure. Right endobronchial intubation should be excluded by chest auscultation. The correct depth of the endotracheal tube (“tip to lip”) is usually 6 cm plus the weight in kilograms. Oxygen saturation can usually be measured by a pulse oximeter probe applied to the palm. Capnography should be used to confirm endotracheal intubation. Transcutaneous oxygen sensors are useful for measuring tissue oxygenation but require time for initial equilibration. Use of a laryngeal mask airway (LMA#1) has been reported in neonates weighing more than 2.5 kg and may be useful if endotracheal intubation is difficult (eg, Pierre Robin syndrome).

**FIGURE 41–6** Intubation of the neonate. The head is placed in a neutral position, and the laryngoscope handle is held with the thumb and index finger as the chin is supported with the remaining fingers. Pressure applied over the hyoid bone with the little finger will bring the larynx into view. A straight blade such as a Miller 0 or 1 usually provides the best view.

**Guidelines for Chest Compressions**

*Indications for chest compressions are a heart rate that is less than 60 beats/min or 60 to 80 beats/min and not rising after 30 s of adequate ventilation with 100% oxygen.*
Cardiac compressions should be provided at a rate of 120/min. The two thumb/encircling hands technique (Figure 41–7) is generally preferred because it appears to generate higher peak systolic and coronary perfusion pressures. Alternatively, the two-finger technique can be used (Figure 41–8). The depth of compressions should be approximately one third of the anterior–posterior diameter of the chest and sufficient to generate a palpable pulse.

**FIGURE 41–7** Chest compressions in the neonate. The neonate is held with both hands as each thumb is placed just beneath a line connecting the nipples and the remaining fingers encircle the chest. The sternum is compressed $1/3$ to $3/4$ in. (1 cm) at a rate of 120/min. (Reproduced with permission from Rudolph CD, Rudolph AM, Lister GE, et al. *Rudolph's Pediatrics*. 22nd ed. New York, NY: McGraw-Hill; 2011.)
FIGURE 41–8 The alternative technique for neonatal chest compressions: two fingers are placed on the lower third of the sternum at right angles to the chest. The chest is compressed approximately 1 cm at a rate of 120/min.

Compressions should be interposed with ventilation in a 3:1 ratio, such that 90 compressions and 30 ventilations are given per minute. The heart rate should be checked periodically. Chest compressions should be stopped when the spontaneous heart rate exceeds 80 beats/min.

**Vascular Access**

Cannulation of the umbilical vein with a 3.5F or 5F umbilical catheter is easiest and the preferred technique. The tip of the catheter should be just below skin level and allow free backflow of blood; further advancement may result in infusion of hypertonic solutions directly into the liver. A peripheral vein or even the endotracheal tube can be used as an alternate route for drug administration.

Cannulation of one of the two umbilical arteries allows measurement of blood pressure and facilitates blood gas measurements but may be more difficult. Specially designed umbilical artery catheters allow continuous Pao$_2$ or oxygen saturation monitoring as well as blood pressure. Care must be taken not to introduce any air into either the artery or the vein.

**Volume Resuscitation**

Nearly two-thirds of premature infants requiring resuscitation are hypovolemic
at birth. Diagnosis is based on physical examination and a poor response to resuscitation. Neonatal blood pressure generally correlates with intravascular volume and should therefore routinely be measured. Normal blood pressure depends on birth weight and varies from 50/25 mm Hg for neonates weighing 1 to 2 kg to 70/40 mm Hg for those weighing over 3 kg. A low blood pressure and pallor suggest hypovolemia. Volume expansion may be accomplished with 10 mL/kg of lactated Ringer’s injection, normal saline, or type O-negative blood cross-matched with maternal blood. Less common causes of hypotension include hypocalcemia, hypermagnesemia, and hypoglycemia.

**Drug Therapy**

**A. Epinephrine**

Epinephrine, 0.01 to 0.03 mg/kg (0.1–0.3 mL/kg of a 1:10,000 solution), should be given for asystole or a spontaneous heart rate of less than 60 beats/min in spite of adequate ventilation and chest compressions. It may be repeated every 3 to 5 min. Epinephrine may be given in 1 mL of saline via the endotracheal tube when venous access is not available.

**B. Naloxone**

Naloxone, 0.1 mg/kg intravenously or 0.2 mg/kg intramuscularly, may be given to reverse the respiratory depressant effect of opioids given to the mother in the last 4 h of labor. Withdrawal symptoms may be precipitated in babies of mothers who chronically consume opioids.

**C. Other Drugs**

Other drugs may be indicated only in specific settings. Sodium bicarbonate (2 mEq/kg of a 0.5 mEq/mL 4.2% solution) should usually be given only for a severe metabolic acidosis documented by blood gas measurements and when ventilation is adequate. It may also be administered during prolonged (>5 min) resuscitation—particularly if blood gas measurements are not readily available. The infusion rate should not exceed 1 mEq/kg/min to avoid hypertonicity and intracranial hemorrhage. As previously noted, in order to prevent hypertonicity-induced hepatic injury, the tip of the umbilical vein catheter should not be in the liver. Calcium gluconate 100 mg/kg (CaCl₂, 30 mg/kg) should be given only to neonates with documented hypocalcemia or those with suspected magnesium intoxication (from maternal magnesium therapy); these neonates are usually hypotensive, hypotonic, and appear vasodilated. Glucose (8 mg/kg/min of a 10%
solution) is given only for documented hypoglycemia because hyperglycemia worsens hypoxic neurological deficits. Blood glucose should be measured because up to 10% of neonates may have hypoglycemia (glucose <35 mg/dL), particularly those delivered by cesarean section. Dopamine may be started at 5 mcg/kg/min to support arterial blood pressure. Lastly, surfactant may be given through the endotracheal tube to premature neonates with respiratory distress syndrome.

CASE DISCUSSION

Appendicitis in a Pregnant Woman
A 31-year-old woman with a 24-week gestation presents for an appendectomy.

How does pregnancy complicate the management of this patient?

Approximately 1% to 2% of pregnant patients require surgery during their pregnancy. The most common procedure during the first trimester is laparoscopy; appendectomy (1:1500 pregnancies) and cholecystectomy (1:2000–10,000 pregnancies) are the most commonly performed general surgical procedures. Cervical cerclage may be necessary in some patients for cervical incompetence. The physiological effects of pregnancy can alter the manifestations of disease process and make diagnosis difficult. Patients may therefore present with advanced or complicated disease. The physiological changes associated with pregnancy (see Chapter 40) further predispose the patient to increased morbidity and mortality. Moreover, both the operation and the anesthesia can adversely affect the fetus.

What are the potentially detrimental effects of surgery and anesthesia on the fetus?

The procedure can have both immediate and long-term adverse effects on the fetus. Maternal hypotension, hypovolemia, severe anemia, hypoxemia, and marked increases in sympathetic tone can seriously compromise the transfer of oxygen and other nutrients across the uteroplacental circulation and promote intrauterine fetal asphyxia. The
stress of the operative procedure and the underlying surgical disease process may also precipitate preterm labor, which often follows intraabdominal surgery near the uterus. Laparoscopy may be safely performed. Mild to moderate maternal hyperventilation and limiting both insufflation pressure and duration of the procedure limit the degree of fetal acidosis. Long-term detrimental effects relate to possible teratogenic effects on the developing fetus.

**When is the fetus most sensitive to teratogenic influences?**

Three stages of susceptibility are generally recognized. In the first 2 weeks of intrauterine life, teratogens have either a lethal effect or no effect on the embryo. *The third to eighth weeks are the most critical period, when organogenesis takes place; drug exposure during this period can produce major developmental abnormalities.* From the eighth week onward, organogenesis is complete, and organ growth takes place. Teratogen exposure during this last period usually results in only minor morphological abnormalities but can produce significant physiological abnormalities and growth retardation. Although the teratogenic influences of anesthetic agents have been extensively studied in animals, retrospective human studies have been inconclusive. Past concerns about possible teratogenic effects of nitrous oxide and benzodiazepines do not appear to be justified. Nonetheless, exposure to all anesthetic agents should be kept to a minimum. We tend to administer only those agents that are required for the pregnant patient—and in our practice, nitrous oxide is never required and benzodiazepines are only rarely needed.

**What would be the ideal anesthetic technique in this patient?**

Toward the end of the second trimester (after 20–24 weeks of gestation), most of the major physiological changes associated with pregnancy have taken place. Regional anesthesia, when feasible, is preferable to general anesthesia in order to decrease the risks of pulmonary aspiration and failed intubation and to minimize drug exposure to the fetus. The patient should be maintained with left lateral uterine displacement when supine. Total drug exposure is least with spinal anesthesia. Moreover, spinal anesthesia may be preferable to epidural anesthesia because it is not associated with unintentional intravascular injection or the potential for accidental intrathecal injection of large epidural doses of local anesthetic. On the other hand, general anesthesia guarantees patient comfort and, when a volatile
agent is used, may even suppress preterm labor (see Chapter 40). Nitrous oxide without concomitant administration of a halogenated anesthetic is reported to reduce uterine blood flow.

Although regional anesthesia is preferable in most instances, the choice between regional and general anesthesia must be individualized according to the patient, the anesthesiologist, and the type of surgery. Spinal anesthesia is usually satisfactory for open appendectomies, whereas general anesthesia is appropriate for laparoscopic procedures.

**Are any special monitors indicated perioperatively?**

In addition to standard monitors, fetal heart rate and uterine activity should be monitored with a Doppler and tocodynamometer immediately prior to surgery and during anesthesia recovery in a woman who is 24 weeks or more pregnant. When regular organized uterine activity is detected, early treatment with a β-adrenergic agonist such as ritodrine usually aborts the preterm labor. Magnesium sulfate and oral or rectal indomethacin may also be used as tocolytics.

**When should elective operations be performed during pregnancy?**

All elective operations should be postponed until 6 weeks after delivery. Only emergency procedures that pose an immediate threat to the mother or fetus should be routinely performed. The timing of semielective procedures, such as those for cancer, valvular heart disease, or intracranial aneurysms, must be individualized and must balance the threat to maternal health versus fetal well-being. Controlled (deliberate) hypotensive anesthesia has been utilized to reduce blood loss during extensive cancer operations; nitroprusside, nitroglycerin, and hydralazine have been used during pregnancy without apparent fetal compromise. Nonetheless, large doses and prolonged infusions of nitroprusside should be avoided because the immature liver of the fetus may have a limited ability to metabolize the cyanide breakdown product. Cardiopulmonary bypass has been employed in pregnant patients successfully without adverse fetal outcome. Elective use of circulatory arrest during pregnancy is not recommended.

**SUGGESTED READINGS**

Pediatric Anesthesia

KEY CONCEPTS

1. Neonates and infants have fewer and smaller alveoli, reducing lung compliance; in contrast, their cartilaginous rib cage makes their chest wall very compliant. The combination of these two characteristics promotes chest wall collapse during inspiration and relatively low residual lung volumes at expiration. The resulting decrease in functional residual capacity (FRC) limits oxygen reserves during periods of apnea (e.g., intubation attempts) and readily predisposes them to atelectasis and hypoxemia.

2. Compared with older children and adults, neonates and infants have a proportionately larger head and tongue, narrower nasal passages, an anterior and cephalad larynx, a longer epiglottis, and a shorter trachea and neck. These anatomic features make neonates and young infants obligate nasal breathers until about 5 months of age. The cricoid cartilage is the narrowest point of the airway in children younger than 5 years of age.

3. Cardiac stroke volume is relatively fixed by the immature, noncompliant left ventricle in neonates and infants. The cardiac output is therefore very sensitive to changes in heart rate.

4. Thin skin, low fat content, and a greater surface area relative to weight promote greater heat loss to the environment in neonates. Heat loss can be made worse by prolonged exposure to an inadequately warmed operating room environment, administration of room-temperature intravenous fluid, and dehumidified anesthetic gases, and the effects of anesthetic agents on temperature regulation. Hypothermia has been associated with delayed awakening from anesthesia, cardiac arrhythmias, respiratory depression, increased pulmonary vascular resistance, and increased susceptibility to anesthetics and other agents.
Neonates, infants, and young children have relatively greater alveolar ventilation and reduced FRC compared with older children and adults. This greater minute ventilation-to-FRC ratio contributes to a rapid increase in alveolar anesthetic concentration that, combined with relatively greater blood flow to the brain, speeds inhalation induction.

The minimum alveolar concentration (MAC) for halogenated agents is greater in infants than in neonates and adults. In contrast to other agents, no increase in the MAC of sevoflurane can be demonstrated between neonates and infants. Sevoflurane appears to have a greater therapeutic index than halothane and is the preferred agent for inhaled induction in pediatric anesthesia.

Children are more susceptible than adults to cardiac arrhythmias, hyperkalemia, rhabdomyolysis, myoglobinemia, masseter spasm, and malignant hyperthermia associated with succinylcholine. When a child experiences cardiac arrest following administration of succinylcholine, immediate treatment for hyperkalemia should be instituted.

Unlike adults, children may have profound bradycardia and sinus node arrest following the first dose of succinylcholine without atropine pretreatment.

A viral infection within 2 to 4 weeks before general anesthesia and endotracheal intubation appears to place the child at an increased risk for perioperative pulmonary complications, such as wheezing, laryngospasm, hypoxemia, and atelectasis.

Temperature must be closely monitored in pediatric patients because of their greater risk for malignant hyperthermia and greater susceptibility for intraoperative hypothermia or hyperthermia.

Meticulous attention to fluid intake and loss is required in younger pediatric patients because these patients have limited margins of error. A programmable infusion pump or a buret with a microdrip chamber is useful for accurate measurements. Drugs can be flushed through low dead-space tubing to minimize unnecessary fluid administration.

Laryngospasm can usually be avoided by extubating the patient either while awake or while deeply anesthetized; both techniques have advocates. Extubation during the interval between these extremes, however, is generally recognized as more hazardous.

Patients with scoliosis due to muscular dystrophy are predisposed to malignant hypertension, cardiac arrhythmias, and untoward effects of succinylcholine (hyperkalemia, myoglobinuria, and sustained muscular
Pediatric anesthesia involves more than simply adjusting drug doses and equipment for smaller patients. Neonates (0–1 months), infants (1–12 months), toddlers (12–24 months), and young children (2–12 years of age) have differing anesthetic requirements. A safe anesthetic requires attention to the physiological, anatomic, and pharmacological characteristics of each group (Table 42–1). Risk is generally inversely proportional to age, and infants are at much greater risk of anesthetic morbidity and mortality than older children. In addition, pediatric patients are prone to illnesses that require unique surgical and anesthetic strategies.

**ANATOMIC & PHYSIOLOGICAL DEVELOPMENT**

**Respiratory System**

The transition from fetal to neonatal physiology is reviewed in Chapter 40. Compared with older children and adults, neonates and infants have weaker intercostal muscles and weaker diaphragms (due to a paucity of type I fibers) and less efficient ventilation, more horizontal and pliable ribs, and protuberant abdomens. The alveoli are fully mature by about 8 years of age. Respiratory rate is increased in neonates and gradually falls to adult values by adolescence. Tidal volume and dead space per kilogram are nearly constant during development. The presence of fewer, smaller airways produces increased airway resistance. The work of breathing is increased and respiratory muscles easily fatigue. Neonates and infants have fewer and smaller alveoli, reducing lung compliance; in contrast, their cartilaginous rib cage makes their chest wall very compliant. The combination of these two characteristics promotes chest wall collapse during inspiration and relatively low residual lung volumes at expiration. The resulting decrease in functional residual capacity (FRC) limits oxygen reserves during periods of apnea (eg, intubation attempts) and predisposes neonates and infants to atelectasis and hypoxemia. These effects of reduced FRC may be exaggerated by the relatively higher rate of oxygen consumption of neonates and infants, 6 to 8 mL/kg/min versus 3 to 4 mL/kg/min in adults. Moreover, hypoxic
and hypercapnic ventilatory drives are not fully developed in neonates and infants. In contrast to adults, hypoxia and hypercapnia may depress respiration in these patients.

Neonates and infants have, compared with older children and adults, a proportionately larger head and tongue, narrower nasal passages, an anterior and cephalad larynx (the glottis is at a vertebral level of C4 versus C6 in adults), a longer epiglottis, and a shorter trachea and neck (Figure 42–1). These anatomic features make neonates and young infants obligate nasal breathers until about 5 months of age. The cricoid cartilage is the narrowest point of the airway in children younger than 5 years of age; in adults, the narrowest point is the glottis (vocal cords). One millimeter of mucosal edema will produce a greater decline in tracheal cross-sectional area and gas flow in children because of their smaller tracheal diameters.

FIGURE 42–1 Sagittal section of the adult (A) and infant (B) airway. (Reproduced with permission from Snell RS, Katz J. Clinical Anatomy for Anesthesiologists. New York, NY: Appleton & Lange; 1988.)

**Cardiovascular System**

Cardiac stroke volume is relatively fixed by the immature, noncompliant left ventricle in neonates and infants. The cardiac output is therefore very sensitive to changes in heart rate (see Chapter 20). Although basal heart rate is greater in neonates and infants than in adults (Table 42–2), in these children activation of the parasympathetic nervous system, anesthetic overdose, or hypoxia can
quickly trigger bradycardia and profound reductions in cardiac output. Sick infants undergoing emergency or prolonged surgical procedures appear particularly prone to episodes of bradycardia that can lead to hypotension, asystole, and intraoperative death. The sympathetic nervous system and baroreceptor reflexes are not fully mature. The infant cardiovascular system displays a blunted response to exogenous catecholamines. The immature heart is more sensitive to depression by volatile anesthetics and to opioid-induced bradycardia. Infants are less able to respond to hypovolemia with compensatory vasoconstriction. Intravascular volume depletion in neonates and infants may be signaled by hypotension without tachycardia.

1Values are mean averages derived from numerous sources. Normal ranges may include measurements that deviate from these as much as 25–50%.

**Metabolism & Temperature Regulation**

Pediatric patients have a larger surface area per kilogram than adults (smaller body-mass index). Metabolism and its associated parameters (oxygen consumption, CO₂ production, cardiac output, and alveolar ventilation) correlate better with surface area than with weight.

Thin skin, low fat content, and a greater surface area relative to weight promote greater heat loss to the environment in neonates. This problem can be made worse by prolonged exposure to an inadequately warmed operating room environment, administration of room temperature intravenous or irrigation fluid, and dehumidified anesthetic gases. There are also effects of anesthetic agents on
temperature regulation (see Chapter 52). Even mild degrees of hypothermia can cause delayed awakening from anesthesia, cardiac arrhythmias, respiratory depression, increased pulmonary vascular resistance, and increased susceptibility to anesthetics, neuromuscular blockers, and other agents. Neonates produce heat by metabolism of brown fat (nonshivering thermogenesis) and by shifting hepatic oxidative phosphorylation to a more thermogenic pathway. Yet, metabolism of brown fat is severely limited in premature infants and in sick neonates, who are deficient in fat stores. Furthermore, volatile anesthetics inhibit this process.

**Kidney & Gastrointestinal Function**

Kidney function usually approaches normal values (corrected for size) by 6 months of age, but this may be delayed until the child is 2 years old. Premature neonates often demonstrate renal immaturity with one or more of the following: decreased creatinine clearance, impaired sodium retention, impaired glucose excretion, impaired bicarbonate reabsorption, reduced diluting ability and reduced concentrating ability. These abnormalities underscore the importance of appropriate fluid administration in neonates.

Neonates also have an increased likelihood of gastroesophageal reflux. The immature liver conjugates drugs and other molecules less readily.

**Glucose Homeostasis**

Neonates have relatively reduced glycogen stores, predisposing them to hypoglycemia. In general, the neonates at greatest risk for hypoglycemia are either premature or small for gestational age, receiving total parenteral nutrition, or had diabetic mothers.

**PHARMACOLOGICAL DIFFERENCES**

Pediatric drug dosing is typically adjusted on a per-kilogram basis for convenience (Table 42–3), although there are strong advocates for allometric dosing, in which adjustments for weight are not made in a linear fashion. In early childhood a patient’s weight can be approximated based on age in years:

*This drug is not yet approved for pediatric administration.*
50th percentile weight (kg) = (Age × 2) + 9

In contrast to weight-adjustment of drug dosing, allometric drug dose calculations take into account age-related physiological differences such as the disproportionately larger pediatric intravascular and extracellular fluid compartments, the immaturity of hepatic biotransformation pathways, the increased organ blood flow, the decreased protein for drug binding, and the higher metabolic rate.

Neonates and infants have a proportionately greater total water content (70–75%) than adults (50–60%). Total body water content decreases while fat and muscle content increase with age. As a result, the volume of distribution for many intravenous drugs (eg, neuromuscular blockers) is disproportionately greater in neonates, infants, and young children, and the optimal dose (per kilogram) is usually greater than in older children and adults. A disproportionately smaller fat and muscle mass in neonates prolongs the clinical duration of action (by delaying redistribution) of lipid-soluble drugs such as propofol and fentanyl. Neonates also have a relatively decreased glomerular filtration rate, decreased hepatic blood flow, impaired renal tubular function, and immature hepatic enzyme systems. Increased intraabdominal pressure and abdominal surgery may further reduce hepatic blood flow. All of these factors can impair renal drug handling, hepatic metabolism, and biliary excretion of drugs in neonates and young infants. Neonates also have decreased drug binding to proteins, notably for local anesthetics and many antibiotics. In the case of bupivacaine, an increase in free drug likely increases the risk of systemic toxicity.

Inhalational Anesthetics

Neonates, infants, and young children have relatively greater alveolar ventilation and reduced FRC compared with older children and adults. This greater minute ventilation-to-FRC ratio contributes to a rapid increase in alveolar anesthetic concentration that, combined with relatively greater blood flow to the brain, speeds inhalation induction. Furthermore, the blood/gas coefficients of volatile anesthetics are reduced in neonates compared with adults, contributing to faster induction times and potentially increasing the risk of accidental overdosage.

The minimum alveolar concentration (MAC) for halogenated agents is greater in infants than in neonates and adults (Table 42–4). In contrast to other agents, no increase in the MAC of sevoflurane can be demonstrated between...
neonates and infants. Nitrous oxide does not appear to reduce the MAC of desflurane or sevoflurane in children to the same extent as it does for other agents.

**TABLE 42–4** Approximate MAC\(^1\) values for pediatric patients reported in % of an atmosphere.\(^2\)

\(^1\)MAC, minimum alveolar concentration.

\(^2\)Values are derived from various sources.

The blood pressure of neonates and infants appears to be especially sensitive to volatile anesthetics. This clinical observation has been attributed to less-well-developed compensatory mechanisms (eg, vasoconstriction, tachycardia) and greater sensitivity of the immature myocardium to myocardial depressants. Halothane (now rarely used) sensitizes the heart to catecholamines; thus, the maximum recommended dose of epinephrine in local anesthetic solutions during halothane anesthesia is reduced. Cardiovascular depression, bradycardia, and arrhythmias are less frequent with sevoflurane than with halothane. Sevoflurane and halothane are less likely than other volatile agents to irritate the airway or cause breath holding or laryngospasm during induction (see Chapter 8). In general, volatile anesthetics appear to depress ventilation more in infants than in older children. Sevoflurane appears to produce the least respiratory depression. Halothane-induced hepatic dysfunction is much rarer in prepubertal children than adults. There are no reported instances of renal toxicity attributed to fluoride production during sevoflurane anesthesia in children. Sevoflurane is the preferred agent for inhaled induction in pediatric anesthesia.

Emergence is fast following desflurane or sevoflurane, but both agents are associated with agitation or delirium upon emergence, particularly in young children. Because of the latter, some clinicians switch to isoflurane for
maintenance anesthesia following a sevoflurane induction (see later discussion).

**Nonvolatile Anesthetics**

After weight-adjustment of dosing, infants and young children require larger doses of propofol because of a larger volume of distribution compared with adults. Children also have a shorter elimination half-life and higher plasma clearance for propofol. Recovery from a single bolus is not appreciably different from that in adults; however, recovery following a continuous infusion may be more rapid. For the same reasons, children may require increased weight-adjusted rates of infusion for maintenance of anesthesia (up to 250 mcg/kg/min). Propofol is not recommended for prolonged sedation of critically ill pediatric patients in the intensive care unit (ICU) due to an association with greater mortality than other agents. This “propofol infusion syndrome” has been reported most often in critically ill children, but has also been reported in adults undergoing long-term propofol sedation, particularly at increased doses (>5 mg/kg/h). Its essential features include rhabdomyolysis, metabolic acidosis, hemodynamic instability, hepatomegaly, and multiorgan failure.

Children require relatively larger doses of thioental compared with adults. The elimination half-life is shorter and the plasma clearance is greater than in adults. In contrast, neonates appear to be more sensitive to barbiturates. Neonates have less protein binding, a longer half-life, and impaired clearance. The thiopental induction dose for neonates is 3 to 4 mg/kg compared with 5 to 6 mg/kg for infants.

Opioids appear to be more potent in neonates than in older children and adults. Morphine sulfate, particularly in repeated doses, should be used with caution in neonates because hepatic conjugation is reduced and renal clearance of morphine metabolites is decreased. The cytochrome P-450 pathways mature at the end of the neonatal period. Older pediatric patients have relatively greater rates of biotransformation and elimination as a result of high hepatic blood flow. Remifentanil clearance is increased in neonates and infants but elimination half-life is unaltered compared with adults. Neonates and infants may require slightly larger doses of ketamine, than adults, but any actual difference, if present, is very small. Pharmacokinetic values do not appear to be significantly different from those of adults. Etomidate has not been well-studied in patients younger than 10 years of age; its profile in older children is similar to that in adults. Midazolam has the fastest clearance of all the benzodiazepines, but its clearance is significantly reduced in neonates compared with older children.
Dexmedetomidine has been used widely for sedation and as a supplement to general anesthesia in children. In patients without an intravenous line, dexmedetomidine can be given intranasally (1–2 mcg/kg) for sedation.

**Muscle Relaxants**

For many reasons (including pharmacodynamic and case mix differences), muscle relaxants are less commonly used during induction of anesthesia in children than in adults. In North America many children will have a laryngeal mask airway (LMA) or endotracheal tube placed after receiving an inhalation induction, placement of an intravenous catheter, and administration of various combinations of propofol, opioids, or lidocaine.

All muscle relaxants generally have a faster onset (up to 50% less delay) in pediatric patients because of shorter circulation times than in adults. In both children and adults, intravenous succinylcholine (1–1.5 mg/kg) has the fastest onset (see Chapter 11). Infants are given significantly larger doses of succinylcholine (2–3 mg/kg) than older children and adults because of the relatively larger volume of distribution (on a per kilogram basis). This discrepancy disappears if dosage is based on body surface area. Table 42–5 lists commonly used muscle relaxants and their ED$_{95}$ (the dose that produces 95% depression of evoked twitches). Infants require significantly smaller nondepolarizing muscle relaxant doses than older children (cisatracurium may possibly be an exception). Moreover, based on weight, older children require larger doses than adults for some neuromuscular blocking agents (eg, atracurium, see Chapter 11).

**TABLE 42–5**  Approximate ED$_{95}$ for muscle relaxants in infants and children.$^{1}$
The response of neonates to nondepolarizing muscle relaxants is variable. Popular explanations for this include “immaturity of the neuromuscular junction” (in premature neonates), tending to increase sensitivity (unproven), counterbalanced by a disproportionately larger extracellular compartment, reducing drug concentrations (proven). The relative immaturity of neonatal hepatic function prolongs the duration of action for drugs that depend primarily on hepatic metabolism (eg, pancuronium, vecuronium, and rocuronium). Atracurium and cisatracurium do not depend on hepatic biotransformation and reliably behave as intermediate-acting muscle relaxants.

Children are more susceptible than adults to cardiac arrhythmias, hyperkalemia, rhabdomyolysis, myoglobinemia, masseter spasm, and malignant hyperthermia (see Chapter 52) associated with succinylcholine. When a child experiences cardiac arrest following administration of succinylcholine, immediate treatment for hyperkalemia should be instituted. Prolonged resuscitative efforts (potentially including cardiopulmonary bypass) may be required. Thus, succinylcholine has long been avoided for routine, elective paralysis for intubation in children and adolescents. Children may have profound bradycardia and sinus node arrest following the first dose of succinylcholine without atropine pretreatment. Therefore, atropine (0.1 mg minimum) is customarily administered prior to succinylcholine in children. Generally accepted indications for intravenous succinylcholine in children include rapid sequence induction with a “full” stomach and laryngospasm that does not respond to positive-pressure ventilation. When rapid muscle relaxation

$^1$Average values during nitrous oxide/oxygen anesthesia.
is required prior to intravenous access (eg, with inhaled inductions in patients with full stomachs), intramuscular succinylcholine (4–6 mg/kg) can be used. Intramuscular atropine (0.02 mg/kg) should be administered with intramuscular succinylcholine to reduce the likelihood of bradycardia. Some clinicians advocate intralingual administration (2 mg/kg in the midline) as an alternate emergency route for succinylcholine.

Many clinicians consider rocuronium (0.6 mg/kg intravenously) the drug of choice (when an intravenous relaxant will be used) for routine intubation in pediatric patients because it has the fastest onset of nondepolarizing neuromuscular blocking agents (see Chapter 11). Larger doses of rocuronium (0.9–1.2 mg/kg) may be used for rapid sequence induction if a prolonged duration (up to 90 min) is not a concern. Rocuronium is the only nondepolarizing neuromuscular blocker that has been adequately studied for intramuscular administration (1.0–1.5 mg/kg), but this approach requires 3 to 4 min for onset. Atracurium or cisatracurium may be preferred in young infants, particularly for short procedures, because these drugs consistently display short to intermediate duration.

As with adults, the effect of muscle relaxants should be monitored with a peripheral nerve stimulator. Sensitivity can vary significantly between patients. Nondepolarizing blockade can be reversed with neostigmine (0.03–0.07 mg/kg) or edrophonium (0.5–1 mg/kg) along with an anticholinergic agent (glycopyrrolate, 0.01 mg/kg, or atropine, 0.01–0.02 mg/kg). Sugammadex, a specific antagonist for rocuronium and vecuronium, was recently released in the United States and will likely change the typical choices and doses of neuromuscular blockers given its effectiveness, even in the face of neuromuscular blockade that could not be reversed with conventional cholinesterase inhibitors.

**PEDIATRIC ANESTHETIC RISK**

The Pediatric Perioperative Cardiac Arrest (POCA) Registry provides a useful database for assessing pediatric anesthetic risk. This registry includes reports derived from millions of pediatric anesthetics administered since 1994. Case records of children experiencing cardiac arrests or death during the administration of or recovery from anesthesia were investigated regarding any possible relationship with anesthesia. Nearly all patients received general anesthesia alone or combined with regional anesthesia. In a preliminary analysis that included 289 cases of cardiac arrest, anesthetic care was judged to have contributed to 150 arrests. Thus, the risk of cardiac arrest in pediatric anesthetic
cases would appear to be approximately 1.4 in 10,000. Thirty-three percent of patients who suffered a cardiac arrest were classified as American Society of Anesthesiologists (ASA) physical status 1 or 2. Infants accounted for 55% of all anesthesia-related arrests in children, with those younger than 1 month of age (ie, neonates) having the greatest risk. After cardiac arrest, mortality was 26%. Six percent suffered permanent injury, but the majority (68%) had either no or only temporary injury. Mortality was 4% in patients classified as ASA physical status 1 and 2 compared with 37% in those with ASA physical status 3 to 5. As with adults, two major predictors of mortality were ASA physical status 3 to 5 and emergency surgery.

Most cardiac arrests occurred during induction of anesthesia; bradycardia, hypotension, and a low Spo$_2$ frequently preceded arrest. The most common mechanism of arrest was judged to be medication related (Figure 42–2). Cardiovascular depression from halothane, alone or in combination with other drugs, was believed to be responsible in two-thirds of all medication-related arrests. Another 9% were due to intravascular injection of a local anesthetic, most often following a negative aspiration test during attempted caudal injection. Presumed cardiovascular mechanisms most often had no clear etiology; in more than 50% of those cases the patient had congenital heart disease. Where a cardiovascular mechanism could be identified, it was most often related to hemorrhage, transfusion, or inadequate or inappropriate fluid therapy. These studies await replication in the modern, virtually “halothane-free,” era in which regional techniques (and, presumably, the attendant risks) are markedly more prevalent.

![Figure 42–2](image-url)
POCA Registry data.

Respiratory mechanisms of injury included laryngospasm, airway obstruction, and difficult intubation (in decreasing order). In most cases the laryngospasm occurred during induction. Nearly all patients who experienced arrest in association with airway obstruction or difficult intubation had at least one major underlying disease.

The most common equipment-related mechanisms that led to a cardiac arrest occurred during attempted central venous catheterization (eg, pneumothorax, hemothorax, or cardiac tamponade).

In recent years increased scientific interest and public concern have focused on whether certain general anesthetic agents might be toxic to the brains of infants and young children. The experimental data in animals have been consistently worrisome, but the clinical data currently available have not identified adverse outcomes comparable to those observed in animals. Progress in this area can be followed on the SmartTots web site (www.smarttots.org), maintained by the International Anesthesia Research Society (see Chapter 8).

Children are at greater risk than adults of developing malignant hyperthermia. This complex and important topic is covered in depth in Chapter 52.

**PEDIATRIC ANESTHETIC TECHNIQUES**

**Preoperative Considerations**

**A. Preoperative Interview**

Depending on age, past experiences, and maturity, children present with varying degrees of fright (even terror) when faced with the prospect of surgery or other procedures requiring anesthesia. Unlike adults, who are usually most concerned about the possibility of injury or death, children, when they verbalize their concerns, worry about pain and separation from their parents. Presurgical preparation programs—such as age-appropriate brochures and videos, or tours—can help prepare both children and parents. When time permits, one can demystify the process of anesthesia and surgery by explaining in age-appropriate terms what lies ahead. For example, the anesthesiologist might bring an anesthesia mask for the child to play with during the interview and describe it as like something the astronauts use. Alternatively, in some centers, someone the child trusts (eg, a parent, nurse, another physician) may be allowed to be in attendance during preanesthetic preparations and induction of anesthesia. This
can have a particularly calming influence on children undergoing repeated procedures (eg, administration of intrathecal chemotherapy). Unfortunately, outpatient and “same day admit” surgery, coupled with a busy operating room schedule, often make it nearly impossible to adequately reassure parents and patients. Thus, premedication (discussed below) often can be helpful. Some pediatric hospitals have induction rooms adjacent to their operating rooms to permit parental attendance and a quieter, less startling environment for anesthetic inductions.

**B. Recent Upper Respiratory Tract Infection**

Children frequently present for surgery with signs and symptoms—a runny nose with fever, cough, or sore throat—of a viral upper respiratory tract infection (URI). Attempts should be made to differentiate between an infectious cause of rhinorrhea and an allergic or vasomotor cause. A viral infection within 2 to 4 weeks before general anesthesia and endotracheal intubation appears to place the child at an increased risk for perioperative pulmonary complications, such as wheezing (10-fold), laryngospasm (5-fold), hypoxemia, and atelectasis. This is particularly likely if the child has a severe cough, high fever, or a family history of reactive airway disease. On the other hand, children can have mild URIs on a nearly monthly basis and it can become nearly impossible to schedule them for anesthesia at a time when they neither currently have, nor are recovering from, a URI. The decision to anesthetize children with URIs remains controversial and should be based on the severity of URI symptoms, the urgency of the surgery, and the presence of other coexisting illnesses. When anesthesia will be provided to a child with a URI, one may consider premedicating with an anticholinergic or a β₂-agonist (eg, albuterol), avoiding intubation (if feasible), and humidifying inspired gases. A longer-than-usual stay in the postanesthesia recovery area may be required.

**C. Laboratory Tests**

Few, if any, preoperative laboratory tests are cost effective. Some pediatric centers require no preoperative laboratory tests in healthy children undergoing minor procedures. Obviously, this places responsibility on the anesthesiologist, surgeon, and pediatrician to correctly identify those patients who should have preoperative testing for specific surgical procedures. Most asymptomatic patients with cardiac murmurs do not have significant cardiac pathology. Innocent murmurs may occur in more than 30% of normal children. These are typically soft, short systolic ejection murmurs that are best
heard along the left upper or left lower sternal border and that do not radiate. Innocent murmurs at the left upper sternal border typically are due to flow across the pulmonic valve (pulmonic ejection) whereas those at the lower left border typically are due to flow from the left ventricle to the aorta (Still’s vibratory murmur). The pediatrician should carefully evaluate patients with a newly diagnosed murmur, particularly in infancy. Consultation with a pediatric cardiologist, echocardiography, or both, should be obtained if the patient is symptomatic (eg, poor feeding, failure to thrive, or easy fatigability). Murmurs that are loud, “harsh,” holosystolic, diastolic, or that radiate widely—or pulses that are either bounding or markedly diminished—require further evaluation and diagnosis.

D. Preoperative Fasting

Because children are more prone to dehydration than adults, their preoperative fluid restriction has always been more lenient. Several studies, however, have documented low gastric pH (<2.5) and relatively high residual volumes in pediatric patients scheduled for surgery, suggesting that children may be at a greater risk for aspiration than was previously thought. The incidence of aspiration is reported to be approximately 1:1000. There is no evidence that prolonged fasting decreases the risk of aspiration. In fact, several studies have demonstrated lower residual volumes and higher gastric pH in pediatric patients who received clear fluids a few hours before induction (see Chapter 53). The guideline on preoperative fasting produced by the American Society of Anesthesiologists specifies that infants may be fed breast milk up to 4 h before induction, and formula or liquids and a “light” meal may be given up to 6 h before induction. Clear fluids are offered until 2 h before induction. These recommendations are for healthy neonates, infants, and children without risk factors for decreased gastric emptying or aspiration. In any case, there is almost no clinical evidence for the recommendations.

E. Premedication

There is great variation in the premedication of pediatric patients. Sedative premedication is generally omitted for neonates and sick infants. Children who appear likely to exhibit uncontrollable separation anxiety may be given a sedative, such as midazolam (0.3–0.5 mg/kg, 15 mg maximum). The oral route is generally preferred because it is less traumatic than intramuscular injection, but it requires 20 to 45 min for effect. Smaller doses of midazolam have been used in combination with oral ketamine (4–6 mg/kg) for inpatients. For
uncooperative patients, intramuscular midazolam (0.1–0.15 mg/kg, 10 mg maximum) or ketamine (2–3 mg/kg) with atropine (0.02 mg/kg) may be helpful. Rectal midazolam (0.5–1 mg/kg, 20 mg maximum) or rectal methohexital (25–30 mg/kg of 10% solution) may also be administered in such cases while the child is in the parent’s arms. Some clinicians administer dexmedetomidine (1–2 mcg/kg) or midazolam premedication intranasally. Fentanyl can also be administered as a lollipop (Actiq, 5–15 mcg/kg); however, fentanyl levels continue to rise intraoperatively and can contribute to postoperative analgesia.

In the past, anesthesiologists routinely premedicated young children with anticholinergic drugs to reduce the likelihood of bradycardia. Atropine reduces the incidence of hypotension during induction in neonates and in infants younger than 3 months. Atropine can also prevent accumulation of secretions that can block small airways and endotracheal tubes. Secretions can be particularly troublesome for children with URIs or those who have been given ketamine. Atropine may be administered orally (0.05 mg/kg), intramuscularly, or occasionally rectally. In current practice, most prefer to administer atropine intravenously during induction.

**Monitoring**

Monitoring requirements for infants and children are generally similar to those for adults with some minor modifications. Alarm limits should be appropriately adjusted. Smaller electrocardiographic electrode pads may be necessary so that they do not encroach on sterile surgical areas. Blood pressure cuffs must be properly fitted. Noninvasive blood pressure monitors have proved to be reliable in infants and children. A precordial or esophageal stethoscope provides an inexpensive means of monitoring heart rate, quality of heart sounds, and airway patency. Finally, monitors may sometimes need to be first attached (or reattached) following induction of anesthesia in less cooperative patients.

Pulse oximetry and capnography assume an even more important role in infants and small children because hypoxia from inadequate ventilation remains a common cause of perioperative morbidity and mortality. In neonates, the pulse oximeter probe should preferably be placed on the right hand or earlobe to measure preductal oxygen saturation. As in adult patients, end-tidal CO₂ analysis allows assessment of adequacy of ventilation, changes in cardiac output, confirmation of endotracheal tube placement, and early warning of malignant hyperthermia. Flow-through (mainstream) analyzers are usually less accurate in patients weighing less than 10 kg. Even with aspiration (sidestream)
capnographs, the inspired (baseline) CO₂ can appear falsely elevated and the expired (peak) CO₂ can be falsely low. The degree of error can be minimized by placing the sampling site as close as possible to the distal tip of the endotracheal tube, reducing the length of sampling line, and lowering gas-sampling flow rates (100–150 mL/min). The weight of some flow-through sensors may lead to kinking of the warmed endotracheal tube.

- Temperature must be closely monitored in pediatric patients because of their greater risk for malignant hyperthermia and greater susceptibility for intraoperative hypothermia or hyperthermia. The risk of hypothermia can be reduced by maintaining a warm operating room environment (26°C or warmer), by warming and humidifying inspired gases, by using a warming blanket and warming lights, and by warming all intravenous and irrigation fluids. These concerns, while important in all patients, are critically important in newborns. Care must be taken to prevent accidental burns and hyperthermia from overzealous warming efforts.

Invasive monitors (eg, arterial cannulation, central venous catheterization) demand expertise and judgment. Air bubbles should be removed from pressure tubing and small volume flushes should be used to avoid air embolism, unintended heparinization, or fluid overload. The right radial artery is often chosen for cannulation in the neonate because its preductal location mirrors the oxygen content of the carotid and retinal arteries. A femoral artery catheter may be a suitable alternative in very small neonates. Left radial or right or left dorsalis pedis arteries are other alternatives. Critically ill neonates may retain an umbilical artery catheter. Internal jugular and subclavian approaches are often used for central lines. Ultrasonography should be used during placement of internal jugular catheters and provides useful information for arterial cannulation as well. Urinary output is an important (but neither sensitive nor specific) indicator of the adequacy of intravascular volume and cardiac output. Noninvasive monitors of stroke volume have only recently been tested in infants and young children.

Premature or small-for-gestational-age neonates, and neonates who have received total parenteral nutrition or whose mothers are diabetic, are prone to hypoglycemia. These infants should have frequent blood glucose measurements: levels below 30 mg/dL in the neonate, below 40 mg/dL in infants, and below 60 mg/dL in children (and below 80 mg/dL in adults) indicate hypoglycemia requiring immediate treatment. Blood sampling for arterial blood gases, hemoglobin, potassium, and ionized calcium concentration can be invaluable in critically ill patients, particularly in those undergoing major surgery or who may
be receiving transfusions.

**Induction**

General anesthesia is usually induced by an intravenous or inhalational technique. Induction with intramuscular ketamine (5–10 mg/kg) is reserved for specific situations, such as those involving combative, particularly mentally challenged, or autistic patients. Intravenous induction is usually preferred when the patient comes to the operating room with a functional intravenous catheter or will allow awake venous cannulation. Prior application of EMLA (*eutectic mixture of local anesthetic*) cream (see Chapter 16) may render intravenous cannulation less painful for the patient, and less stressful for the parent and anesthesiologist. However, EMLA cream is neither a perfect nor a complete solution. Some children become anxious at the sight of a needle, particularly those who have had multiple needle punctures in the past, with or without EMLA. Furthermore, it can be difficult to anticipate in which extremity intravenous cannulation will prove to be successful. Finally, to be effective, EMLA cream must remain in contact with the skin for at least 30 to 60 min. Awake or sedated-awake intubation with topical anesthesia should be considered for emergency procedures in neonates and small infants when they are critically ill or a potential difficult airway is present.

**Intravenous Induction**

The same induction sequence can be used as in adults: propofol (2–3 mg/kg) followed by a nondepolarizing muscle relaxant (eg, rocuronium, cisatracurium, atracurium), or succinylcholine. We recommend that atropine be given routinely prior to succinylcholine. The advantages of an intravenous technique include availability of intravenous access if emergency drugs need to be administered and rapidity of induction in the child at risk for aspiration. Alternatively (and very commonly in pediatric practice), intubation can be accomplished after the combination of propofol, lidocaine, and an opiate, with or without an inhaled agent, avoiding the need for a paralytic agent. Finally, paralytic agents are not needed for placement of LMA*s, which are commonly used in pediatric anesthesia.

**Inhalational Induction**

Many children do not arrive in the operating room with an intravenous line in
place and nearly all dread the prospect of being stuck with a needle. Fortunately, sevoflurane can render small children unconscious within minutes. We find this easier in children who have been sedated (most often with oral midazolam) prior to entering the operating room and who are sleepy enough to be anesthetized without ever knowing what has happened (steal induction). One can also insufflate the anesthetic gases over the face, place a drop of food flavoring on the inside of the mask (eg, oil of orange), and allow the child to sit during the early stages of induction. Specially contoured masks minimize dead space (see Figure 19–11).

There are many differences between adult and pediatric anatomy that influence mask ventilation and intubation. Equipment appropriate for age and size should be selected (Table 42–6). Neonates and most young infants are obligate nasal breathers and obstruct easily. Oral airways will help displace an oversized tongue; nasal airways, so useful in adults, can traumatize small nares or prominent adenoids in small children. Compression of submandibular soft tissues should be avoided during mask ventilation to prevent upper airway obstruction.

*ET, endotracheal tube.

Typically, the child can be coaxed into breathing an odorless mixture of nitrous oxide (70%) and oxygen (30%). Sevoflurane (or halothane) can be added to the gas mixture in 0.5% increments every few breaths. As previously discussed, we favor sevoflurane in most situations. Desflurane and isoflurane are avoided for inhalation induction because they are pungent and associated with more coughing, breath-holding, and laryngospasm. We use a single (sometimes two) breath induction technique with sevoflurane (7–8% sevoflurane in 60% nitrous oxide) to speed the induction in cooperative patients. After an adequate depth of anesthesia has been achieved, an intravenous line can be started and
propofol and an opioid (or a muscle relaxant) administered to facilitate intubation. Patients typically pass through an excitement stage during which any stimulation can induce laryngospasm. Breath-holding must be distinguished from laryngospasm. Steady application of 10 cm of positive end-expiratory pressure will usually overcome laryngospasm.

Alternatively, the anesthesiologist can deepen the level of anesthesia, by increasing the concentration of volatile anesthetic, and place an LMA or intubate the patient under “deep” sevoflurane anesthesia. Because of the greater anesthetic depth required for tracheal intubation, the risk of cardiac depression, bradycardia, or laryngospasm occurring without intravenous access detracts from this latter technique. Intramuscular succinylcholine (4 mg/kg, not to exceed 150 mg) and atropine (0.02 mg/kg, not to exceed 0.4 mg) should be available if laryngospasm or bradycardia occurs before an intravenous line is established.

Positive-pressure ventilation during mask induction and prior to intubation sometimes causes gastric distention, with impairment of lung expansion. Suctioning with an orogastric or nasogastric tube will decompress the stomach, but it must be done without traumatizing fragile mucous membranes.

**Intravenous Access**

Intravenous cannulation in infants can be a vexing ordeal. This is particularly true for infants who have spent weeks in a neonatal intensive care unit and have few intact veins. Even healthy 1-year-old children can prove a challenge because of extensive subcutaneous fat. Venous cannulation usually becomes easier after 2 years of age. The saphenous vein has a consistent location at the ankle and an experienced practitioner can usually cannulate it even if it is not visible or palpable. Transillumination of the hands or ultrasonography will often reveal previously hidden cannulation sites. Twenty-four-gauge over-the-needle catheters are adequate in neonates and infants when blood transfusions are not anticipated. All air bubbles should be removed from the intravenous line to reduce the risk of paradoxical air embolism from occult patent foramen ovale. In emergency situations where intravenous access is impossible, fluids can be effectively infused through an 18-gauge needle inserted into the medullary sinusoids within the tibial bone. This intraosseous infusion can be used for all medications normally given intravenously, with almost as rapid results (see Chapter 55), and is considered part of the standard trauma resuscitation, advanced cardiac life support (ACLS), and pediatric advanced life support (PALS) protocols when intravenous access cannot be obtained.
Tracheal Intubation

One hundred percent oxygen should be administered prior to intubation to increase patient safety during the obligatory period of apnea prior to and during intubation. The choice of muscle relaxant has been discussed earlier in this chapter. For awake intubations in neonates or infants, adequate preoxygenation and continued oxygen insufflation during laryngoscopy may help prevent hypoxemia.

The infant’s prominent occiput tends to place the head in a flexed position prior to intubation. This is easily corrected by slightly elevating the shoulders on towels and placing the head on a doughnut-shaped pillow. In older children, prominent tonsillar tissue can obstruct visualization of the larynx. Straight laryngoscope blades aid intubation of the anterior larynx in neonates, infants, and young children (Table 42–6). Endotracheal tubes that pass through the glottis may still impinge upon the cricoid cartilage, which is the narrowest point of the airway in children younger than 5 years of age. Mucosal trauma from trying to force a tube through the cricoid cartilage can cause postoperative edema, stridor, croup, and airway obstruction.

The appropriate diameter inside the endotracheal tube can be estimated by a formula based on age:

\[ 4 + \text{Age}/4 = \text{Tube diameter (in mm)} \]

For example, a 4-year-old child would be predicted to require a 5-mm uncuffed tube. This formula provides only a rough guideline, however. Exceptions include premature neonates (2.5–3 mm tube) and full-term neonates (3–3.5 mm tube). Alternatively, the practitioner can remember that a newborn takes a 2.5- or 3-mm tube, and a 5-year-old takes a 5-mm tube. It should not be that difficult to identify which of the three sizes of tube between 3 and 5 mm is required in small children. In larger children, small (5–6 mm) cuffed tubes can be used either with or without the cuff inflated to minimize the need for precise sizing. Endotracheal tubes 0.5 mm larger and smaller than predicted should be readily available in or on the anesthetic cart. In the past, uncuffed endotracheal tubes were selected for children aged 5 years or younger in the hope of decreasing the risk of postintubation croup. Currently, many anesthesiologists no longer use size 4.0 or larger uncuffed tubes. The leak test will minimize the likelihood that an excessively large tube has been inserted. Correct tube size and appropriate cuff inflation is confirmed by easy passage into the larynx and the development of a gas leak at 15 to 25 cm H\textsubscript{2}O pressure. No leak indicates an
oversized tube or overinflated cuff that should be replaced or deflated to prevent postoperative edema, whereas an excessive leak may preclude adequate ventilation and contaminate the operating room with anesthetic gases. As previously noted, many clinicians use a down-sized cuffed tube in younger patients at high risk for aspiration; minimal inflation of the cuff can stop any air leak. There is also a formula to estimate endotracheal length:

\[12 + \text{Age}/2 = \text{Length of tube (in cm)}\]

Again, this formula provides only a guideline, and the result must be confirmed by auscultation and clinical judgment. To avoid endobronchial intubation, the tip of the endotracheal tube should pass only 1 to 2 cm beyond an infant’s glottis. Alternatively, one can intentionally advance the tip of the endotracheal tube into the right mainstem bronchus and then withdraw it until breath sounds are equal over both lung fields.

**Maintenance**

Ventilation is almost always controlled during anesthesia of neonates and infants when using a conventional semiclosed circle system. During spontaneous ventilation, even the low resistance of a circle system can become a significant obstacle for a sick neonate to overcome. Unidirectional valves, breathing tubes, and carbon dioxide absorbers account for most of this resistance. For patients weighing less than 10 kg, some anesthesiologists prefer the Mapleson D circuit or the Bain system because of their low resistance and light weight (see Chapter 3). Nonetheless, because breathing-circuit resistance is easily overcome by positive-pressure ventilation, the circle system can be safely used in patients of all ages if ventilation is controlled. Monitoring of airway pressure may provide early evidence of obstruction from a kinked endotracheal tube or accidental advancement of the tube into a mainstem bronchus.

Many anesthesia ventilators on older machines are designed for adult patients and cannot reliably provide the reduced tidal volumes and rapid rates required by neonates and infants. Unintentional delivery of large tidal volumes to a small child can generate excessive peak airway pressures and cause barotrauma. Pressure control ventilation, which is found on nearly all newer anesthesia ventilators, should be used for neonates, infants, and toddlers. Small tidal volumes can also be manually delivered with greater ease with a 1-L breathing bag than with a 3-L adult bag. For children less than 10 kg, adequate tidal volumes are achieved with peak inspiratory pressures of 15 to 18 cm H₂O. For
larger children the volume control ventilation may be used and tidal volumes may be set at 6 to 8 mL/kg. Many spirometers are less accurate at lower tidal volumes. In addition, the gas lost in long, compliant adult breathing circuits becomes large relative to a child’s small tidal volume. For this reason, pediatric breathing circuits are usually shorter, lighter, and stiffer (less compliant). Nevertheless, one should recall that the additional dead space contributed by the tube and circle system consists only of the volume of the distal limb of the Y-connector and that portion of the endotracheal tube that extends beyond (proximal to) the airway. In other words, the dead space is unchanged by switching from adult to pediatric breathing circuits. Condenser humidifiers or heat and moisture exchangers (HMEs) can add considerable dead space; depending on the size of the patient, they either should not be used or an appropriately sized, pediatric HME should be employed.

Anesthesia can be maintained in pediatric patients with the same agents as in adults. Some clinicians switch to isoflurane following a sevoflurane induction in the hope of reducing the likelihood of emergence agitation or postoperative delirium (see earlier discussion). Administration of an opioid (eg, fentanyl, 1–1.5 mcg/kg) or dexmedetomidine (0.5 mcg/kg, given slowly with heart rate monitoring) 15 to 20 min before the end of the procedure can reduce the incidence of emergence delirium and agitation if the surgical procedure is likely to produce postoperative pain. Although the MAC is greater in children than in adults (see Table 42–4), neonates may be particularly susceptible to the cardiac-depressing effects of general anesthetics and may not tolerate the concentrations of volatile agents required when the volatile agent alone is used to maintain good surgical operating conditions.

**Perioperative Fluid Requirements**

Meticulous attention to fluid intake and loss is required in younger pediatric patients because these patients have limited margins for error. A programmable infusion pump or a buret with a microdrip chamber is useful for accurate measurements. Drugs can be flushed through low dead-space tubing to minimize unnecessary fluid administration. Fluid overload is diagnosed by prominent veins, flushed skin, increased blood pressure, decreased serum sodium, and a loss of the folds in the upper eyelids.

Fluid therapy can be divided into maintenance, deficit, and replacement requirements.
A. Maintenance Fluid Requirements

Maintenance requirements for pediatric patients can be determined by the “4:2:1 rule”: 4 mL/kg/h for the first 10 kg of weight, 2 mL/kg/h for the second 10 kg, and 1 mL/kg/h for each remaining kilogram. The choice of maintenance fluid remains controversial. A solution such as D$_5$½ NS with 20 mEq/L of potassium chloride provides adequate dextrose and electrolytes at these maintenance infusion rates. D$_5$¾ NS may be a better choice in neonates because of their limited ability to handle sodium loads. Children up to the age of 8 years require 6 mg/kg/min of glucose to maintain euglycemia (40–125 mg/dL); premature neonates require 6–8 mg/kg/min. Euglycemia is normally well maintained in older children and adults by hepatic glycogenolysis and gluconeogenesis despite administration of glucose-free solutions. Both hypoglycemia and hyperglycemia should be avoided; however, the amount of hepatic glucose production is widely variable during major surgery and critical illness. Thus glucose infusion rates during longer surgeries, particularly in neonates and infants, should be adjusted based on blood glucose measurements.

B. Deficits

In addition to a maintenance infusion, any preoperative fluid deficits must be replaced. For example, if a 5-kg infant has not received oral or intravenous fluids for 4 h prior to surgery, a deficit of 80 mL has accrued (5 kg × 4 mL/kg/h × 4 h). In contrast to adults, infants respond to dehydration with decreased blood pressure and without increased heart rate. Preoperative fluid deficits are often administered with hourly maintenance requirements in aliquots of 50% in the first hour and 25% in the second and third hours. In the example above, a total of 60 mL would be given in the first hour (80/2 + 20) and 40 mL in the second and third hours (80/4 + 20). Bolus administration of dextrose-containing solutions should be avoided to prevent hyperglycemia. Preoperative fluid deficits are usually replaced with a balanced salt solution (e.g., lactated Ringer’s injection) or ½NS. Glucose is omitted to prevent hyperglycemia. Compared with lactated Ringer’s injection, normal saline has the disadvantage of promoting hyperchloremic acidosis.

C. Replacement Requirements

Replacement can be subdivided into blood loss and third-space loss.

1. Blood loss—The blood volume of premature neonates (100 mL/kg), full-term neonates (85–90 mL/kg), and infants (80 mL/kg) is proportionately larger than
that of adults (65–75 mL/kg). An initial hematocrit of 55% in the healthy full-term neonate gradually falls to as low as 30% in the 3-month-old infant before rising to 35% by 6 months. Hemoglobin (Hb) type is also changing during this period: from a 75% concentration of HbF (greater oxygen affinity, reduced PaO₂, poor tissue unloading) at birth to almost 100% HbA (reduced oxygen affinity, high PaO₂, good tissue unloading) by 6 months.

Blood loss has been typically replaced with non–glucose-containing crystalloid (eg, 3 mL of lactated Ringer’s injection for each milliliter of blood lost) or colloid solutions (eg, 1 mL of 5% albumin for each milliliter of blood lost) until the patient’s hematocrit reaches a predetermined lower limit. In recent years there has been increased emphasis on avoiding excessive fluid administration; thus blood loss is now commonly replaced by either colloid (eg, albumin) or packed red blood cells. In premature and sick neonates, the target hematocrit (for transfusion) may be as great as 40%, whereas in healthy older children a hematocrit of 20% to 26% is generally well tolerated. Because of their small intravascular volume, neonates and infants are at an increased risk for electrolyte disturbances (eg, hyperglycemia, hyperkalemia, and hypocalcemia) that can accompany rapid blood transfusion. Dosing of packed red blood cell transfusions is discussed in Chapter 51. Platelets and fresh frozen plasma, 10 to 15 mL/kg, should be given when blood loss exceeds one to two blood volumes. Recent practice, particularly with blood loss from trauma, favors “earlier” administration of plasma and platelets as part of a massive transfusion protocol. One unit of platelets per 10 kg weight raises the platelet count by about 50,000/μL. The pediatric dose of cryoprecipitate is 1 unit/10 kg weight.

2. “Third-space” loss—These losses are impossible to measure and must be estimated by the extent of the surgical procedure. In recent years some investigators have questioned the very existence of the third space, and some have asserted that the third space exists as a consequence of excessive fluid administration.

One popular fluid administration guideline is 0 to 2 mL/kg/h for relatively atraumatic surgery (eg, strabismus correction where there should be no third-space loss) and up to 6 to 10 mL/kg/h for traumatic procedures (eg, abdominal abscess). Third-space loss is usually replaced with lactated Ringer’s injection (see Chapter 49). It is safe to say that all issues relating to the third space have never been more controversial.

Regional Anesthesia and Analgesia
The primary uses of regional techniques in pediatric anesthesia have been to supplement and reduce general anesthetic requirements and to provide better postoperative pain relief. Blocks range in complexity from relatively simple peripheral nerve blocks (eg, penile block, ilioinguinal block); to brachial plexus, sciatic nerve, femoral nerve, and transversus abdominis plane (TAP) blocks; to major conduction blocks (eg, spinal or epidural techniques). Regional blocks in children (as in adults) are often facilitated by ultrasound guidance, sometimes with nerve stimulation.

Caudal blocks have proved useful following a variety of surgeries, including circumcision, inguinal herniorrphaphy, hypospadias repair, anal surgery, clubfoot repair, and other subumbilical procedures. Contraindications include infection around the sacral hiatus, coagulopathy, or anatomic abnormalities. The patient is usually lightly anesthetized or sedated and placed in the lateral position.

For pediatric caudal anesthesia, a short-bevel 22-gauge needle can be used. If the loss-of-resistance technique is used, the glass syringe should be filled with saline, not air, because of the latter’s possible association with air embolism. After the characteristic pop that signals penetration of the sacrococcygeal membrane, the needle angle of approach is reduced and the needle is advanced only a few more millimeters to avoid entering the dural sac or the anterior body of the sacrum. Aspiration is used to check for blood or cerebrospinal fluid; local anesthetic can then be slowly injected; failure of a 2-mL test dose of local anesthetic with epinephrine (1:200,000) to produce tachycardia helps exclude intravascular placement.

Many anesthetic agents have been used for caudal anesthesia in pediatric patients, with 0.125% to 0.25% bupivacaine (up to 2.5 mg/kg) or 0.2% ropivacaine being most common. Ropivacaine, 0.2%, can provide analgesia similar to bupivacaine but with less motor blockade. Ropivacaine appears to have less cardiac toxicity than bupivacaine when compared milligram to milligram. Addition of epinephrine to caudal solutions tends to increase the degree of motor block. Clonidine, either by itself or combined with local anesthetics, has also been widely used. Morphine sulfate (25 mcg/kg) or hydromorphone (6 mcg/kg) may be added to the local anesthetic solution to prolong postoperative analgesia for inpatients, but will increase the risk of delayed postoperative respiratory depression. The volume of local anesthetic required depends on the level of blockade desired, ranging from 0.5 mL/kg for a sacral block to 1.25 mL/kg for a midthoracic block. Single-shot injections generally last 4 to 12 h. Placement of 20-gauge caudal catheters with continuous infusion of local anesthetic (eg, 0.125% bupivacaine or 0.1% ropivacaine at 0.2–
0.4 mg/kg/h) or an opioid (eg, fentanyl, 2 mcg/mL at 0.6 mcg/kg/h) allows prolonged anesthesia and postoperative analgesia. Complications are rare but include local anesthetic toxicity from increased blood concentrations (eg, seizures, hypotension, arrhythmias), spinal blockade, and respiratory depression. Urinary retention is not a problem following single-dose caudal anesthesia.

Lumbar and thoracic epidural catheters can be placed in anesthetized children using the standard loss-of-resistance technique and either a midline or paramedian approach. In small children, caudal epidural catheters have been passed into a thoracic position with the tip localized radiographically.

Unilateral TAP blocks are commonly used to provide analgesia after hernia repair. Bilateral TAP blocks can be used to provide effective postoperative analgesia after abdominal surgery with a lower midline incision. Rectus sheath blocks can be used for midline incision in the upper abdomen.

Spinal anesthesia has been used in some centers for infraumbilical procedures in neonates and infants. Infants and children typically have minimal hypotension from sympathectomy. Intravenous access can be established (conveniently in the foot) after the spinal anesthetic has been administered. This technique has become more widely used for neonates and infants as the potential risk of neurotoxicity from general anesthesia has received greater attention.

Many children will not tolerate placement of nerve blocks or nerve block catheters while awake; however, most peripheral block techniques can be performed safely in anesthetized children. When the area of operation is the upper extremity, we recommend those brachial plexus procedures that can most readily be performed using ultrasound guidance, specifically axillary, supraclavicular, and infraclavicular blocks. We suggest that interscalene block be performed in anesthetized patients only by those with experience and skill with ultrasound guidance and only for procedures where other block techniques would be inferior (eg, upper shoulder procedures) due to the reported rare occurrence of accidental intramedullary injections when interscalene blocks were performed in anesthetized adults. Single-shot and continuous femoral, adductor canal, and sciatic blocks are easily performed in children using ultrasound guidance. The latter can be performed using either a gluteal or a popliteal approach.

A wide variety of other terminal nerve blocks (eg, digital nerve, median nerve, occipital nerve, etc) are easily performed to reduce postoperative pain in children.

**Sedation for Procedures In & Out of the Operating**
Sedation is often requested for pediatric patients inside and outside the operating room for nonsurgical procedures. Cooperation and motionlessness may be required for imaging studies, bronchoscopy, gastrointestinal endoscopy, cardiac catheterization, dressing changes, and minor procedures (eg, casting and bone marrow aspiration). Requirements vary depending on the patient and the procedure, ranging from anxiolysis (minimal sedation), to conscious sedation (moderate sedation and analgesia), to deep sedation/analgesia, and finally to general anesthesia. Anesthesiologists are held to the same standards whether they provide moderate or deep sedation or they provide general anesthesia. This includes preoperative preparation (eg, fasting), assessment, monitoring, and postoperative care. Airway obstruction and hypoventilation are the most commonly encountered problems associated with moderate or deep sedation. With deep sedation and general anesthesia cardiovascular depression can also be a problem.

Table 42–3 includes doses of sedative-hypnotic drugs. One of the sedatives commonly used by nonanesthesia personnel in the past was chloral hydrate, 25 to 100 mg/kg orally or rectally. It has a slow onset of up to 60 min and a long half-life (8–11 h) that results in prolonged somnolence. Although it generally has little effect on ventilation, it can cause fatal airway obstruction in patients with sleep apnea. Moreover, chloral hydrate is a poor choice given its propensity for producing cardiac arrhythmias when it is used in the larger doses needed for moderate sedation. Midazolam, 0.5 mg/kg orally or 0.1 to 0.15 mg/kg intravenously, is particularly useful because its effects can be readily reversed with flumazenil. Doses should be reduced whenever more than one agent is used because of the potential for synergistic respiratory and cardiovascular depression.

Propofol is by far the most useful sedative-hypnotic drug. Although the drug is not approved for sedation of pediatric ICU patients and is not approved for administration by anyone other than those trained in the administration of general anesthesia, it can be dosed safely for most procedures at infusion rates up to 200 mcg/kg/min. In countries other than the United States, propofol is often administered using the Diprifusor, a computer-controlled infusion pump that maintains a constant target site concentration. Supplemental oxygen and close monitoring of the airway, ventilation, and other vital signs are mandatory (as with other agents). An LMA is usually well tolerated at higher doses.

For imaging studies, intranasal dexmedetomidine has also proven useful, especially with infants who do not have or need intravenous access.
Emergence & Recovery

Pediatric patients are particularly vulnerable to two common postanesthetic complications: laryngospasm and postintubation croup. As with adult patients, postoperative pain requires close, careful attention. Pediatric anesthesia practice varies widely, particularly in regard to extubation following a general anesthetic. In some pediatric hospitals, all children who will be extubated after a general anesthetic arrive in the postanesthesia care unit (PACU) with the tube or LMA still in place. They are subsequently extubated by the PACU nurse when defined criteria are reached. In other centers, nearly all children are extubated in the operating room before arriving in the PACU. High quality and safety are reported at centers following either protocol.

A. Laryngospasm

Laryngospasm is a forceful, involuntary spasm of the laryngeal musculature caused by stimulation of the superior laryngeal nerve (see Chapter 19). It may occur at induction, emergence, or any time in between without an endotracheal tube. Presumably, it can also occur when a tube is in place, but its occurrence will not be recognized. Laryngospasm is more common in young pediatric patients (almost 1 in 50 anesthetics) than in adults, and is most common in infants 1 to 3 months old. Laryngospasm at the end of a procedure can usually be avoided by extubating the patient either while awake (opening the eyes) or while deeply anesthetized (spontaneously breathing but not swallowing or coughing); both techniques have advocates, and despite strong opinions, evidence is lacking as to which is the better approach. Extubation during the interval between these extremes, however, is generally recognized as more hazardous. Recent URI or exposure to secondhand tobacco smoke predisposes children to laryngospasm on emergence. Treatment of laryngospasm includes gentle positive-pressure ventilation, forward jaw thrust, deepening of the anesthetic with intravenous propofol, intravenous lidocaine (1–1.5 mg/kg), or paralysis with intravenous succinylcholine (0.5–1 mg/kg), or rocuronium (0.4 mg/kg) and controlled ventilation. Intramuscular succinylcholine (4–6 mg/kg) remains an acceptable alternative in patients without intravenous access and in whom conservative measures have failed. Laryngospasm is usually an immediate postoperative event but may occur in the recovery room as the patient wakes up and chokes on pharyngeal secretions. For this reason, recovering pediatric patients should be positioned in the lateral position so that oral secretions pool and drain away from the vocal cords. When the child begins to regain consciousness, having the parents at the bedside may reduce his or her anxiety.
B. Postintubation Croup

Croup is due to glottic or tracheal edema. Because the narrowest part of the pediatric airway is the cricoid cartilage, this is the most susceptible area. Croup is less common with properly sized endotracheal tubes that are small enough to allow a slight gas leak at 10 to 25 cm H$_2$O. Postintubation croup is associated with early childhood (age 1–4 years), repeated intubation attempts, overly large endotracheal tubes, prolonged surgery, head and neck procedures, and excessive movement of the tube (eg, coughing with the tube in place, moving the patient’s head). Intravenous dexamethasone (0.25–0.5 mg/kg) may prevent formation of edema, and inhalation of nebulized racemic epinephrine (0.25–0.5 mL of a 2.25% solution in 2.5 mL normal saline) is an often-effective treatment. Although postintubation croup occurs later than laryngospasm, it will almost always appear within 3 h after extubation.

C. Postoperative Pain Management

Pain in pediatric patients has received considerable attention in recent years, and over that time the use of regional anesthetic and analgesic techniques (as previously above) has greatly increased. Commonly used parenteral opioids include fentanyl (1–2 mcg/kg), morphine (0.05–0.1 mg/kg), and hydromorphone (15 mcg/kg). A multimodal technique incorporating ketorolac (0.5–0.75 mg/kg) and intravenous dexmedetomidine will reduce opioid requirements. Oral, rectal, or intravenous acetaminophen will also reduce opioid requirements and can be a helpful substitute for ketorolac.

Patient-controlled analgesia (see Chapter 48) can also be successfully used in patients as young as 5 years old, depending on their maturity and on preoperative preparation. Commonly used opioids include morphine and hydromorphone. With a 10-min lockout interval, the recommended interval dose is either morphine, 20 mcg/kg, or hydromorphone, 5 mcg/kg. As with adults, continuous infusions increase the risk of respiratory depression; typical continuous infusion doses are morphine, 0 to 12 mcg/kg/h, or hydromorphone, 0 to 3 mcg/kg/h. The subcutaneous route may be used with morphine. Nurse-controlled and parent-controlled analgesia remain controversial but widely used techniques for pain control in children.

As with adults, epidural infusions for postoperative analgesia often consist of a local anesthetic combined with an opioid. Bupivacaine, 0.1% to 0.125%, or ropivacaine, 0.1% to 0.2%, are often combined with fentanyl, 2 to 2.5 mcg/mL (or equivalent concentrations of morphine or hydromorphone). Recommended infusion rates depend on the size of the patient, the final drug concentration, and
the location of the epidural catheter, and range from 0.1 to 0.4 mL/kg/h. Local anesthetic infusions can also be used with continuous nerve block techniques, but this is less common than in adults.

---

**Anesthetic Considerations in Specific Pediatric Conditions**

**PREMATURITY**

**Pathophysiology**

*Prematurity* is defined as birth before 37 weeks of gestation. This is in contrast to *small for gestational age*, which describes an infant (full-term or premature) whose age-adjusted weight is less than the fifth percentile. The multiple medical problems of premature neonates are usually due to immaturity of major organ systems or to intrauterine asphyxia. Pulmonary complications include hyaline membrane disease, apneic spells, and bronchopulmonary dysplasia. Exogenous pulmonary surfactant has proved to be an effective treatment for respiratory distress syndrome in premature infants. A patent ductus arteriosus leads to shunting and may possibly lead to pulmonary edema and congestive heart failure. Persistent hypoxia or shock may result in ischemic gut and necrotizing enterocolitis. Prematurity increases susceptibility to infection, hypothermia, intracranial hemorrhage, and kernicterus. Premature neonates also have an increased incidence of congenital anomalies.

**Anesthetic Considerations**

The small size (often <1000 g) and fragile medical condition of premature neonates demand that special attention be paid to airway control, fluid management, and temperature regulation. The problem of *retinopathy of prematurity*, a fibrovascular proliferation overlying the retina that may lead to progressive visual loss, deserves special consideration. Recent evidence suggests that fluctuating oxygen levels may be more damaging than increased oxygen tension. Moreover, other major risk factors, such as respiratory distress, apnea, mechanical ventilation, hypoxia, hypercarbia, acidosis, heart disease, bradycardia, infection, parenteral nutrition, anemia, and multiple blood transfusions, must be present. Nonetheless, oxygenation should be continuously
monitored (typically with pulse oximetry), with particular attention given to infants younger than 44 weeks postconception. Normal PaO₂ is 60 to 80 mm Hg in neonates. Excessive inspired oxygen concentrations are avoided by blending oxygen with air. Excessive inspired oxygen tensions can also predispose to chronic lung disease.

Anesthetic requirements of premature neonates are reduced. Opioid-based anesthetics are often favored over pure volatile anesthetic-based techniques because of the perceived tendency of the latter to cause myocardial depression.

Premature infants whose age is less than 50 (some authorities would say 60) weeks postconception at the time of surgery are prone to postoperative episodes of obstructive and central apnea for up to 24 h. In fact, even term infants can experience rare apneic spells following general anesthesia. **Risk factors for postanesthetic apnea include a low gestational age at birth, anemia (<30%), hypothermia, sepsis, and neurological abnormalities.** The risk of postanesthetic apnea may be decreased by intravenous administration of caffeine (10 mg/kg) or aminophylline.

Thus, elective (particularly outpatient) procedures should be deferred until the preterm infant reaches the age of at least 50 weeks postconception. A 6-month symptom-free interval has been suggested for infants with a history of apneic episodes or bronchopulmonary dysplasia. If surgery must be performed earlier, monitoring with pulse oximetry for 12 to 24 h postoperatively is mandatory for infants less than 50 weeks postconception; infants between 50 and 60 weeks postconception should be closely observed in the postanesthesia recovery unit for at least 2 h.

Sick, premature neonates often receive multiple transfusions of blood during their stay in the intensive care nursery. Their immunocompromised status predisposes them to cytomegalovirus infection following transfusion. Preventive measures include transfusing only with leukocyte-reduced red blood cells.

**INTESTINAL MALROTATION & VOLVULUS**

**Pathophysiology**

Malrotation of the intestines is a developmental abnormality that permits spontaneous abnormal rotation of the midgut around the mesentery (superior mesenteric artery). The incidence of malrotation is estimated to be about 1:500 live births. Most patients with malrotation of the midgut present during infancy with symptoms of bowel obstruction. Coiling of the duodenum with the
ascending colon can produce complete or partial duodenal obstruction. The most serious complication of malrotation, a midgut volvulus, can rapidly compromise intestinal blood supply causing infarction. Midgut volvulus is a true surgical emergency that most commonly occurs in infancy, with up to one third occurring in the first week of life. The mortality rate is high (up to 25%). Typical symptoms are bilious vomiting, progressive abdominal distention and tenderness, metabolic acidosis, and hemodynamic instability. Bloody diarrhea may be indicative of bowel infarction. Abdominal ultrasonography or upper gastrointestinal imaging confirms the diagnosis.

Anesthetic Considerations
Surgery provides the only definitive treatment of malrotation and midgut volvulus. If obstruction is present but obvious volvulus has not yet occurred, preoperative preparation may include stabilization of any coexisting conditions, insertion of a nasogastric (or orogastric tube) to decompress the stomach, broad-spectrum antibiotics, and fluid and electrolyte replacement before prompt transport to the operating room.

These patients are at increased risk for pulmonary aspiration. Depending on the size of the patient, rapid sequence induction (or awake intubation) should be employed. Patients with volvulus are usually hypovolemic and acidotic, and may be prone to hypotension. Postoperative ventilation will often be necessary, making an opioid-based anesthetic a reasonable choice. Fluid resuscitation, likely including blood products, with correction of acidosis is usually necessary. Arterial and central venous lines are helpful. Surgical treatment includes reducing the volvulus, freeing the obstruction, and resecting any obviously necrotic bowel. Bowel edema can complicate abdominal closure and has the potential to produce an abdominal compartment syndrome. The latter can impair ventilation, hinder venous return, and produce acute kidney injury; delayed fascial closure or temporary closure with a Silastic “silo” may be necessary. A second-look laparotomy may be required 24 to 48 h later to ensure viability of the remaining bowel and close the abdomen.

CONGENITAL DIAPHRAGMATIC HERNIA
Pathophysiology
During fetal development, the gut can herniate into the thorax through one of three diaphragmatic defects: the left or right posterolateral foramina of
Bochdalek or the anterior foramen of Morgagni. The reported incidence of diaphragmatic hernia is 1 in 3000 to 5000 live births. Left-sided herniation is the most common type (90%). Hallmarks of diaphragmatic herniation include hypoxia, a scaphoid abdomen, and evidence of bowel in the thorax by auscultation or radiography. Congenital diaphragmatic hernia is often diagnosed antenatally during a routine obstetric ultrasound examination. A reduction in alveoli and bronchioli (pulmonary hypoplasia) and malrotation of the intestines are almost always present. The ipsilateral lung is particularly impaired and the herniated gut can compress and retard the maturation of both lungs.

Diaphragmatic hernia, often accompanied by marked pulmonary hypertension, is associated with 40% to 50% mortality. Cardiopulmonary compromise is primarily due to pulmonary hypoplasia and pulmonary hypertension rather than to the mass effect of the herniated viscera.

Treatment is aimed at immediate stabilization with sedation, paralysis, and moderate hyperventilation. Pressure-limited ventilation is used. Some centers employ permissive hypercapnia (postductal PaCO₂ < 65 mm Hg) and accept mild hypoxemia (preductal SpO₂ > 85%) in an effort to reduce pulmonary barotrauma. High-frequency oscillatory ventilation (HFOV) can improve ventilation and oxygenation with less barotrauma. Inhaled nitric oxide may be used to lower pulmonary artery pressures, but it does not appear to improve survival. If the pulmonary hypertension stabilizes and there is little right-to-left shunting, early surgical repair may be undertaken. If the patient fails to stabilize, venoarterial extracorporeal membrane oxygenation (ECMO) may be undertaken. Treatment with prenatal intrauterine surgery has not improved outcomes.

Anesthetic Considerations

Gastric distention must be minimized by placement of a nasogastric tube and avoidance of high levels of positive-pressure ventilation. The neonate is preoxygenated and typically intubated without the aid of muscle relaxants. Anesthesia is maintained with low concentrations of volatile agents or opioids, muscle relaxants, and oxygen-enriched air. Hypoxia and expansion of air in the bowel contraindicate use of nitrous oxide. If possible, peak inspiratory airway pressures should be less than 30 cm H₂O. A sudden fall in lung compliance, blood pressure, or oxygenation may signal a contralateral (usually right-sided) pneumothorax and necessitate placement of a chest tube. Arterial blood gases are monitored by sampling a preductal artery if an umbilical artery catheter is not already in place. Surgical repair is performed via a subcostal...
incision of the affected side; the bowel is reduced into the abdomen and the diaphragm is closed. Aggressive attempts at expansion of the ipsilateral lung following surgical decompression are detrimental. The extent of pulmonary hypoplasia and the presence of other congenital defects determine the prognosis.

**TRACHEOESOPHAGEAL FISTULA**

**Pathophysiology**

There are several types of tracheoesophageal fistulae (Figure 42–3). The most common (type IIIB) is the combination of an upper esophagus that ends in a blind pouch and a lower esophagus that connects to the trachea. Breathing results in gastric distention, whereas feeding leads to choking, coughing, and cyanosis (three Cs). The diagnosis is suspected by failure to pass a catheter into the stomach and confirmed by visualization of the catheter coiled in a blind, upper esophageal pouch. Aspiration pneumonia and the coexistence of other congenital anomalies (eg, cardiac) are common. These may include the association of vertebral defects, anal atresia, tracheoesophageal fistula with esophageal atresia, and radial dysplasia, known as the VATER syndrome. The VACTERL variant also includes cardiac and limb anomalies. Preoperative management is directed at identifying all congenital anomalies and preventing aspiration pneumonia. This may include maintaining the patient in a head-up position, using an oral-esophageal tube, and avoiding feedings. In some instances gastrostomy may be performed under local anesthesia. Definitive surgical treatment is usually postponed until any pneumonia clears or improves with antibiotic therapy.

![Figure 42–3](image)

**FIGURE 42–3** Of the five types of tracheoesophageal fistula, type IIIB represents 90% of cases.
Anesthetic Considerations

These neonates tend to have copious pharyngeal secretions that require frequent suctioning before and during surgery. Positive-pressure ventilation is avoided prior to intubation, as the resulting gastric distention may interfere with lung expansion. Intubation is often performed awake and without muscle relaxants. These neonates are often dehydrated and malnourished due to poor oral intake.

The key to successful management is correct endotracheal tube position. Ideally, the tip of the tube lies distal to the fistula and proximal to the carina, so that anesthetic gases pass into the lungs instead of the stomach. This is impossible if the fistula connects to the carina or a mainstem bronchus. In these situations, intermittent venting of a gastrostomy tube may permit positive-pressure ventilation without excessive gastric distention. Suctioning of the gastrostomy tube and upper esophageal pouch tube helps prevent aspiration pneumonia. Surgical division of the fistula and esophageal anastomosis is performed via a right extrapleural thoracotomy with the patient in the left lateral position. A precordial stethoscope should be placed in the dependent (left) axilla, since obstruction of the mainstem bronchus during surgical retraction is not uncommon. A drop in oxygen saturation indicates that the retracted lung needs to be reexpanded. Surgical retraction can also compress the great vessels, trachea, heart, and vagus nerve. Blood pressure should be continuously monitored with an arterial line. These infants often require ventilation with 100% oxygen. Blood should be immediately available for transfusion. Postoperative complications include gastroesophageal reflux, aspiration pneumonia, tracheal compression, and anastomotic leakage. Most patients must remain intubated and receive positive-pressure ventilation in the immediate postoperative period. Neck extension and instrumentation (eg, suctioning) of the esophagus may disrupt the surgical repair and should be avoided.

GASTROSCHISIS & OMPHALOCELE

Pathophysiology

Gastroschisis and omphalocele are congenital disorders characterized by defects in the abdominal wall that allow external herniation of viscera. Omphaloceles occur at the base of the umbilicus, have a hernia sac, and are often associated with other congenital anomalies such as trisomy 21, diaphragmatic hernia, and cardiac and bladder malformations. In contrast, the gastroschisis defect is usually lateral to the umbilicus, does not have a hernia sac, and is often an isolated
finding. Antenatal diagnosis by ultrasound can be followed by elective cesarean section at 38 weeks and immediate surgical repair. Perioperative management focuses on preventing hypothermia, infection, and dehydration. These problems are usually more serious in gastroschisis, as the protective hernial sac is absent.

**Anesthetic Considerations**

The stomach is decompressed with a nasogastric tube before induction. Intubation can be accomplished with the patient awake or anesthetized and with or without muscle relaxation. Nitrous oxide should be avoided. Muscle relaxation is required for replacing the bowel into the abdominal cavity. A one-stage closure (primary repair) is often not advisable, as it can cause an abdominal compartment syndrome. A staged closure with a temporary Silastic “silo” may be necessary, followed by a second procedure a few days later for complete closure. Suggested criteria for a staged closure include intragastric or intravesical pressure greater than 20 cm H₂O, peak inspiratory pressure greater than 35 cm H₂O, or an end-tidal CO₂ greater than 50 mm Hg. The neonate remains intubated after the procedure and is weaned from the ventilator over the next 1 to 2 days in the ICU.

**HYPERTROPHIC PYLORIC STENOSIS**

**Pathophysiology**

Hypertrophic pyloric stenosis impedes emptying of gastric contents. Persistent vomiting depletes potassium, chloride, hydrogen, and sodium ions, causing hypochloremic metabolic alkalosis. Initially, the kidney tries to compensate for the alkalosis by excreting sodium bicarbonate in the urine. Later, as hyponatremia and dehydration worsen, the kidneys must conserve sodium even at the expense of hydrogen ion excretion (paradoxic aciduria). Correction of the volume and ion deficits and metabolic alkalosis is an indication for hydration with a sodium chloride (rather than lactated Ringer’s) solution supplemented with potassium chloride.

**Anesthetic Considerations**

Surgery should be delayed until fluid and electrolyte abnormalities have been corrected. Operation for correction of pyloric stenosis is never an emergency.
The stomach should be emptied with a nasogastric or orogastric tube; the tube should be suctioned with the patient in the supine and lateral positions. Diagnosis often requires contrast radiography, and all contrast media must be suctioned from the stomach before induction. Techniques for intubation and induction vary, but in all cases the patient’s increased risk of aspiration must be considered. Experienced clinicians have variously advocated awake intubation, rapid sequence intravenous induction, and even careful inhalation induction in selected patients. Pyloromyotomy typically is a short procedure that may require muscle relaxation. These neonates may be at increased risk for respiratory depression and hypoventilation in the recovery room because of persistent metabolic (measurable in arterial blood) or cerebrospinal fluid alkalosis (despite neutral arterial pH).

INFECTIONOUS CROUP, FOREIGN BODY ASPIRATION, & ACUTE EPIGLOTTITIS

Pathophysiology

Croup is obstruction of the airway characterized by a barking cough. One type of croup, postintubation croup, has already been discussed. Another type is due to viral infection. Infectious croup usually follows a viral URI in children aged 3 months to 3 years. The airway below the epiglottis is involved (laryngotracheobronchitis). Infectious croup progresses slowly and rarely requires intubation. Foreign body aspiration is typically encountered in children aged 6 months to 5 years. Commonly aspirated objects include peanuts, coins, small batteries, screws, nails, tacks, and small pieces of toys. Onset is typically acute and the obstruction may be supraglottic, glottic, or subglottic. Stridor is prominent with the first two, whereas wheezing is more common with the latter. A clear history of an aspiration may be absent. Acute epiglottitis is a bacterial infection (most commonly Haemophilus influenzae type B) classically affecting 2- to 6-year-old children but also occasionally appearing in older children and adults. It rapidly progresses from a sore throat to dysphagia and complete airway obstruction. The term supraglottitis has been suggested because the inflammation typically involves all supraglottic structures. Endotracheal intubation and antibiotic therapy can be lifesaving. Epiglottitis has increasingly become a disease of adults because of the widespread use of H influenzae vaccines in children.
Anesthetic Considerations

Patients with croup are managed conservatively with oxygen and mist therapy. Nebulized racemic epinephrine and intravenous dexamethasone (0.25–0.5 mg/kg) are used. Indications for intubation include progressive intercostal retractions, obvious respiratory fatigue, and central cyanosis.

Anesthetic management of a foreign body aspiration is challenging, particularly with supraglottic and glottic obstruction. Minor manipulation of the airway can convert partial into complete obstruction. Experts recommend careful inhalational induction for a supraglottic object and gentle upper airway endoscopy to remove the object, secure the airway, or both. When the object is subglottic, a rapid-sequence or inhalational induction is usually followed by rigid bronchoscopy by the surgeon or endotracheal intubation and flexible bronchoscopy. Surgical preferences may vary according to the size of the patient and the nature and location of the foreign body. Close cooperation between the surgeon and anesthesiologist is essential.

Children with impending airway obstruction from epiglottitis present in the operating room for definitive diagnosis by laryngoscopy followed by intubation. A preoperative lateral neck radiograph may show a characteristic thumblike epiglottic shadow, which is very specific but often absent. The radiograph is also helpful in revealing other causes of obstruction, such as foreign bodies.

Rapid onset and progression of stridor, drooling, hoarseness, tachypnea, chest retractions, and a preference for the upright position are predictive of airway obstruction. Total obstruction can occur at any moment, and preparations for a possible tracheostomy must be made prior to induction of general anesthesia. Laryngoscopy should not be performed before induction of anesthesia because of the increased risk of laryngospasm. In most cases, an inhalational induction is performed with the patient in the sitting position, using a volatile anesthetic and oxygen. Oral intubation with an endotracheal tube one-half to one size smaller than usual is attempted as soon as an adequate depth of anesthesia is established. The oral tube may be replaced with a well-secured nasal endotracheal tube at the end of the procedure, as the latter is better tolerated in the postoperative period. If intubation is impossible, rigid bronchoscopy or emergency tracheostomy must be performed.

TONSILLECTOMY & ADENOIDECTION

Pathophysiology
Lymphoid hyperplasia can lead to upper airway obstruction, obligate mouth breathing, and even pulmonary hypertension with cor pulmonale. Although these extremes of pathology are unusual, all children undergoing tonsillectomy or adenoidectomy should be considered to be at increased risk for perioperative airway problems.

**Anesthetic Considerations**

Surgery should be postponed if there is evidence of acute infection or suspicion of a clotting abnormality. Administration of an anticholinergic agent will decrease pharyngeal secretions. A history of airway obstruction or apnea suggests an inhalational induction without paralysis until the ability to ventilate with positive pressure is established. A reinforced or preformed endotracheal tube (eg, RAE tube) may decrease the risk of kinking by the surgeon’s self-retaining mouth gag. Blood transfusion is rarely necessary, but one must be wary of occult blood loss. Gentle inspection and suctioning of the pharynx precede extubation. Although deep extubation decreases the chance of laryngospasm and may prevent blood clot dislodgment from coughing, an awake extubation is generally preferred to reduce the likelihood of aspiration. Postoperative vomiting is common and gastric suctioning is usually performed prior to extubation. One must be alert in the recovery room for postoperative bleeding, signs of which may include restlessness, pallor, tachycardia, or hypotension. If reoperation is necessary to control bleeding, intravascular volume must first be restored. Evacuation of stomach contents with a nasogastric tube is followed by a rapid-sequence induction. Because of the possibility of bleeding and airway obstruction, children younger than 3 years old may be hospitalized for the first postoperative night. Sleep apnea and recent infection increase the risk of postoperative complications and may necessitate admission.

**MYRINGOTOMY & INSERTION OF TYPANOSTOMY TUBES**

**Pathophysiology**

Children presenting for myringotomy and insertion of tympanostomy tubes have a long history of URIs that have spread through the eustachian tube, causing repeated episodes of otitis media. Causative organisms are usually bacterial and include pneumococcus, *H influenzae, Streptococcus*, and *Mycoplasma*. 
pneumoniae. Myringotomy, a radial incision in the tympanic membrane, releases any fluid that has accumulated in the middle ear. Tympanostomy tubes provide long-term drainage. Because of the chronic and recurring nature of this illness, it is not surprising that these patients often have symptoms of a URI on the day of scheduled surgery.

**Anesthetic Considerations**

These are typically very short (10–15 min) outpatient procedures. Inhalational induction is a common technique. Unlike tympanoplasty surgery, nitrous oxide diffusion into the middle ear is not a concern during myringotomy because of the brief period of anesthetic exposure before the middle ear is vented. Because most of these patients are otherwise healthy and there is no blood loss, intravenous access is usually not necessary. Ventilation with a face mask or LMA minimizes the risk of perioperative respiratory complications (eg, laryngospasm) associated with intubation.

**TRISOMY 21 SYNDROME (DOWN SYNDROME)**

**Pathophysiolog**

An additional chromosome 21—part or whole—results in the most common pattern of congenital human malformation: Down syndrome. Characteristic abnormalities of interest to the anesthesiologist include a short neck, atlantooccipital instability, irregular dentition, mental retardation, hypotonia, and a large tongue. Associated abnormalities include congenital heart disease in 40% of patients (particularly endocardial cushion defects and ventricular septal defect), subglottic stenosis, tracheoesophageal fistula, chronic pulmonary infections, and seizures. These neonates are often premature and small for their gestational age. Later in life many patients with Down syndrome undergo multiple procedures requiring general anesthesia.

**Anesthetic Considerations**

Because of anatomic differences, these patients often have difficult airways, particularly during infancy. The size of the endotracheal tube required is typically smaller than that predicted by age. Respiratory complications such as postoperative stridor and apnea are common. Neck flexion during laryngoscopy and intubation may result in atlantooccipital dislocation because of the
congenital laxity of these ligaments. The possibility of associated congenital
diseases must always be considered. As in all pediatric patients, care must be
taken to avoid air bubbles in the intravenous line because of possible right-to-left
shunts and paradoxical air emboli.

**CYSTIC FIBROSIS**

**Pathophysiology**

Cystic fibrosis is a genetic disease of the exocrine glands primarily affecting the
pulmonary and gastrointestinal systems. Abnormally thick and viscous
secretions coupled with decreased ciliary activity lead to pneumonia, wheezing,
and bronchiectasis. Pulmonary function studies reveal increased residual volume
and airway resistance with decreased vital capacity and expiratory flow rate.
Malabsorption syndrome may lead to dehydration and electrolyte abnormalities.

**Anesthetic Considerations**

Anticholinergic drugs have been used without ill effects, and the choice whether
to use them appears to be inconsequential. Induction with inhalational
anesthetics may be prolonged in patients with severe pulmonary disease.
Intubation should not be performed until the patient is deeply anesthetized to
avoid coughing and stimulation of mucus secretions. The patient’s lungs should
be suctioned during general anesthesia and before extubation to minimize the
accumulation of secretions. Outcome is favorably influenced by preoperative
and postoperative respiratory therapy that includes bronchodilators, incentive
spirometry, postural drainage, and pathogen-specific antibiotic therapy.

**SCOLIOSIS**

**Pathophysiology**

Scoliosis is lateral rotation and curvature of the vertebrae and a deformity of the
rib cage. It can have many etiologies, including idiopathic, congenital,
neuromuscular, and traumatic. Scoliosis can affect cardiac and respiratory
function. Elevated pulmonary vascular resistance from chronic hypoxia causes
pulmonary hypertension and right ventricular hypertrophy. Respiratory
abnormalities include reduced lung volumes and chest wall compliance. PaO₂ is
reduced as a result of ventilation/perfusion mismatching, whereas an increased
Paco2 signals severe disease.

**Anesthetic Considerations**

Preoperative evaluation may include pulmonary function tests, arterial blood gases, and electrocardiography. Corrective surgery is complicated by prone positioning, and by the possibility of major blood loss and of paraplegia. Spinal cord function can be assessed by neurophysiological monitoring (somatosensory and motor evoked potentials, see Chapters 6 and 26) or by awakening the patient intraoperatively to test lower limb muscle strength. Patients with severe respiratory disease may remain intubated postoperatively. Patients with scoliosis due to muscular dystrophy are predisposed to malignant hyperthermia, cardiac arrhythmias, and untoward effects of succinylcholine (hyperkalemia, myoglobinuria, and sustained muscular contractures).

**GUIDELINES**

**SUGGESTED READINGS**

WEB SITE
In the absence of coexisting disease, resting systolic cardiac function seems to be preserved, even in octogenarians. Increased vagal tone and decreased sensitivity of adrenergic receptors lead to a decline in heart rate.

Elderly patients undergoing echocardiographic evaluation for surgery have an increased incidence of diastolic dysfunction compared with younger patients.

Diminished cardiac reserve in many elderly patients may be manifested as exaggerated decreases in blood pressure during induction of general anesthesia. A prolonged circulation time delays the onset of intravenous drugs, but speeds induction with inhalational agents.

Aging decreases the elasticity of lung tissue, allowing overdistention of alveoli and collapse of small airways. Residual volume and the functional residual capacity increase with aging. Airway collapse increases residual volume and closing capacity. Even in normal persons, closing capacity exceeds functional residual capacity at age 45 years in the supine position and age 65 years in the sitting position.

The neuroendocrine response to stress seems to be largely preserved or, at most, only slightly decreased in healthy elderly patients. Aging is associated with a decreasing response to β-adrenergic agents.

Impairment of Na⁺ handling, concentrating ability, and diluting capacity predispose elderly patients to both dehydration and fluid overload.

Liver mass and hepatic blood flow decline with aging. Hepatic function declines in proportion to the decrease in liver mass.

Aging produces both pharmacokinetic and pharmacodynamic changes. Disease-related changes and wide variations among individuals in
similar populations prevent convenient generalizations.

9. The principal pharmacodynamic change associated with aging is a reduced anesthetic requirement, represented by a reduced minimum alveolar concentration (MAC).

10. Elderly patients display a lower dose requirement for propofol, etomidate, opioids, benzodiazepines, and barbiturates.

The elderly patient typically presents for surgery with multiple chronic medical conditions, in addition to any acute surgical illness. Age is not a contraindication to anesthesia and surgery; however, perioperative morbidity and mortality are greater in elderly than younger surgical patients.

As with pediatric patients, optimal anesthetic management of geriatric patients depends upon an understanding of the normal changes in physiology, anatomy, and response to pharmacological agents that accompany aging. In fact, there are many similarities between elderly and pediatric patients (Table 43–1). Individual genetic polymorphisms and lifestyle choices can modulate the inflammatory response, which contributes to the development of many systemic diseases. Consequently, chronologic age may not fully reflect an individual patient’s true physical condition. The relatively high frequency of serious physiological abnormalities in elderly patients demands a particularly careful preoperative evaluation.

Elderly patients are frequently treated with β-blockers. β-Blockers should be continued perioperatively, if patients are taking such medications chronically, to avoid the effects of β-blocker withdrawal. A careful review of patients’ often extensive medication lists can reveal the routine use of oral hypoglycemic...
agents, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers, antiplatelet agents, statins, and anticoagulants. Because elderly patients frequently take multiple drugs for multiple conditions, they often benefit from an evaluation before the day of surgery, even when scheduled for outpatient surgery. Preoperative laboratory studies should be guided by patient condition and history. Patients who have cardiac stents requiring antiplatelet therapy present particularly vexing problems. Their management should be closely coordinated among the surgeon, cardiologist, and anesthesiologist and adhere to appropriate management guidelines (see Chapter 21). At no time should the anesthesia staff discontinue antiplatelet/anticoagulant therapy without discussing the plan with the patient’s primary physicians.

**PREOPERATIVE ASSESSMENT**

To promote quality improvement in geriatric surgical care, extensive best practice guidelines have been issued by the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) and the American Geriatrics Society (AGS). These guidelines provide a systematic approach to perioperative geriatric care. In particular they require the care team to confirm that the patient’s wishes regarding treatment preferences and advanced directives are understood and documented. A checklist to ensure optimal preoperative assessment in the geriatric surgical patient is suggested (Table 43–2).

**TABLE 43–2  Checklist for the optimal preoperative assessment of the geriatric surgical patient.**

<table>
<thead>
<tr>
<th>Checklist</th>
</tr>
</thead>
<tbody>
<tr>
<td>In addition to conducting a complete history and physical examination of the patient, the following assessments are strongly recommended:</td>
</tr>
<tr>
<td>□ Assess the patient’s <strong>cognitive ability</strong> and <strong>capacity</strong> to understand the anticipated surgery.</td>
</tr>
<tr>
<td>□ Screen the patient for <strong>depression</strong>.</td>
</tr>
<tr>
<td>□ Identify the patient’s risk factors for developing postoperative <strong>delirium</strong>.</td>
</tr>
<tr>
<td>□ Screen for <strong>alcohol</strong> and other <strong>substance abuse/dependence</strong>.</td>
</tr>
<tr>
<td>□ Perform a preoperative <strong>cardiac</strong> evaluation according to the American College of Cardiology/American Heart Association algorithm for patients undergoing noncardiac surgery.</td>
</tr>
<tr>
<td>□ Identify the patient’s risk factors for postoperative <strong>pulmonary</strong> complications and implement appropriate strategies for prevention.</td>
</tr>
<tr>
<td>□ Document <strong>functional status</strong> and history of <strong>falls</strong>.</td>
</tr>
</tbody>
</table>
Determine baseline frailty score.

Assess patient’s nutritional status and consider preoperative interventions if the patient is at severe nutritional risk.

Take an accurate and detailed medication history and consider appropriate perioperative adjustments. Monitor for polypharmacy.

Determine the patient’s treatment goals and expectations in the context of the possible treatment outcomes.

Determine patient’s family and social support system.

Order appropriate preoperative diagnostic tests focused on elderly patients.

A cognitive assessment such as the Mini Cog examination is recommended for patients who do not have a history of dementia or cognitive impairment (Figure 43-1). In addition to screening for cognitive impairment, depression screening should also be conducted. Frailty reflects a decrease in functional reserve capacity and an inability to respond to the physiological challenges presented by the stress of surgery. Frailty can be assessed using one of several scoring systems available. A simple scoring system from Makary et al is presented in Table 43-3.
Mini-Cog®

Instructions for Administration & Scoring

ID: __________ Date: ______________

Step 1: Three Word Registration

Look directly at person and say, "Please listen carefully. I am going to say three words that I want you to repeat back to me now and try to remember. The words are [select a list of words from the versions below]. Please say them for me now." If the person is unable to repeat the words after three attempts, move on to Step 2 (clock drawing).

The following and other word lists have been used in one or more clinical studies. For repeated administrations, use of an alternative word list is recommended.

<td>Nation</td>
<td>Garden</td>
<td>Heaven</td>
</tr>
<tr>
<td>Chair</td>
<td>Table</td>
<td>Baby</td>
<td>Finger</td>
<td>Picture</td>
<td>Mountain</td>
</tr>
</tbody>
</table>

Step 2: Clock Drawing

Say: "Next, I want you to draw a clock for me. First, put in all of the numbers where they go." When that is completed, say: "Now, set the hands to 10 past 11."

Use preprinted circle (see next page) for this exercise. Repeat instructions as needed as this is not a memory test. Move to Step 3 if the clock is not complete within three minutes.

Step 3: Three Word Recall

Ask the person to recall the three words you stated in Step 1. Say: "What were the three words I asked you to remember?" Record the word list version number and the person's answers below.

Word List Version: ______ Person's Answers: _____________________________

Scoring

<table>
<thead>
<tr>
<th>Word Recall: ______ (0-3 points)</th>
<th>1 point for each word spontaneously recalled without cueding.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Clock Draw: ______ (0 or 2 points)</td>
<td>Normal clock = 2 points. A normal clock has all numbers placed in the correct sequence and approximately correct position (e.g. 12, 3, 6 and 9 are in anchor positions) with no missing or duplicate numbers. Hands are pointing to the 11 and 2 (11:10). Hand length is not scored. Inability or refusal to draw a clock (abnormal) = 6 points.</td>
</tr>
<tr>
<td>Total Score: ______ (0-5 points)</td>
<td>Total score = Word Recall score + Clock Draw score. A cut point of &lt;3 on the Mini-Cog® has been validated for dementia screening, but many individuals with clinically meaningful cognitive impairment will score higher. When greater sensitivity is desired, a cut point of &lt;4 is recommended as it may indicate a need for further evaluation of cognitive status.</td>
</tr>
</tbody>
</table>

**TABLE 43–3** Frailty score (operational definition).1,2
Optimal preoperative assessment provides the care team with information to identify patients at high risk for adverse perioperative outcomes and to enact strategies to mitigate those risks where possible. Moreover, such assessment permits realistic discussions of likely patient outcomes when considering surgical interventions.

### Age-Related Anatomic & Physiological Changes

**CARDIOVASCULAR SYSTEM**

Cardiovascular diseases are more prevalent in the geriatric than general population. Still, it is important to distinguish between changes in physiology that normally accompany aging and the pathophysiology of diseases common in the geriatric population (Table 43–4). For example, atherosclerosis is pathological—it is not present in healthy elderly patients. On the other hand, a reduction in arterial elasticity caused by fibrosis of the media is part of the normal aging process. Changes in the cardiovascular system that accompany aging include decreased vascular and myocardial compliance and autonomic responsiveness. In addition to myocardial fibrosis, calcification of the valves can occur. Elderly patients with systolic murmurs should be suspected of having aortic stenosis. However, in the absence of coexisting disease, resting systolic

cardiac function seems to be preserved, even in octogenarians. Functional capacity of less than 4 metabolic equivalents (METS) is associated with potential adverse outcomes (see Chapter 21). Increased vagal tone and decreased sensitivity of adrenergic receptors lead to a decline in heart rate; maximal heart rate declines by approximately 1 beat/min per year of age over 50. Fibrosis of the conduction system and loss of sinoatrial node cells increase the incidence of dysrhythmias, particularly atrial fibrillation and flutter. Preoperative risk assessment and evaluation of the patient with cardiac disease were previously reviewed in this text (see Chapters 18, 20, and 21). Age per se does not mandate any particular battery of tests or evaluative tools, although there is a long tradition of routinely requesting tests such as 12-lead electrocardiography in patients who are older than a defined age. Additionally, the NSQIP/AGS guidelines recommend that patient hemoglobin, kidney function tests, and albumin be determined (Table 43–5).

</table>
Some elderly individuals will present for surgery with previously undetected conditions that require an intervention, such as arrhythmias, congestive heart failure, or myocardial ischemia. Cardiovascular evaluation should be guided by American Heart Association guidelines.

Elderly patients undergoing echocardiographic evaluation for surgery have an increased incidence of diastolic dysfunction compared with younger patients. Diastolic dysfunction prevents the ventricle from optimally relaxing and consequently inhibits diastolic ventricular filling. The ventricle becomes less compliant, and filling pressures are increased. Diastolic dysfunction is not equivalent to diastolic heart failure. In some patients, systolic ventricular function can be well preserved; however, the patient can have signs of congestion secondary to severe diastolic dysfunction. Diastolic heart failure most often coexists with systolic dysfunction.

Echocardiography is used to assess diastolic dysfunction. A ratio of greater than 15 between the peak E velocity of transmitral diastolic filling and the E' tissue Doppler velocity is associated with elevated left ventricular end-diastolic pressure and diastolic dysfunction. Conversely, a ratio of less than 8 is consistent with normal diastolic function (Figure 43–2).
FIGURE 43–2  A: In this Doppler study of diastolic inflow, the E wave is seen with a peak velocity of 90.9 cm/s. This Doppler study reflects the velocity of blood as it fills the left ventricle early in diastole. B: In tissue Doppler, the velocity of the movement of the lateral annulus of the mitral valve is measured. The E’ wave in this image is 6.95 cm/s. This corresponds to the movement of the myocardium during diastole. (Reproduced with permission from Wasnick J, Hillel Z, Kramer D, et al. Cardiac Anesthesia & Transesophageal Echocardiography. New York, NY: McGraw-Hill; 2011.)

Marked diastolic dysfunction may be seen with systemic hypertension,
coronary artery disease, cardiomyopathies, and valvular heart disease (particularly aortic stenosis), all of which are more common in older than younger patients. Patients may be asymptomatic or complain of exercise intolerance, dyspnea, cough, or fatigue. Diastolic dysfunction results in relatively large increases in ventricular end-diastolic pressure, with small changes of left ventricular volume; the atrial contribution to ventricular filling becomes even more important than in younger patients. Atrial enlargement predisposes patients to atrial fibrillation and flutter. Patients are at increased risk of developing congestive heart failure. The elderly patient with diastolic dysfunction may poorly tolerate perioperative fluid administration, resulting in elevated left ventricular end-diastolic pressure and pulmonary congestion.

Diminished cardiac reserve in many elderly patients may be manifested as exaggerated decreases in blood pressure during induction of general anesthesia. A prolonged circulation time delays the onset of intravenous drugs, but speeds induction with inhalational agents. Like infants, elderly patients have less ability to respond to hypovolemia, hypotension, or hypoxia with an increase in heart rate. Ultimately, cardiovascular diseases, including heart failure, stroke, arrhythmias, and hypertension, contribute to an increased risk of morbidity, mortality, increased cost of care, and frailty in elderly patients.

**RESPIRATORY SYSTEM**

- Aging decreases the elasticity of lung tissue, allowing overdistention of alveoli and collapse of small airways. Residual volume and the functional residual capacity increase with aging. Airway collapse increases residual volume and closing capacity. Even in normal persons, closing capacity exceeds functional residual capacity at age 45 years in the supine position and age 65 years in the sitting position. When this happens, some airways close during part of normal tidal breathing, resulting in a mismatch of ventilation and perfusion. The additive effect of these changes variably decreases arterial oxygen tension. Both anatomic and physiological dead space increase. Other pulmonary effects of aging are summarized in Table 43–4.

- Decreased respiratory muscle function/mass, a less compliant chest wall, and intrinsic changes in lung function can increase the work of breathing and make it more difficult for elderly patients to muster a respiratory reserve in settings of acute illness (eg, infection). Many patients also present with obstructive or restrictive lung diseases. In patients who have no intrinsic pulmonary disease, gas exchange is unaffected by aging.
Measures to prevent perioperative hypoxia in elderly patients include a longer preoxygenation period prior to induction, increased inspired oxygen concentrations during anesthesia, positive end-expiratory pressure, and pulmonary toilet. Aspiration pneumonia is a potentially life-threatening complication in elderly patients. Ventilatory impairment in the recovery room is more common in elderly than younger patients. Factors associated with an increased risk of postoperative pulmonary complications include older age, chronic obstructive pulmonary disease, sleep apnea, malnutrition, and abdominal or thoracic surgical incisions.

**METABOLIC & ENDOCRINE FUNCTION**

Basal and maximal oxygen consumption declines with age. After reaching peak weight at about age 60 years, most men and women begin losing weight; the average elderly man and woman weigh less than their younger counterparts. Heat production decreases, heat loss increases, and hypothalamic temperature-regulating centers may reset at a lower level.

Diabetes affects approximately 15% of patients older than age 70 years. Its impact on numerous organ systems can complicate perioperative management. Diabetic neuropathy and autonomic dysfunction are particular problems for the elderly.

Increasing insulin resistance leads to a progressive decrease in the ability to avoid hyperglycemia with glucose loads. Institutions typically have their own protocols on how to manage increased blood glucose perioperatively, and these protocols reflect the changing literature on appropriate blood glucose targets. Attempts to maintain blood glucose within a strictly normal range during surgery, anesthesia, or critical illness may lead to hypoglycemia and adverse outcomes. Anesthesia practitioners are advised to be aware of changing performance benchmarks related to this measure.

The neuroendocrine response to stress seems to be largely preserved or, at most, only slightly decreased in healthy elderly patients. Aging is associated with a decreasing response to β-adrenergic agents.

**KIDNEY FUNCTION**

Kidney blood flow and kidney mass (eg, glomerular number and tubular length) decrease with age. Kidney function, as determined by glomerular filtration rate and creatinine clearance, is reduced (*Table 43–4*). The serum creatinine level is unchanged because of a decrease in muscle mass and creatinine production,
whereas blood urea nitrogen gradually increases with aging. Impairment of Na\(^+\) handling, concentrating ability, and diluting capacity predispose elderly patients to both dehydration and fluid overload. The response to antidiuretic hormone and aldosterone is reduced. The ability to reabsorb glucose is decreased. The combination of reduced kidney blood flow and decreased nephron mass in elderly patients increases the risk of acute kidney failure in the postoperative period, particularly when patients are exposed to nephrotoxic drugs and techniques.

As kidney function declines, so does the kidney’s ability to excrete drugs. The decreased capacity to handle water and electrolyte loads makes proper fluid management more critical; elderly patients are more predisposed to developing hypokalemia and hyperkalemia. This is further complicated by the common use of diuretics in the elderly population. The search is ongoing for drugs that might protect the kidney perioperatively, as well as for specific genetic profiles of patients at greater risk of perioperative kidney injury.

**GASTROINTESTINAL FUNCTION**

Liver mass and hepatic blood flow decline with aging. Hepatic function declines in proportion to the decrease in liver mass. Thus, the rate of biotransformation and albumin production decreases. Plasma cholinesterase levels are reduced in elderly men. Malnutrition is associated with adverse surgical outcomes. Nutritional screening should be a part of preoperative assessment. NSQIP/AGS guidelines, in particular, note a severe nutritional risk is present when:

1. Body mass index (BMI) is less than 18.5 kg/m\(^2\)
2. Serum albumin is less than 3 g/dL
3. Unintended weight loss is greater than 10% within 6 months

**NERVOUS SYSTEM**

Brain mass decreases with age; neuronal loss is prominent in the cerebral cortex, particularly the frontal lobes. Cerebral blood flow also decreases about 10% to 20% in proportion to neuronal losses. It remains tightly coupled to metabolic rate, and autoregulation is intact. Neurons lose complexity of their dendritic tree and the number of synapses. The synthesis of neurotransmitters is reduced. Serotonergic, adrenergic, and \(\gamma\)-aminobutyric acid (GABA) binding sites are also
reduced. Astrocytes and microglial cells increase in number.

Dosage requirements for general (minimum alveolar concentration [MAC]) anesthetics are reduced. Administration of a given volume of epidural local anesthetic tends to result in more extensive spread in elderly patients. A longer duration of action should be expected from a given dose of spinal local anesthetic.

Currently, much work is being done to determine whether surgery and anesthesia harm the brain in some manner. Postoperative cognitive dysfunction (POCD) is diagnosed by neurobehavioral testing. Unlike delirium, which is a clinical diagnosis of a confusional state, cognitive dysfunction must be sought by using evaluative techniques. Up to 30% of elderly patients can demonstrate abnormal neurobehavioral testing within the first week after an operation; however, such testing may identify dysfunction already present in these individuals prior to any surgery or anesthesia exposure. Ultimately, the question arises as to whether general anesthetic agents result in neurotoxicity in the aged brain. Some current investigations are attempting to determine whether anesthetic agents produce POCD through a mechanism similar to that underlying Alzheimer disease.

It is also possible that side effects of illness (eg, inflammation) and the neuroendocrine stress response contribute to perioperative brain injury in some manner, independent of anesthesia. In one study, 20% of elderly patients presenting for elective total joint arthroplasty demonstrated preoperative cognitive impairment; furthermore, POCD was independent of type of anesthesia or surgery at 3 months postoperatively. Postoperative delirium is common in elderly patients, especially those with reduced preoperative neurocognitive test scores. Frailty is common in elderly patients awaiting surgery and predicts postoperative delirium. Delirium has a particularly frequent incidence following hip surgery. Factors associated with postoperative delirium in the elderly and ways to avoid it are presented in Tables 43–6 and 43–7.

**TABLE 43–7** Prevention of delirium after surgery.¹
Additionally, the AGS has developed guidelines for the prevention and treatment of postoperative delirium in older adults. These guidelines suggest that nonopioid analgesia techniques be employed where possible to reduce the incidence of postoperative delirium. Additionally, they recommend avoidance of meperidine, drugs with anticholinergic effects, and benzodiazepines. Some studies have suggested that lighter planes of general anesthesia are associated with a reduction in postoperative delirium.

Elderly patients often take more time to recover from the central nervous system effects of general anesthesia, especially if they were confused or
disoriented preoperatively. This is important in outpatient surgery when the lack of a caretaker at home may necessitate that patients assume a higher level of self-care. In the absence of disease, any perioperative decrease in cognitive function is normally modest. Short-term memory seems to be most affected. Continued physical and intellectual activity seems to have a positive effect on preservation of cognitive functions.

The etiology of POCD is likely multifactorial and includes drug effects, pain, underlying dysfunction, hypothermia, and metabolic disturbances. Elderly patients are particularly sensitive to centrally acting anticholinergic agents, such as scopolamine and atropine. Some patients experience prolonged or permanent POCD after surgery and anesthesia. Some studies suggest that POCD can be detected in 10% to 15% of patients older than age 60 years up to 3 months following major surgery. In some settings (eg, following cardiac and major orthopedic procedures), intraoperative arterial emboli may be contributory. Animal studies suggest that anesthesia without surgery can impair learning for weeks, particularly in older animals. Elderly inpatients seem to have a significantly higher risk of POCD than elderly outpatients.

**MUSCULOSKELETAL SYSTEM**

Muscle mass is reduced in elderly patients. With aging, skin atrophies and is more susceptible to trauma from removal of adhesive tape, electrocautery pads, and electrocardiographic electrodes. Veins are often frail and easily ruptured by intravenous infusions. Arthritic joints may interfere with positioning or regional anesthesia. Degenerative cervical spine disease can limit neck extension, potentially making intubation difficult.

---

**Age-Related Pharmacological Changes**

- Aging produces both pharmacokinetic (the relationship between drug dose and plasma concentration) and pharmacodynamic (the relationship between plasma concentration and clinical effect) changes. Disease-related changes and wide variations among individuals in similar populations prevent generalizations.

  A progressive decrease in muscle mass and increase in body fat (particularly in older women) results in decreased total body water. The reduced volume of distribution for water-soluble drugs can lead to greater plasma concentrations; conversely, an increased volume of distribution for lipid-soluble drugs could...
theoretically reduce their plasma concentration. Any change in volume of distribution sufficient to significantly change concentrations will influence the elimination time. Because renal and hepatic functions decline with age, reductions in clearance prolong the duration of action of many drugs.

Distribution and elimination are also affected by any altered plasma protein concentrations. Albumin binds acidic drugs (eg, barbiturates, benzodiazepines, opioid agonists). α₁-Acid glycoprotein binds basic drugs (eg, local anesthetics). Concentrations of these binding proteins may vary depending upon diseases associated with aging.

The principal pharmacodynamic change associated with aging is a reduced anesthetic requirement, represented by a reduced MAC. Careful titration of anesthetic agents helps to avoid adverse side effects and unexpected, prolonged duration; short-acting agents, such as propofol, desflurane, remifentanil, and succinylcholine, may be particularly useful in elderly patients. Drugs that are not significantly dependent on hepatic or renal function or blood flow, such as atracurium or cisatracurium, are useful.

INHALATIONAL ANESTHETICS

The MAC for inhalational agents is reduced by 4% per decade of age over 40 years. Onset of action is faster if cardiac output is depressed, whereas it is delayed if there is a significant ventilation/perfusion abnormality. Recovery from anesthesia with a volatile anesthetic may be prolonged because of an increased volume of distribution (increased body fat) and decreased pulmonary gas exchange. Decreased hepatic function is of less importance as modern inhalational agents undergo little metabolism. Agents that are rapidly eliminated (eg, desflurane) are good choices for speeding emergence in the elderly patient.

NONVOLATILE ANESTHETIC AGENTS

In general, elderly patients display a lower dose requirement for propofol, etomidate, opioids, benzodiazepines, and barbiturates. The typical octogenarian will require a smaller induction dose of propofol than that required by a 20-year-old patient.

Although propofol may be close to an ideal induction agent in elderly patients because of its rapid elimination, it is more likely to cause apnea and hypotension than in younger patients. Both pharmacokinetic and pharmacodynamic factors are responsible for this enhanced sensitivity. Elderly patients require nearly 50%
lower blood levels of propofol for anesthesia than do younger patients. Moreover, both the rapidly equilibrating peripheral compartment and systemic clearance for propofol are significantly reduced in elderly patients. The initial volume of distribution for etomidate significantly decreases with aging: lower doses are required to achieve the same electroencephalographic endpoint in elderly patients (compared with young patients).

Enhanced sensitivity to fentanyl, alfentanil, and sufentanil is primarily pharmacodynamic. Pharmacokinetics for these opioids are not significantly affected by age. Dose requirements for the same EEG endpoint using fentanyl and alfentanil are 50% lower in elderly patients.

Aging increases the volume of distribution for all benzodiazepines, which effectively prolongs their elimination half-lives. Enhanced pharmacodynamic sensitivity to benzodiazepines is also observed. Midazolam requirements are generally 50% less in elderly patients, and its elimination half-life is prolonged by about 50%.

Anticholinergic drugs and benzodiazepines are associated with an increased risk of postoperative delirium. Conversely, a single bolus of ketamine (0.5 mg/kg) has been suggested in one trial to reduce the incidence of delirium. Use of sedative and antinausea agents with anticholinergic and antidopaminergic properties may produce adverse effects in patients with Parkinson disease.

**MUSCLE RELAXANTS**

The response to succinylcholine is not altered by aging. Decreased cardiac output and reduced muscle blood flow, however, may cause up to a two-fold prolongation in the onset of neuromuscular blockade in elderly patients. Recovery from nondepolarizing muscle relaxants that depend on kidney excretion (eg, pancuronium) may be delayed due to decreased drug clearance. Likewise, decreased hepatic excretion from a loss of liver mass prolongs the elimination half-life and duration of action of rocuronium and vecuronium. The pharmacological profiles of atracurium and cisatracurium are not significantly affected by age.

**CASE DISCUSSION**

The Elderly Patient with a Fractured Hip
An 86-year-old patient is scheduled for open reduction and internal fixation of a subtrochanteric fracture of the femur.

**How should this patient be evaluated for the risk of perioperative morbidity?**

Anesthetic risk correlates much better with the presence of coexisting disease than chronological age. Therefore, preanesthetic evaluation should concentrate on the identification of age-related diseases (Table 43–4) and an estimation of physiological reserve. There is a tremendous physiological difference between a patient who walks three blocks to a grocery store on a regular basis and one who is bedridden, even though both may be the same age. Obviously, any condition that may be amenable to preoperative therapy (eg, bronchodilator administration) must be identified and addressed. On the other hand, lengthy delays may compromise surgical repair and increase overall morbidity.

**What factors might influence the choice between regional and general anesthesia?**

Advancing age is not a contraindication for either regional or general anesthesia. Each technique, however, has its advantages and disadvantages in the elderly population. For hip surgery, regional anesthesia can be achieved with a spinal or epidural block extending to the T10 sensory level. Both of these blocks require patient cooperation and the ability to lie still for the duration of the surgery. A paramedian approach may be helpful when optimal positioning is not possible. Unless regional anesthesia is accompanied by heavy sedation, postoperative confusion and disorientation may be less troublesome than after general anesthesia. Cardiovascular changes are usually limited to a decrease in arterial blood pressure as sympathetic block is established. Although this decrease can be treated with fluid loading, a patient with borderline heart function may develop congestive heart failure when the block dissipates and sympathetic tone returns. Vasoconstrictors can be used to support the blood pressure during periods of sympathetic blockade. Reduced peripheral vascular resistance can result in profound hypotension and cardiac arrest in patients with aortic stenosis, a common valvular lesion in the elderly population. Likewise, patients can become profoundly hypotensive secondary to reduced peripheral vascular resistance accompanying neuraxial anesthesia. Invasive arterial pressure monitoring is at times useful when taking the elderly
patient to surgery. Monitors of hemodynamic function using pulse contour analysis that estimate stroke volume variation in addition to transesophageal echocardiography can all be employed to guide fluid therapy. The benefits of transesophageal echocardiography must be considered in the context of the risks of esophageal rupture and mediastinitis in the elderly.

**Are there any specific advantages or disadvantages to a regional technique in elderly patients having hip surgery?**

A major advantage in regional anesthesia—particularly for hip surgery—is a lower incidence of postoperative thromboembolism. This is presumably due to peripheral vasodilation and maintenance of venous blood flow in the lower extremities. Many anesthesiologists believe that regional anesthesia maintains respiratory function better than general anesthesia. Unless the anesthetic level involves the intercostal musculature, ventilation and the cough reflex are well maintained. Studies conflict as to whether regional anesthesia offers a mortality advantage in the management of surgical treatment for fractures of the hip, and a randomized clinical trial is underway currently to answer this important question.

Technical problems associated with regional anesthesia in the elderly include obscured landmarks as a result of degeneration of the vertebral column and the difficulty of obtaining adequate patient positioning secondary to pain related to the fracture. To avoid having the patient lie on the fracture, a hypobaric or isobaric solution can be injected intrathecally. Postpuncture headache is less of a problem in the elderly population.

**If the patient refuses regional anesthesia, is general anesthesia acceptable?**

General anesthesia is an acceptable alternative to regional block. One advantage is that the patient can be induced in bed and moved to the operating room table after intubation, avoiding the pain of positioning.

**What specific factors should be considered during induction and maintenance of general anesthesia with this patient?**

It is important to remember that because a subtrochanteric fracture can be associated with more than 1 L of occult blood loss, induction with propofol may lead to an exaggerated decrease in arterial blood pressure. Initial hypotension may be replaced by hypertension and tachycardia during
laryngoscopy and intubation. This rollercoaster volatility in blood pressure increases the risk of myocardial ischemia. Elderly patients often have poor vascular compliance and wide pulse pressures, leading to dramatic swings in both systolic and diastolic blood pressure during anesthesia.

Intraoperative paralysis with a nondepolarizing muscle relaxant improves surgical conditions and allows maintenance of a lighter plane of anesthesia. Reduced anesthetic depth as guided by processed electroencephalographic monitors may possibly result in a reduced incidence of postoperative delirium, although this remains controversial.

SUGGESTED READINGS

Crosby G, Culley D, Patel P. At the sharp end of spines. Anesthesiology. 2010;112:521.

Lin D, Feng C, Cao M, Zuo Z. Volatile anesthetics may not induce significant toxicity to human neuron like cells. *Anesth Analg*. 2011;112:1194.

KEY CONCEPTS

1. Non–operating room anesthesia requires the anesthesia provider to work in remote locations in a hospital, where ease of access to the patient and anesthesia equipment may both be limited; furthermore, the support staff at these locations may be unfamiliar with the requirements for safe anesthetic delivery.

2. Anesthesia providers should confirm that both the infrastructure and operational policies are consistent with acceptable anesthesia practice standards before providing anesthesia in such settings.

3. In general, ambulatory procedures should be of a complexity and duration such that one could reasonably assume that the patient will make an expeditious recovery and not require post-procedure hospital admission.

4. Factors considered in selecting patients for ambulatory procedures include systemic illnesses and their current management, airway management problems, sleep apnea, morbid obesity, previous adverse anesthesia outcomes (eg, malignant hyperthermia), allergies, and the patient’s social network (eg, availability of someone to be responsive to the patient for 24 h).

Outpatient/ambulatory anesthesia is the subspecialty of anesthesiology that deals with the preoperative, intraoperative, and postoperative anesthetic care of patients undergoing elective, same-day surgical procedures. Patients undergoing ambulatory surgery rarely require admission to a hospital and are fit enough to be discharged from the surgical facility less than 24 hours after the procedure.
Non–operating room anesthesia (NORA; also referred to as out of the operating room anesthesia) encompasses both inpatients and ambulatory surgery patients who undergo anesthesia in settings outside of a traditional operating room. These patients can vary greatly, ranging from claustrophobic individuals in need of anesthesia for magnetic resonance imaging (MRI) procedures to critically ill septic patients undergoing endoscopic retrograde cholangiopancreatography in the endoscopy suite. NORA requires the anesthesia provider to work in remote locations in a hospital, where ease of access to the patient and anesthesia equipment may both be limited; furthermore, the support staff at these locations may be unfamiliar with the requirements for safe anesthetic delivery.

Office-based anesthesia refers to the delivery of anesthesia in a practitioner’s office that has a procedural suite incorporated into its design. Office-based anesthesia is frequently administered to patients undergoing cosmetic surgery or dental procedures.

Although anesthetic techniques may be similar for inpatients, ambulatory surgery center patients, out of the operating room patients, and office-based anesthesia patients, these patients have differing needs. Thus, there are guidelines and statements from the American Society of Anesthesiologists (ASA) that pertain to these different locations. All of these recommendations should be reviewed at the ASA website (www.asahq.org/For-Healthcare-Professionals/Standards-Guidelines-and-Statements.aspx), as they are subject to change and modification. Accreditation agencies, such as the Joint Commission (TJC), Accreditation Association for Ambulatory Healthcare, and American Association for the Accreditation of Ambulatory Surgical Facilities, engage in various inspections and reviews to ensure that facilities meet acceptable standards for the procedural services provided. Anesthesia providers should confirm that both the infrastructure and operational policies are consistent with acceptable anesthesia practice standards before providing anesthesia in such settings.

CANDIDATES FOR AMBULATORY & OFFICE-BASED ANESTHESIA

In recent years, patients with increasing burdens of comorbid conditions have presented for ambulatory procedures. Each patient must be considered in the context of his or her comorbidities, the type of surgery to be performed, and the expected response to anesthesia. In general, ambulatory procedures should be
of a complexity and duration such that one could reasonably assume that the patient will make an expeditious recovery and not require post-procedure hospital admission. ASA physical status and a thorough history and physical exam are crucial in the screening of patients selected for ambulatory or office-based procedures. ASA 4 and 5 patients would not generally be candidates for ambulatory surgery. ASA 3 patients with diabetes, hypertension, and stable coronary artery disease should not be precluded from an ambulatory procedure provided that their diseases are well controlled. Ultimately, the surgeon and anesthesia provider must identify patients for whom an ambulatory or office-based setting is likely to provide benefits (eg, convenience, reduced costs and charges) that outweigh risks (eg, the lack of immediate availability of all hospital services, such as a cardiac catheterization laboratory, emergency cardiovascular stents, assistance with airway rescue, rapid consultation).

Factors considered in selecting patients for ambulatory procedures include systemic illnesses and their current management, airway management problems, sleep apnea, morbid obesity, previous adverse anesthesia outcomes (eg, malignant hyperthermia), allergies, and the patient’s social network (eg, availability of someone to be responsive to the patient for 24 h). Patients with difficult airways should probably not be candidates for office-based procedures; however, they may be appropriately cared for in a well-equipped and fully staffed ambulatory surgery center. Important considerations for such patients include the availability of difficult airway equipment, such as an intubating laryngeal mask airway and videolaryngoscope, the availability of additional experienced anesthesia providers, and someone capable of performing emergency tracheostomy/cricothyroidotomy. If there are concerns regarding the ability to manage the airway in an ambulatory surgery setting, the patient will be better served in a hospital setting where immediate consultation and assistance is available.

Similarly, patients with unstable comorbid conditions, such as decompensated congestive heart failure or uncontrolled hypertension, may benefit from having their procedure performed in a hospital rather than a freestanding facility. The hospital-based ambulatory surgery center provides such patients with both the availability of a hospital’s resources and the convenience of being an ambulatory patient. Should their condition warrant additional care, hospital admission is possible; however, such flexibility comes with increased costs associated with hospital care.

The anesthesiologist must know which preexisting medical conditions may predict a specific intraoperative or postoperative adverse event (AE) for the
patient in question. Likewise, procedures suitable for ambulatory surgery should have a minimal risk of perioperative hemorrhage, airway compromise, and no particular requirement for specialized postoperative care. Based on risk identification, the anesthesiologist should be able to reduce the likelihood of unforeseen AEs. Although current evidence-based medicine can provide recommendations for some high-risk ambulatory issues, evidence is lacking for most such situations.

SPECIFIC PATIENT CONDITIONS & AMBULATORY SURGERY

Obesity & Obstructive Sleep Apnea

Obesity is associated with many concomitant disease states, such as hypertension, diabetes, hyperlipidemia, the combination of the preceding three disease states (metabolic syndrome), and obstructive sleep apnea (OSA). The physiological derangements that accompany these conditions include changes in oxygen demand, carbon dioxide production, alveolar ventilation, and cardiac output. There is no precise “cutoff” body mass index (BMI) for patients who may or may not undergo ambulatory surgery. However, Joshi and colleagues suggest that patients with a BMI less than 40 kg/m$^2$ tolerate ambulatory surgery adequately, assuming control of comorbidities. Conversely, patients with a BMI greater than 50 kg/m$^2$ are thought to be at greater risk in the ambulatory surgical care environment. Patients with obesity and OSA are at increased risk of postoperative respiratory complications, such as prolonged airway obstruction and apnea, particularly if they will receive opioids postoperatively. Scores for predicting the probability of these complications can aid in the preoperative assessment and referral to a hospital setting (Tables 44–1 and 44–2). However, the ASA guidelines note that the literature is insufficient to offer guidance as to which OSA patients can be safely managed on an inpatient versus an outpatient basis. Although a sleep study is the standard way to diagnose sleep apnea, many patients with OSA have never been identified as having OSA. Consequently, an anesthesiologist may be the first physician to detect the presence or risk of sleep apnea. Preoperative initiation of continuous positive airway pressure (CPAP) may reduce the incidence of postoperative cardiac complications, according to ASA guidelines. Avoidance of respiratory depressants to the degree possible through the use of opioid-sparing multimodal analgesia, neuraxial, and regional anesthetic techniques is likewise suggested when appropriate. In addition to the
usual discharge criteria, the ASA also recommends that patients at increased risk from OSA not be discharged to an unmonitored setting until they no longer are at risk for perioperative respiratory depression. Other ASA recommendations include:

- Return of room air oxygen saturation to baseline level prior to discharge
- Observation of respiratory function when unstimulated, such as when sleeping
- Consideration of CPAP or noninvasive positive-pressure ventilation (NIPPV) if frequent airway obstruction or hypoxemia develops postoperatively
- A possible prolonged period of postoperative observation to ensure that patients with OSA are not at increased risk from postoperative respiratory depression compared with non-OSA patients undergoing similar procedures

TABLE 44–1  Identification and assessment of obstructive sleep apnea: example.¹²
A. Clinical signs and symptoms suggesting the possibility of OSA
   1. Predisposing physical characteristics
      a. BMI 35 kg/m² [95th percentile for age and gender]¹
      b. Neck circumference 17 inches (men) or 16 inches (women)
      c. Craniofacial abnormalities affecting the airway
      d. Anatomical nasal obstruction
      e. Tongue nearly touching or touching the midline
   2. History of apparent airway obstruction during sleep (two or more of the following are present if patient lives alone or
      sleep is not observed by another person, then only one of the following needs to be present)
      a. Snoring (loud enough to be heard through closed doors)
      b. Frequent snoring
      c. Observed pauses in breathing during sleep
      d. Awakened from sleep with choking sensation
      e. Frequent arousals from sleep
      f. [Intermittent vocalization during sleep]²
   3. Somnolence (one or more of the following is present)
      a. Frequent somnolence or fatigue despite adequate sleep
      b. Falls asleep readily in a nonstimulating environment (e.g., watching TV, reading, riding in or driving a car) despite
         adequate sleep
      c. [Parent or teacher comments that child appears sleepy during the day, is easily distracted, is overly aggressive, or has
         difficulty concentrating]³
      d. [Child often difficult to arouse at usual awakening time]³
   If a patient has signs or symptoms in two or more of the above categories, there is a significant probability that he or she has
   OSA. The severity of OSA may be determined by sleep study (see below). If a sleep study is not available, such patients
   should be treated as though they have moderate sleep apnea unless one or more of the signs or symptoms above is
   severely abnormal (e.g., markedly increased BMI or neck circumference, respiratory pauses that are frightening to
   the observer, patient regularly falls asleep within minutes after being left unstimulated), in which case they should be treated
   as though they have severe sleep apnea.

B. If a sleep study has been done, the results should be used to determine the perioperative anesthetic management of a
   patient. However, because sleep laboratories differ in their criteria for detecting episodes of apnea and hypopnea, the Task
   force believes that the sleep laboratory’s assessment (none, mild, moderate, or severe) should take precedence over the
   actual AHI (the number of episodes of sleep-disordered breathing per hour). If the overall severity is not indicated, it may be
   determined by using the table below:

The literature is insufficient to offer guidance regarding an appropriate time to discharge patients with OSA from the surgical facility.

The Society for Ambulatory Anesthesia has issued its own consensus statement regarding the management of OSA perioperatively (Table 44–3). This statement recommends the use of the STOP-Bang criteria for preoperative OSA screening. Additionally, the consensus statement provides a decision tree to assist in determining which known and presumed OSA patients are candidates for ambulatory surgery (Figure 44–1). The Society of Anesthesia and Sleep Medicine has also issued guidelines to assist in the screening for OSA. Their recommendations are summarized in Table 44–4. Perioperative complications associated with OSA are increasingly the subject of malpractice litigation.
Difficult airway management and cardiopulmonary arrest associated with death or brain injury are often the basis of such claims.

TABLE 44-4 Society of Anesthesia and Sleep Medicine recommendations for obstructive sleep apnea.1

- Patients with obstructive sleep apnea (OSA) undergoing procedures under anesthesia are at increased risk for perioperative complications compared with patients without the disease diagnosis. Identifying patients at high risk for OSA before surgery for targeted perioperative precautions and interventions may help to reduce perioperative patient complications.
- Screening tools help to risk stratify patients with suspected OSA with reasonable accuracy. Practice groups should consider making OSA screening part of standard preanaesthetic evaluation.
- There is insufficient evidence in the current literature to support canceling or delaying surgery for a formal diagnosis (laboratory or
home polysomnography) in patients with suspected OSA, unless there is evidence of an associated significant or uncontrolled systemic disease or additional problems with ventilation or gas exchange.

- The patient and the health care team should be aware that both diagnosed OSA (whether treated, partially treated, or untreated) and suspected OSA may be associated with increased postoperative morbidity.
- If available, consideration should be given to obtaining results of the sleep study and, where applicable, the patient’s recommended positive airway pressure (PAP) setting before surgery.
- If resources allow, facilities should consider having PAP equipment for perioperative use or have patients bring their own PAP equipment with them to the surgical facility.
- **Additional evaluation to allow preoperative cardiopulmonary optimization** should be considered in patients with diagnosed, partially treated/untreated, and suspected OSA where there is indication of an associated significant or uncontrolled systemic disease or additional problems with ventilation or gas exchange such as: (i) hypoventilation syndromes, (ii) severe pulmonary hypertension, and (iii) resting hypoxemia in the absence of other cardiopulmonary disease.
- **Where management of comorbid conditions has been optimized,** patients with diagnosed, partially treated/untreated OSA, or suspected OSA may proceed to surgery provided strategies for mitigation of postoperative complications are implemented.
- The risks and benefits of the decision to proceed with or delay surgery include consultation and discussion with the surgeon and the patient.
- **The use of PAP therapy in previously undiagnosed but suspected OSA patients should be considered case by case.** Because of the lack of evidence from randomized controlled trials, we cannot recommend its routine use.
- **Continued use of PAP therapy at previously prescribed settings is recommended during periods of sleep while hospitalized, both preoperatively and postoperatively.** Adjustments may need to be made to the settings to account for perioperative changes such as facial swelling, upper airway edema, fluid shifts, pharmacotherapy, and respiratory function.

---

Cardiac Conditions

Increasingly, patients present for ambulatory procedures with a variety of cardiac conditions treated both pharmacologically and mechanically (eg, cardiac resynchronization therapy, implantable cardioverter-defibrillators [ICDs], stents). Anesthesia staff working in ambulatory settings likely will encounter increasing numbers of such patients, who, despite a substantial cardiac history, are now medically stable. Patients with stents are likely to be receiving antiplatelet regimens. As always, these agents should not be discontinued unless a discussion has occurred between the patient, cardiologist, and surgeon regarding both the necessity of surgery and the risk of discontinuation of antiplatelet therapy. Likewise, β-blockers should be continued perioperatively. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may contribute to transient hypotension with anesthesia induction, but their continuation or discontinuation perioperatively remains controversial as patients so treated likely will need to have intraoperative hypotension or postoperative hypertension, or both, corrected in either case. The ASA guidelines recommend that patients presenting with a pacemaker or ICD should not leave a monitored setting until the device is interrogated, if electrocautery was employed; however, we believe that this ASA recommendation is overly conservative, if bipolar cautery is used at a distance of greater than 15 cm from the device or if unipolar cautery is used below the umbilicus and the ground pad is on the leg. Likewise, if an ICD is present, and there is anticipated electromagnetic interference the device’s antitachycardia features should be inhibited perioperatively (Figures 44–2 and 44–3). An external defibrillation capability should always be available whenever the ICD’s antitachycardia features are inactivated.
FIGURE 44–2 Preoperative considerations in a patient with an implanted cardioverter defibrillator. EMI, electromagnetic interference; ICD, implanted cardioverter defibrillator. (Reproduced with permission from Joshi GP. Perioperative management of outpatients with implantable cardioverter defibrillators. Curr Opin Anaesthesiol. 2009 Dec;22(6):701-704.)

**Glucose Control**

In a consensus statement on perioperative glucose control, the Society for Ambulatory Anesthesia found insufficient evidence to make strong recommendations about glucose management in ambulatory patients, and thus management suggestions parallel those of the inpatient population; however, the panel recommends a target intraoperative blood glucose concentration of less than 180 mg/dL.

**Malignant Hyperthermia**

Patients with a history of malignant hyperthermia can be safely given nontriggering anesthetics and discharged as ambulatory patients. Prophylactic dantrolene should not be administered.

**INTRAOPERATIVE CONSIDERATIONS**

Intraoperative management in the ambulatory patient undergoing surgery is aimed at providing rapid emergence, good post-procedure analgesia, minimal postoperative nausea and vomiting (PONV), and rapid return of fitness for discharge while creating acceptable operating conditions. Often these goals compete with one another. Although inhalational anesthesia with sevoflurane may speed emergence, compared with total intravenous anesthesia (TIVA), the likelihood of PONV may be greater if an additional prophylactic drug is not administered. Numerous studies have shown how regional anesthesia can speed discharge time, compared with general anesthetics, in the ambulatory population—in part, by potentially reducing the incidence of PONV and the need for opioid analgesia. Nitrous oxide increases the likelihood of PONV, but this effect can be overcome by adding a prophylactic agent. Likewise, multimodal perioperative analgesia can be approached using a variety of drugs, including local anesthetics, acetaminophen, and nonsteroidal anti-inflammatory agents (NSAIDs) to reduce the use of opioids, which contribute to PONV risk.

Thromboembolism remains a risk after ambulatory and office-based surgery, as with inpatient surgery. Pneumatic compression devices and pharmacological
thromboprophylaxis should be used in patients at increased risk. During monitored anesthesia care, supplemental oxygen can contribute to operating room fires by creating an oxygen-rich environment that facilitates ignition by cautery devices. During head and neck surgery, anesthesia providers must be especially vigilant not to create an environment where fire becomes more likely. When oxygen is administered via a nasal cannula or face mask, the minimal amount of supplemental oxygen should be delivered, if any, and tenting of the drapes around the patient’s head should be prevented.

**POSTANESTHESIA RECOVERY & DISCHARGE**

Managing a patient’s emergence, postoperative pain, and PONV is critical to expediting discharge. A plan to handle complications, such as postoperative pain and PONV, should be in place preoperatively to standardize and streamline management as much as possible.

The entire anesthetic experience of the ambulatory surgery patient should be focused on minimizing complications, especially postoperative pain and PONV, and facilitating readiness for discharge. Multimodal approaches are advised; see Chapter 17 for a discussion of PONV prophylaxis and management. Use of a combination of agents (eg, ondansetron, dexamethasone, and droperidol) has shown greater efficacy than monotherapy (eg, ondansetron alone) in patients at high risk of PONV. Likewise, analgesia regimens that minimize opioid use reduce PONV.

Pain management is centered on the combined use of regional techniques, opioids, and NSAIDs (multimodal analgesia). Gabapentinoids (gabapentin, pregabalin) may have beneficial effects as part of a multimodal pain regimen. Likewise, oral, rectal, or intravenous acetaminophen or NSAIDs, or both, can be useful in the ambulatory setting.

**DISCHARGE CRITERIA**

Scoring systems have been devised to facilitate timely and safe postanesthesia care unit (PACU) discharge and assess home readiness after ambulatory surgery. The Aldrete scoring system, which includes activity, respiration, circulation, consciousness, and oxygen saturation, helps guide recovery from the PACU in the ambulatory surgery unit. Scoring systems and guidelines that standardize patient discharge from the ambulatory surgery center to home are also available (Tables 44–5 through 44–8).

**TABLE 44–7 Guidelines for safe discharge after ambulator surgery.**

Vital signs must have been stable for at least 1 h
- The patient must be
- Oriented to person, place, and time
- Able to retain orally administered fluids
- Able to void
- Able to dress
- Able to walk without assistance
The patient must not have
   More than minimal nausea and vomiting
   Excessive pain
   Bleeding
The patient must be discharged by both the person who administered
anaesthesia and the person who performed surgery, or by their designates.
Written instructions for the postoperative period at home, including a contact
place and person, must be reinforced.
The patient must have a responsible, “vested” adult escort them home and stay
with them at home.

</table>
Criteria for discharge generally require that the patient:

- Be alert and oriented to time and place
- Have stable vital signs
- Have pain controlled by oral analgesics, liposomal bupivacaine, or peripheral nerve block
- Have nausea or emesis controlled
- Be able to walk without dizziness
- Have no unexpected bleeding from the operative site
- Be able to take oral fluids and void
- Have discharge instructions and prescriptions from the surgeon and anesthesiologist

**Pain**

The patient should have minimal or no pain before discharge

The level of pain that the patient has should be acceptable to the patient

Pain should be controllable by oral analgesics

The location, type, and intensity of pain should be consistent with anticipated postoperative discomfort

Acceptability

| Yes | 2 |
| No  | 1 |

**Surgical bleeding**

Postoperative bleeding should be consistent with expected blood loss for the procedure

Minimal: does not require dressing change | 2 |

Moderate: up to two dressing changes required | 1 |

Severe: more than three dressing changes required | 0 |

---

2BP, blood pressure; PO, per os; IM, intramuscular.

3Maximal score = 10; patients scoring ≥9 are fit for discharge.
• Accept readiness for discharge
• Have a responsible adult escort present

Increasingly, patients are not being required to drink or void before discharge from ambulatory surgery centers (ASCs). Such patients require plans and instructions for follow-up care to provide for possible rehydration and bladder catheterization, if required.

UNANTICIPATED HOSPITAL ADMISSION FOLLOWING AMBULATORY SURGERY

Occasionally an ambulatory surgery patient may require emergent transfer to a nearby hospital. Some surgical complications cannot be repaired in the ambulatory operating suite. Inadequately controlled pain and postoperative nausea and vomiting are the two most frequent causes of unplanned hospital admission from ASCs. Accreditation agencies mandate that office-based operating rooms have appropriate emergency equipment, drugs, and protocols for patient transfer to a nearby hospital. In addition to advanced cardiac life support medications, dantrolene and intravenous lipid emulsion should be available to treat malignant hyperthermia and local anesthetic systemic toxicity, respectively. Additionally, surgeons operating in an office-based practice must have admitting privileges at a nearby hospital or arrangements with an accepting physician to provide for patient transfer.

NON–OPERATING ROOM ANESTHESIA

Off-site anesthesia (NORA) encompasses all sedation/anesthesia provided by anesthesiology services outside of the operating room environment. Our experience has been that requests for these services in remote locations have been steadily increasing, and in some hospitals today, more anesthetics are routinely administered for procedures off-site than in the operating room suite. We and others assign “block time” for such procedures just as we do for the various surgeons and surgical services. We and other institutions have constructed procedural suites where bronchoscopy, gastrointestinal endoscopy, and other procedures can be performed in a centralized area for increased safety and efficiency. The same basic standards for anesthesia care must be met, regardless of the location. Furthermore, the challenges of unfamiliar environments that are far removed from the surgical suite require advance
planning for the off-site anesthesia provider.

In contrast to patients undergoing office-based or ambulatory surgery center procedures, out of the operating room patients are frequently among the sickest of inpatients. Often such locations as the endoscopy suite, cardiac catheterization laboratory, electrophysiology laboratory, radiology suite, or radiotherapy unit were constructed without anticipation that anesthesia would be provided there. Consequently, anesthesia work space is routinely constrained, and access to the patient is limited. Moreover, the procedure physicians and ancillary staff in these areas often fail to understand what is required to safely deliver anesthesia (hence the frequent request to “give them a squirt” of propofol) and do not know how to assist the anesthesia provider when difficulty arises. As noted in the ASA guidelines, the standard of care for NORA is the same as in the operating room (Table 44–9).

Basic principles for NORA can be broadly classified into three categories: patient factors, environmental issues, and procedure-related aspects. Patient
factors include comorbidity, airway assessment, fasting status, and monitoring. Environmental issues include anesthesia equipment, emergency equipment, and magnetic and radiation hazards. Procedure-related aspects include duration, level of discomfort, patient position, and surgical support.

The ASA Closed Claims Database has demonstrated that claims related to NORA care have a greater severity of injury than closed claims related to operating room anesthesia care. Monitored anesthesia care was the primary technique in more than half of the claims reviewed. Many of these closed claims arose from injuries related to inadequate oxygenation/ventilation during endoscopy.

Increasingly, personnel in the endoscopy suite and the emergency department who are not qualified anesthesia providers provide sedation with a variety of agents, including propofol and ketamine. In fact, some reports indicate that nonanesthesia providers administer sedation and analgesia for almost 40% of the procedures performed in the United States. The ASA guidelines and the Joint Commission have described the continuum of depth of sedation, ranging from minimal sedation to general anesthesia (Table 44–10). The Centers for Medicare and Medicaid Services has mandated that all sedation in a hospital be under the direction of a physician—generally, the anesthesia service chief. Consequently, anesthesiologists must not only from time to time provide anesthesia in a non–operating room setting, but must also develop policies and quality assurance review mechanisms for non–anesthesia providers to safely and legally provide sedation. Such policies should be focused on assuring that the “sedationist” has the necessary skills to provide for patient rescue should mild or moderate sedation unintentionally progress to deep sedation or general anesthesia.

Risks associated with sedation/analgesia are highlighted in Table 44–11. Sedation providers should know how to reverse benzodiazepines and opioids and provide bag/mask airway support and to be facile in the use of airway adjuvants.
A mechanism to ensure the timely arrival of anesthesia personnel capable of airway rescue must likewise be incorporated into such policies.

**SPECIAL CONSIDERATIONS IN & OUT OF OPERATING ROOM LOCATIONS**

Anesthesia services are requested at various locations throughout the hospital facility; some of these are delineated in Table 44–12. Post-procedure disposition (whether discharge or admission) needs appropriate coordination by the
anesthesiologist for postanesthesia care or safe transport from the remote unit, or both.

² CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

Patients presenting to the gastrointestinal endoscopy suite include healthy individuals for routine diagnostic screenings, as well as patients with fulminant
cholangitis, sepsis, or gastrointestinal hemorrhage. As always, the patient’s current illness and comorbidities, as well as the specific diagnostic/therapeutic procedure, determine both the anesthetic techniques (sedation or general anesthesia) and the monitoring required.

Patients undergoing cardiac catheterization are routinely sedated by cardiologists without involvement of an anesthesiologist. Occasionally, a patient with significant comorbidities (eg, morbid obesity) requires the presence of a qualified anesthesia provider. General anesthesia is sometimes required for placement of aortic stents, which are increasingly performed by cardiologists in the cardiac catheterization laboratory. Specially built hybrid surgical suites enable both open and catheter-based vascular repairs. Increasingly, patients for transcatheter aortic valve replacement are managed with local anesthesia and sedation rather than general anesthesia. Institutional protocols and patient characteristics determine the anesthetic/sedation management of these patients. General anesthesia is frequently administered to patients in the neurointerventional suite for treatment of cerebral aneurysms and ischemic strokes.

Patients requiring electrophysiology procedures for catheter-mediated arrhythmia ablation often need general anesthesia. Such patients may have both systolic and diastolic heart failure, leading to potential hemodynamic difficulties perioperatively. Sudden hypotension can herald the development of pericardial tamponade secondary to catheter perforation of the heart. Other patients require sedation for the placement of ICDs. Once placed, the device will be tested by inducing ventricular fibrillation. During testing, deeper levels of sedation are required, as the defibrillation shock can be frightening and very uncomfortable. Likewise, anesthesia staff are called upon to provide anesthesia for cardioversion of patients in atrial fibrillation. These patients usually have associated cardiac diseases and require brief intravenous anesthetics to facilitate cardioversion. Oftentimes, a transesophageal echocardiogram must be performed prior to cardioversion to rule out clot in the left atrial appendage. In such cases, anesthesia staff may also provide sedation for this procedure. Determination as to whether a patient needs sedation or general anesthesia with or without intubation is dependent upon routine patient assessment.

Children and some adults (ie, those who are claustrophobic, developmentally disabled, or have conditions that prevent them from remaining still or lying flat) require anesthesia or sedation for MRI and computed tomography (CT) imaging. Additionally, painful CT-guided biopsies may require anesthesia management. Anesthetic technique is dependent upon patient comorbidities.
MRI creates numerous problems for anesthesia staff. First, all ferromagnetic materials must be excluded from the area of the magnet. Most institutions have policies and training protocols to prevent catastrophes (eg, oxygen tanks flying into the scanner). Second, all anesthetic equipment must be compatible with the magnet in use. Third, patients must be free of implants that could interact with the magnet, such as pacemakers, vascular clips, ICDs, and infusion pumps. As with all NORA, the exact choice of technique is dependent upon the patient’s comorbidities. Both deep sedation and general anesthesia approaches with intubation or supraglottic airways can be used, depending on practitioner preference and patient requirements.

Patients often require general anesthesia and tight blood pressure control to facilitate coiling and embolization of cerebral aneurysms, arteriovenous malformations, or stenting and clot removal for acute strokes. Patients taken to the radiology suite for relief of portal hypertension (see Chapters 33 and 34) via creation of a transjugular intrahepatic portosystemic shunt (TIPS) are frequently intravascularly depleted, with profound ascites, and are at risk of esophageal variceal bleeding and aspiration. General anesthesia with intubation is preferred for management of the TIPS procedure.

Anesthesia for electroconvulsive therapy is often provided in a separate suite in the psychiatry unit or a monitored area in the hospital (eg, PACU). Patient comorbidity, drug interactions with various psychotropic medications, multiple anesthetic procedures, and effects of anesthetic agents on the quality of electroconvulsive therapy also need to be considered (see Chapter 28).

Anesthesia providers are at times called to deliver anesthesia in the intensive care unit (ICU) for bedside tracheostomy or emergent chest and abdominal exploration in patients considered too critically ill to tolerate transport to the operating room. In most of these cases, the anesthesia staff generally employ the ICU ventilator and monitors. Intravenous agents are typically used along with muscle relaxants. When performing anesthesia for bedside tracheostomy, it is important that the endotracheal tube not be withdrawn from the trachea until end-tidal CO₂ is measured from the newly placed tracheostomy tube.

**CASE DISCUSSION**

**Acute Hypoxia After TIPS Procedure in the Radiology Suite**

A 58-year-old Caucasian woman with decompensated cryptogenic
cirrhosis and refractory ascites, currently on the liver transplant list, is scheduled for an urgent TIPS procedure.

What does a TIPS procedure entail? What are its indications and contraindications?

TIPS (transjugular intrahepatic portosystemic shunt) involves the passage of a catheter, usually inserted through the internal jugular vein and directed into the liver, which creates a low-resistance conduit between a portal vein and a hepatic vein by deployment of an intrahepatic expandable stent. Hemodynamically, this allows immediate decompression of portal hypertension by partial or complete diversion of portal flow from hepatic sinusoids into the inferior vena cava and the systemic circulation.

Indications for the TIPS procedure include variceal bleeding not controlled by endoscopic or medical therapy, intractable ascites, hepatic hydrothorax, Budd–Chiari syndrome, hepatorenal syndrome and hepatopulmonary syndrome, and bridge to liver transplantation. Some contraindications of TIPS are primary prevention of variceal hemorrhage, congestive heart failure, severe pulmonary hypertension and tricuspid regurgitation, severe hepatic failure, hepatocellular carcinoma, active intrahepatic or systemic infection, and severe coagulopathy or thrombocytopenia.

What are the anesthetic strategies for TIPS? What are some preoperative and intraoperative concerns in these patients?

TIPS can be performed under moderate sedation, monitored anesthesia care, or general anesthesia. Given the usual need for long immobilization, potential risk of aspiration, and significant comorbidity, general anesthesia is often the recommended anesthetic plan.

Preoperative considerations include risk of aspiration, gastrointestinal bleeding, decreased functional residual capacity from ascites, pleural effusions, coagulopathy, thrombocytopenia, and hepatic encephalopathy. Intraoperative considerations should include careful hemodynamic monitoring (usually via arterial catheter) and frequent measurement of blood gases, electrolytes, and coagulation parameters. Altered pharmacokinetics of anesthetic agents from liver failure should also be kept in mind.

The patient is induced with etomidate, fentanyl, and succinylcholine, using rapid sequence induction; atraumatic intubation is accomplished
uneventfully. Prior to placement of the TIPS, the radiologist evacuates approximately 8 L of ascitic fluid.

**What are your concerns about this paracentesis? How would you balance these hemodynamic fluid shifts?**

Large volume paracentesis is believed to be a relatively safe and effective procedure; however, it can lead to paracentesis-induced circulatory dysfunction (PICD). PICD is characterized by a marked activation of the renin–angiotensin axis, as well as accentuation of the arteriolar vasodilation that is present in cirrhotic patients. Administration of albumin may mitigate the hemodynamic effects of large volume paracentesis.

Regional Anesthesia & Pain Management
KEY CONCEPTS

1. Neuraxial anesthesia greatly expands the anesthesiologists’ armamentarium, in many cases providing alternatives to general anesthesia. Neuraxial anesthesia may also be used simultaneously with general anesthesia or afterward for postoperative analgesia. Neuraxial blocks can be performed as a single injection or with a catheter to allow intermittent boluses or continuous infusions.

2. Performing a lumbar (subarachnoid) spinal puncture below L1 in an adult (L3 in a child) usually avoids potential needle trauma to the spinal cord.

3. The principal site of action for neuraxial blockade is believed to be the nerve root, at least during initial onset of block.

4. Differential blockade typically results in sympathetic blockade (judged by temperature sensitivity) that may be two segments or more cephalad than the sensory block (pain, light touch), which, in turn, is usually several segments more cephalad than the motor blockade.

5. Interruption of efferent autonomic transmission at the spinal nerve roots during neuraxial blocks produces sympathetic blockade.

6. Neuraxial blocks typically produce variable decreases in blood pressure that may be accompanied by a decrease in heart rate.

7. Deleterious cardiovascular effects should be anticipated and steps undertaken to minimize the degree of hypotension. However, volume loading with 10 to 20 mL/kg of intravenous fluid in a healthy patient before initiation of the block has been shown repeatedly to fail to prevent hypotension (in the absence of preexisting hypovolemia).

8. Excessive or symptomatic bradycardia should be treated with atropine, and hypotension should be treated with vasopressors.
Major contraindications to neuraxial anesthesia include lack of consent, coagulation abnormalities, severe hypovolemia, elevated intracranial pressure, and infection at the site of injection.

For epidural anesthesia, a sudden loss of resistance (to injection of air or saline) is encountered as the needle passes through the ligamentum flavum and enters the epidural space. For spinal anesthesia, the needle is advanced through the epidural space and penetrates the dura–subarachnoid membranes, as signaled by freely flowing cerebrospinal fluid.

Continuous epidural anesthesia is a neuraxial technique offering a range of applications wider than single dose spinal anesthesia. An epidural block can be performed at the lumbar, thoracic, or cervical level.

Epidural techniques are widely used for surgical anesthesia, obstetric analgesia, postoperative pain control, and chronic pain management.

Epidural anesthesia is slower in onset (10–20 min) and may not be as dense as spinal anesthesia, a feature that can be useful clinically.

The quantity (volume and concentration) of local anesthetic needed for epidural anesthesia is larger than that needed for spinal anesthesia. Toxic side effects are almost guaranteed if a “full epidural dose” is injected intrathecally or intravascularly.

Caudal epidural anesthesia is a common regional technique in pediatric patients.

Spinal, caudal, and epidural blocks were first used for surgical procedures at the turn of the twentieth century. These central blocks were widely used worldwide until reports of permanent neurological injury appeared, most prominently in the United Kingdom. However, a large-scale epidemiological study conducted in the 1950s proved that complications were rare when these blocks were performed skillfully, with attention to asepsis, and when newer, safer local anesthetics were used. Today, neuraxial blocks are routinely employed for labor analgesia, cesarian delivery, orthopedic surgery, perioperative analgesia, and chronic pain management. However, they are still associated with various complications, and much literature has examined the incidence of complications following neuraxial blocks associated with different disease states.

Neuraxial anesthesia greatly expands the anesthesiologists’ armamentarium, in many cases providing alternatives to general anesthesia. Neuraxial anesthesia may be used simultaneously with general anesthesia or
afterward for postoperative analgesia. Neuraxial blocks can be performed as a single injection or with a catheter to allow intermittent boluses or continuous infusions.

Adverse reactions and complications associated with regional anesthesia range from self-limited back soreness to debilitating permanent neurological deficits and even death. The practitioner must therefore be thoroughly familiar with the anatomy involved and the pharmacology and toxic dosages of the agents employed. The practitioner must diligently employ sterile techniques and quickly address physiological derangements arising from neuraxial techniques.

THE ROLE OF NEURAXIAL ANESTHESIA IN ANESTHETIC PRACTICE

Some studies suggest that postoperative morbidity may be reduced when neuraxial blockade is used either alone or in combination with general anesthesia. Some less convincing studies suggest that neuraxial blocks are associated with reduced perioperative mortality. Neuraxial blocks may reduce the incidence of venous thrombosis and pulmonary embolism, cardiac complications in high-risk patients, bleeding and transfusion requirements, vascular graft occlusion, and pneumonia and respiratory depression following upper abdominal or thoracic surgery in patients with chronic lung disease. Neuraxial blocks may also allow earlier return of gastrointestinal function following surgery. Proposed mechanisms (in addition to avoidance of larger doses of anesthetics and opioids) include reducing the hypercoagulable state associated with surgery, increasing tissue blood flow, improving oxygenation from decreased splinting, enhancing peristalsis, and suppressing the neuroendocrine stress response to surgery. Reduction of parenteral opioid administration may decrease the incidence of atelectasis, hypoventilation, and aspiration pneumonia and reduce the duration of ileus. Postoperative epidural analgesia may also significantly reduce both the need for mechanical ventilation and the time until extubation after major abdominal or thoracic surgery.

The Sick Elderly Patient

Anesthesiologists are all too familiar with situations in which a consultant “clears” a sick elderly patient with significant cardiac disease for surgery “under spinal anesthesia.” A spinal anesthetic with little or no intravenous sedation may reduce the likelihood of postoperative delirium or cognitive dysfunction, which
is sometimes seen in the elderly. Unfortunately, many patients will require some sedation during the procedure, either for comfort or to facilitate cooperation. Is spinal anesthesia always safer in a patient with severe coronary artery disease or with a decreased ejection fraction? Ideally, an anesthetic technique should produce neither hypotension (which decreases myocardial perfusion pressure) nor hypertension and tachycardia (which increase myocardial oxygen consumption). Spinal anesthesia may produce both hypotension and bradycardia. Administration of large intravenous volumes may lead to fluid overload in the elderly patient with diastolic dysfunction, especially after the sympathetic block resolves postoperatively. General anesthesia, on the other hand, also poses potential problems for patients with cardiac compromise. Most general anesthetics are cardiac depressants, and many cause vasodilation. Deep anesthesia can readily cause hypotension, whereas light anesthesia relative to the level of stimulation causes hypertension and tachycardia. Research is ongoing to discern if neuraxial techniques offer survival and other benefits to patients compared with general anesthetics for major operations such as open reduction and internal fixation of femoral neck fractures. To date, the results are conflicting.

The Obstetric Patient
Currently, epidural anesthesia is widely used for analgesia in women in labor and during vaginal delivery. Cesarean delivery is most commonly performed under spinal or epidural anesthesia. Both blocks allow a mother to remain awake and experience the birth of her child. Large population studies in Great Britain and the United States have shown that regional anesthesia for cesarean delivery is associated with less maternal morbidity and mortality than is general anesthesia. This may be largely due to a reduction in the incidence of pulmonary aspiration and failed intubation when neuraxial anesthesia is employed. Fortunately, the increased availability of video laryngoscopes may also reduce the incidence of adverse outcomes related to airway difficulties associated with general anesthesia for cesarean delivery.

Anatomy

THE VERTEBRAL COLUMN
The spine is composed of the vertebral bones and intervertebral disks (Figure
There are 7 cervical (C), 12 thoracic (T), and 5 lumbar (L) vertebrae (Figure 45–2). The sacrum is a fusion of 5 sacral (S) vertebrae, and there are small rudimentary coccygeal vertebrae. The spine as a whole provides structural support for the body and protection for the spinal cord and nerves and allows a degree of mobility in several spatial planes. At each vertebral level, paired spinal nerves exit the central nervous system (Figure 45–2).

**FIGURE 45–1** A: Sagittal section through lumbar vertebrae. B, C: Common features of vertebrae.
Vertebrae differ in shape and size at the various levels. The first cervical vertebra, the atlas, lacks a body and has unique articulations with the base of the skull and with the second vertebra. The second vertebra, called the axis, consequently has atypical articulating surfaces. All 12 thoracic vertebrae articulate with their corresponding rib. Lumbar vertebrae have a large anterior cylindrical vertebral body. A hollow ring is defined anteriorly by the vertebral body, laterally by the pedicles and transverse processes, and posteriorly by the lamina and spinous processes (Figure 45–1B and C). The laminae extend between the transverse processes and the spinous processes, and the pedicle extends between the vertebral body and the transverse processes. When stacked vertically, the hollow rings become the spinal canal in which the spinal cord and its coverings sit. The individual vertebral bodies are connected by the intervertebral disks. There are four small synovial joints at each vertebra, two articulating with the vertebra above it and two with the vertebra below. These are the facet joints, which are adjacent to the transverse processes (Figure 45–1C). The pedicles are notched superiorly and inferiorly, these notches forming the intervertebral foramina from which the spinal nerves exit. Sacral vertebrae normally fuse into one large bone, the sacrum, but each one retains discrete anterior and posterior intervertebral foramina. The laminae of S5 and all or part of S4 normally do not fuse, leaving a caudal opening to the spinal canal, the sacral hiatus (Figure 45–3).
FIGURE 45–3 Posterior and sagittal views of the sacrum and coccyx.

The spinal column normally forms a double C, being convex anteriorly in the cervical and lumbar regions (Figure 45–2). Ligamentous elements provide structural support, and, together with supporting muscles, help to maintain the unique shape. Ventrally, the vertebral bodies and intervertebral disks are connected and supported by the anterior and posterior longitudinal ligaments (Figure 45–1A). Dorsally, the ligamentum flavum, interspinous ligament, and supraspinous ligament provide additional stability. Using the midline approach, a needle passes through these three dorsal ligaments and through an oval space between the bony lamina and spinous processes of adjacent vertebra (Figure 45–4).
THE SPINAL CORD

The spinal canal contains the spinal cord with its coverings (the meninges), fatty tissue, and a venous plexus (Figure 45–5). The meninges are composed of three layers: the pia mater, the arachnoid mater, and the dura mater; all are contiguous with their cranial counterparts (Figure 45–6). The pia mater is adherent to the spinal cord, whereas the arachnoid mater is usually adherent to the thicker and denser dura mater. Cerebrospinal fluid (CSF) is contained between the pia and arachnoid maters in the subarachnoid space. The spinal subdural space is generally a poorly demarcated, potential space that exists between the dura and arachnoid membranes. The epidural space is a better defined potential space within the spinal canal that is bounded by the dura and the ligamentum flavum (Figures 45–1 and 45–5).
The spinal cord normally extends from the foramen magnum to the level of L1 in adults (Figure 45–7). In children, the spinal cord ends at L3 and moves up
with age. The anterior and posterior nerve roots at each spinal level join one another and exit the intervertebral foramina, forming spinal nerves from C1 to S5 (Figure 45–2). At the cervical level, the nerves arise above their respective vertebrae, but starting at T1, exit below their vertebrae. As a result, there are eight cervical nerve roots, but only seven cervical vertebrae. The cervical and upper thoracic nerve roots emerge from the spinal cord and exit the vertebral foramina nearly at the same level (Figure 45–2). But, because the spinal cord normally ends at L1, lower nerve roots course some distance before exiting the intervertebral foramina. These lower spinal nerves form the cauda equina (“horse’s tail”; Figure 45–2). Therefore, performing a lumbar (subarachnoid) puncture below L1 in an adult (L3 in a child) usually avoids potential needle trauma to the spinal cord; damage to the cauda equina is unlikely, as these nerve roots float in the dural sac below L1 and tend to be pushed away (rather than pierced) by an advancing needle.
FIGURE 45–7  Sagittal view through the lumbar vertebrae and sacrum. Note the end of the spinal cord rises with development from approximately L3 to L1. The dural sac normally ends at S2.

A dural sheath invests most nerve roots for a small distance, even after they exit the spinal canal (Figure 45–5). Nerve blocks close to the intervertebral foramen therefore carry a risk of subdural or subarachnoid injection. The dural sac and the subarachnoid and subdural spaces usually extend to S2 in adults and often to S3 in children, important considerations in avoiding accidental dural puncture during caudal anesthesia. An extension of the pia mater, the filum terminale, penetrates the dura and attaches the terminal end of the spinal cord (conus medullaris) to the periosteum of the coccyx (Figure 45–7).

The blood supply to the spinal cord and nerve roots is derived from a single anterior spinal artery and paired posterior spinal arteries (Figure 45–8). The anterior spinal artery is formed from the vertebral artery at the base of the skull and courses down along the anterior surface of the cord. The anterior spinal artery supplies the anterior two-thirds of the cord, whereas the two posterior spinal arteries supply the posterior one-third. The posterior spinal arteries arise from the posterior inferior cerebellar arteries and course down along the dorsal surface of the cord medial to the dorsal nerve roots. The anterior and posterior spinal arteries receive additional blood flow from the intercostal arteries in the thorax and the lumbar arteries in the abdomen. One of these radicular arteries is typically large, the artery of Adamkiewicz, or arteria radicularis magna, arising from the aorta (Figures 45–8A). It is typically unilateral and nearly always arises on the left side, providing the major blood supply to the anterior, lower two-thirds of the spinal cord. Injury to this artery can result in the anterior spinal artery syndrome (see Chapter 22).
**Mechanism of Action**

- The principal site of action for neuraxial blockade is believed to be the nerve root, at least during initial onset of block. Local anesthetics may also have actions on structures within the spinal cord during epidural and spinal anesthesia. Local anesthetic is injected into CSF (spinal anesthesia) or the epidural space (epidural and caudal anesthesia) and bathes the nerve root in the subarachnoid space or epidural space, respectively. Direct injection of local anesthetic into CSF for spinal anesthesia allows a relatively small dose and volume of local anesthetic to achieve dense sensory and motor blockade. In contrast, neuraxial block is achieved only with much larger volumes and quantities of local anesthetic molecules during epidural and caudal anesthesia. The injection site (level) for epidural anesthesia is ideally sited in the middle of the nerve roots that must be anesthetized. Blockade of neural transmission (conduction) in the posterior nerve root fibers interrupts somatic and visceral sensation, whereas blockade of anterior nerve root fibers prevents efferent motor and autonomic outflow.

**SOMATIC BLOCKADE**

By interrupting the afferent transmission of painful stimuli and abolishing the efferent impulses responsible for skeletal muscle tone, neuraxial blocks provide excellent operating conditions. Sensory blockade interrupts both somatic and visceral painful stimuli. The mechanism of action of local anesthetic agents is discussed in **Chapter 16**. Smaller and myelinated fibers are generally more easily blocked than larger and unmyelinated ones. The size and character of the fiber types, and the fact that the concentration of local anesthetic decreases with increasing distance from the level of injection, explains the phenomenon of differential blockade during neuraxial anesthesia. Differential blockade typically results in sympathetic blockade (judged by temperature sensitivity) that may be two segments or more cephalad than the sensory block (pain, light touch), which, in turn, is usually several segments more cephalad than the motor...
blockade.

**AUTONOMIC BLOCKADE**

 Interruption of efferent autonomic transmission at the spinal nerve roots during neuraxial blocks produces sympathetic blockade. Sympathetic outflow from the spinal cord may be described as thoracolumbar, whereas parasympathetic outflow is craniosacral. Sympathetic preganglionic nerve fibers (small, myelinated B fibers) exit the spinal cord with the spinal nerves from T1–L2 and may course many levels up or down the sympathetic chain before synapsing with a postganglionic cell in a sympathetic ganglion. In contrast, parasympathetic preganglionic fibers exit the spinal cord with the cranial and sacral nerves. Neuraxial anesthesia does not block the vagus nerve (tenth cranial nerve). The physiological responses to neuraxial blockade therefore result from decreased sympathetic tone or unopposed parasympathetic tone, or both.

**Cardiovascular Manifestations**

 Neuraxial blocks produce variable decreases in blood pressure that may be accompanied by a decrease in heart rate. These effects generally increase with more cephalad dermatomal levels and more extensive sympathectomy. Vasomotor tone is primarily determined by sympathetic fibers arising from T5 to L1, innervating arterial and venous smooth muscle. Blocking these nerves causes vasodilation of the venous capacitance vessels and pooling of blood in the viscera and lower extremities, thereby decreasing the effective circulating blood volume and often decreasing cardiac output. Arterial vasodilation may also decrease systemic vascular resistance. The effects of arterial vasodilation may be minimized by compensatory vasoconstriction above the level of the block, particularly when the extent of sensory anesthesia is limited to the lower thoracic dermatomes. A high sympathetic block not only prevents compensatory vasoconstriction but may also block the sympathetic cardiac accelerator fibers that arise at T1 to T4. Profound hypotension may result from arterial dilation and venous pooling combined with bradycardia. These effects are exaggerated if venous pooling is further augmented by a head-up position or the weight of a gravid uterus. Unopposed vagal tone may explain the sudden cardiac arrest sometimes seen with spinal anesthesia.

 Deleterious cardiovascular effects should be anticipated and steps undertaken to minimize the degree of hypotension. However, volume loading with 10 to 20 mL/kg of intravenous fluid in a healthy patient before initiation of
the block has been shown repeatedly to fail to prevent hypotension (in the absence of preexisting hypovolemia). Left uterine displacement in the third trimester of pregnancy helps to minimize physical obstruction to venous return in some patients. Despite these efforts, hypotension may still occur and should be treated promptly. Autotransfusion may be accomplished by placing the patient in a head-down position. A bolus of intravenous fluid (5–10 mL/kg) may be helpful in patients who have adequate cardiac and renal function to be able to “handle” the fluid load after the block wears off. Excessive or symptomatic bradycardia should be treated with atropine, and hypotension should be treated with vasopressors. Direct α-adrenergic agonists (such as phenylephrine) primarily produce vasoconstriction, increasing systemic vascular resistance, and may reflexively increase bradycardia. The “mixed” agent ephedrine has direct and indirect β-adrenergic effects that increase heart rate and contractility, and indirect effects that also produce vasoconstriction. Much like ephedrine, small doses of epinephrine (2–5 mcg boluses) are particularly useful in treating spinal anesthesia–induced hypotension. If profound hypotension or bradycardia persists, vasopressor infusions may be required.

**Pulmonary Manifestations**

Alterations in pulmonary physiology are usually minimal with neuraxial blocks because the diaphragm is innervated by the phrenic nerve, with fibers originating from C3 to C5. Even with high thoracic levels, tidal volume is unchanged; there is only a small decrease in vital capacity, which results from a loss of the abdominal muscles’ contribution to forced expiration.

Patients with severe chronic lung disease may rely upon accessory muscles of respiration (intercostal and abdominal muscles) to actively inspire or exhale. High levels of neural blockade will impair these muscles. Similarly, effective coughing and clearing of secretions require these muscles for expiration. For these reasons, neuraxial blocks should be used with caution in patients with limited respiratory reserve. These deleterious effects need to be weighed against the advantages of avoiding airway instrumentation and positive-pressure ventilation. For surgical procedures above the umbilicus, a pure regional technique may not be the best choice in patients with severe lung disease. On the other hand, these patients may benefit from the effects of thoracic epidural analgesia (with dilute local anesthetics and opioids) or intrathecal opioids in the postoperative period, particularly following upper abdominal or thoracic surgery. Some evidence suggests that postoperative thoracic epidural analgesia in high-risk patients can improve pulmonary outcome by decreasing the incidence of
pneumonia and respiratory failure, improving oxygenation, and decreasing the duration of mechanical ventilatory support.

**Gastrointestinal Manifestations**

Neuraxial block–induced sympathectomy allows vagal “dominance” with a small, contracted gut and active peristalsis. This can improve operative conditions during intestinal surgery when used as an adjunct to general anesthesia. Postoperative epidural analgesia with local anesthetics and minimal systemic opioids hastens the return of gastrointestinal function after open abdominal procedures.

Hepatic blood flow will decrease with reductions in mean arterial pressure from any anesthetic technique, including neuraxial anesthesia.

**Urinary Tract Manifestations**

Renal blood flow is maintained through autoregulation, and there is little effect of neuraxial anesthesia on kidney function. Neuraxial anesthesia at the lumbar and sacral levels blocks both sympathetic and parasympathetic control of bladder function. Loss of autonomic bladder control results in urinary retention until the block wears off. If no urinary catheter is placed perioperatively, it is prudent to use the regional anesthetic of shortest duration sufficient for the surgical procedure and to administer the minimal safe volume of intravenous fluid. Patients with urinary retention should be checked for bladder distention after neuraxial anesthesia.

**Metabolic & Endocrine Manifestations**

Surgical trauma produces a systemic neuroendocrine stress response via activation of somatic and visceral afferent nerve fibers, in addition to a localized inflammatory response. This systemic response includes increased concentrations of adrenocorticotropic hormone, cortisol, epinephrine, norepinephrine, and vasopressin levels, as well as activation of the renin–angiotensin–aldosterone system. Clinical manifestations include intraoperative and postoperative hypertension, tachycardia, hyperglycemia, protein catabolism, suppressed immune responses, and altered renal function. Neuraxial blockade can partially suppress (during major invasive abdominal or thoracic surgery) or totally block (during lower extremity surgery) the neuroendocrine stress response. To maximize this blunting of the neuroendocrine stress response,
Clinical Considerations Common to Spinal & Epidural Blocks

Indications

Neuraxial blocks may be used alone or in conjunction with general anesthesia for many procedures below the neck. As a primary anesthetic, neuraxial blocks have proved most useful in lower abdominal, inguinal, urogenital, rectal, and lower extremity surgery. Lumbar spinal surgery may also be performed under spinal anesthesia. Upper abdominal procedures (e.g., gastrectomy) have been performed with spinal or epidural anesthesia, but because it can be difficult to safely achieve a sensory level adequate for patient comfort, these techniques are less commonly used.

If a neuraxial anesthetic is being considered, the risks and benefits must be discussed with the patient, and informed consent should be obtained. The patient must be mentally prepared for neuraxial anesthesia, and neuraxial anesthesia must be appropriate for the type of surgery. Patients should understand that they will have little or no lower extremity motor function until the block resolves. Procedures that require maneuvers that might compromise respiratory function (e.g., pneumoperitoneum or pneumothorax) or those operations that are unusually of long duration are typically performed with general anesthesia, with or without neuraxial blockade.

Contraindications

- Major contraindications to neuraxial anesthesia include lack of consent, coagulation abnormalities, severe hypovolemia, elevated intracranial pressure (particularly with an intracranial mass), and infection at the site of injection. Other relative contraindications include severe aortic or mitral stenosis and severe left ventricular outflow obstruction (hypertrophic obstructive cardiomyopathy); however, with close monitoring and control of the anesthetic level, neuraxial anesthesia can be performed safely in patients with stenotic valvular heart disease, particularly if extensive dermatomal spread of anesthesia is not required (e.g., “saddle” block spinal anesthetics).

Relative and controversial contraindications are also shown in Table 45–1.
Inspection and palpation of the back can reveal surgical scars, scoliosis, skin lesions, and whether or not the spinous processes can be identified. Although preoperative screening tests are not required in healthy patients undergoing neuraxial blockade, appropriate testing should be performed if the clinical history suggests a coagulation abnormality. Neuraxial anesthesia in the presence of sepsis or bacteremia could theoretically predispose patients to hematogenous spread of the infectious agents into the epidural or subarachnoid space.

Patients with preexisting neurological deficits or demyelinating diseases may report worsening symptoms following a neuraxial block. It may be impossible to discern effects or complications of the block from preexisting deficits or
unrelated exacerbation of preexisting disease. For these reasons, some risk-averse practitioners argue against neuraxial anesthesia in such patients. A preoperative neurological examination should thoroughly document any deficits. In a retrospective study examining the records of 567 patients with preexisting neuropathies, 2 of the patients developed new or worsening neuropathy following neuraxial anesthesia. Although this finding indicates a relatively low risk of further injury, study investigators suggest that an injured nerve is vulnerable to additional injury, increasing the likelihood of poor neurological outcomes. However, a history of preexisting neurological deficits or demyelinating disease is at best a relative contraindication, and the balance of perioperative risks in this patient population may favor neuraxial anesthesia in certain select patients.

Regional anesthesia requires at least some degree of patient cooperation. This may be difficult or impossible for patients with dementia, psychosis, or emotional instability. The decision must be individualized. Unsedated young children may not be suitable for pure regional techniques; however, regional anesthesia is frequently used with general anesthesia in children.

**Neuraxial Blockade in the Setting of Anticoagulants & Antiplatelet Agents**

Whether a block should be performed in the setting of anticoagulants and antiplatelet agents can be problematic. The American Society of Regional Anesthesia and Pain Medicine (ASRA) has issued guidelines on this subject. Because guidelines are frequently revised and updated, practitioners are advised to seek the most recent edition. Fortunately, the incidence of epidural hematoma is reported to be infrequent (1 in 150,000 epidurals). The use of anticoagulant and antiplatelet medications continues to increase, placing an ever-larger number of patients at potential risk of epidural hematomas. However, because of the rarity of epidural hematomas, most guidelines are based on expert opinion and case series reviews, as clinical trials are not feasible.

**A. Oral Anticoagulants**

If neuraxial anesthesia is to be used in patients receiving warfarin therapy, a normal prothrombin time and international normalized ratio usually will be documented prior to the block, unless the drug has been discontinued for weeks. Anesthesia staff should always consult with the patient’s primary physicians whenever considering the discontinuation of antiplatelet or antithrombotic
therapy. New agents such as the direct thrombin inhibitor dabigatran and the factor X\textsubscript{a} inhibitors rivaroxaban and apixaban are increasingly encountered by anesthesia staff (Figure 45–9).

![Schematic diagram of the coagulation cascade](image)

**FIGURE 45–9** Sites of action of anticoagulant drugs. Clotting factors are indicated by Roman numerals. Warfarin reduces production of factors VII, IX, X, and prothrombin. Heparin and LMWH inhibit factor X\textsubscript{a} and thrombin. Fondaparinux, rivaroxaban, and apixaban are direct factor X\textsubscript{a} inhibitors. Dabigatran is a direct thrombin inhibitor. HMWK, high-molecular-weight kininogen; LMWH, low-molecular-weight heparin. (Reproduced with permission from Benzon H, Avram M, Green D, Bonow R. New oral anticoagulants and regional anesthesia. *Br J Anaesth.* 2013 Dec;111(Suppl 1):i96-i113.)

Two drug half-life intervals have been suggested as the time from drug discontinuation until neuraxial procedures are performed. However, depending upon patient factors two half-life intervals may not be sufficient to mitigate the increased risk of bleeding following neuraxial procedures. A period from drug discontinuation of up to five to six drug half-life intervals may be necessary to avoid increased bleeding risk. Thrombin clotting time assays can be used to detect the effects of dabigatran. Likewise, factor X\textsubscript{a} inhibitors can be assessed through assays of factor X\textsubscript{a} inhibition. Anesthesia providers planning neuraxial procedures should consult closely with the patient’s primary providers to discern if suspension of anticoagulation is advised when considering a neuraxial technique. Bridging therapy with low-molecular-weight heparin can be
considered during the time that oral anticoagulation is suspended if there is increased thrombotic risk. It has been suggested that new oral anticoagulants can be resumed 24 to 48 h following a neuraxial procedure or removal of an epidural catheter.

B. Antiplatlet Drugs
By themselves, aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) drugs do not increase the risk of spinal hematoma from neuraxial anesthesia procedures or epidural catheter removal. This assumes a normal patient with a normal coagulation profile who is not receiving other medications that might affect clotting mechanisms. In contrast, more potent agents should be stopped, and neuraxial blockade should generally be administered only after their effects have worn off. The waiting period depends on the specific agent: for ticlopidine it is 14 days; clopidogrel, 7 days; prasugrel, 7 to 10 days; ticagrelor, 5 days; abciximab, 48 h; and eptifibatide, 8 h. Neuraxial techniques should be avoided in patients receiving antiplatelet medications until platelet function has been recovered. Metabolites of clopidogrel and prasugrel block the P2Y12 receptor, impeding platelet aggregation. Ticagrelor directly inhibits the P2Y12 receptor. Both prasugrel and ticagrelor have greater platelet inhibition compared with clopidogrel. In patients with a recently placed cardiac stent, discontinuation of antiplatelet therapy can result in stent thrombosis and acute ST-segment elevation myocardial infarction. Risks versus benefits of a neuraxial technique should be discussed with the patient and the patient’s primary physicians.

C. Standard (Unfractionated) Heparin
“Minidose” subcutaneous heparin prophylaxis is not a contraindication to neuraxial anesthesia or epidural catheter removal. In patients who are to receive systemic heparin intraoperatively, blocks may be performed 1 h or more before heparin administration. A bloody epidural or spinal catheter placement does not necessarily require cancellation of surgery, but discussion of the risks with the surgeon and careful postoperative monitoring is needed. Removal of an epidural catheter should occur 1 h prior to, or 4 h following, subsequent heparin dosing.

Neuraxial anesthesia should be avoided in patients on therapeutic doses of intravenous heparin and with increased partial thromboplastin time. If the patient is started on heparin after the placement of an epidural catheter, the catheter should be removed only after discontinuation or interruption of heparin infusion and evaluation of the coagulation status. The risk of spinal hematoma is unclear in the setting of the anticoagulation required for cardiac surgery, and we have
used epidural techniques for pain control after such procedures as off-pump coronary bypass only in the rare instances where the anticipated benefits exceed the perceived risks. Prompt diagnosis and evacuation of symptomatic epidural hematomas increase the likelihood that neuronal function will be preserved.

D. Low-Molecular-Weight Heparin (LMWH)
A number of cases of spinal hematoma were reported associated with neuraxial anesthesia after patients began receiving low-molecular-weight heparin (LMWH) enoxaparin (Lovenox) in the United States in 1993. Many of these cases involved intraoperative or early postoperative LMWH use, and several patients were receiving concomitant antiplatelet medication. The ASRA guideline provides useful recommendations for risk reduction in such circumstances. Some of the draft recommendations include that if an unusually bloody needle or catheter placement occurs, LMWH should be delayed until 24 h postoperatively, because this trauma may increase the risk of spinal hematoma. If postoperative LMWH thromboprophylaxis will be utilized, epidural catheters should be removed 4 h prior to the first LMWH dose.

E. Fibrinolytic or Thrombolytic Therapy
Neuraxial anesthesia should not be performed if a patient has received fibrinolytic or thrombolytic therapy.

ASRA has developed a smartphone application (ASRA Coags Regional app) to assist in the perioperative management of patients taking drugs that affect coagulation.

Awake or Asleep?
Should lumbar neuraxial anesthesia, when used in conjunction with general anesthesia, be performed after induction of general anesthesia? This is controversial. The major arguments for having the patient asleep are that (1) most patients, if given a choice, would prefer to be asleep, and (2) the possibility of sudden patient movement causing injury is markedly diminished. The major argument in favor of neuraxial blockade administration only while the patient is still awake is that the patient can alert the clinician to paresthesias and pain on injection in this circumstance, both of which have been associated with postoperative neurological deficits. Although many clinicians are comfortable performing lumbar epidural or spinal puncture in anesthetized or deeply sedated adults, there is greater consensus, although not unanimous opinion, that thoracic
and cervical punctures should, except under unusual circumstances, only be performed in awake, responsive patients. Pediatric neuraxial blocks, particularly caudal and epidural blocks, are usually performed under general anesthesia.

**Technical Considerations**

Neuraxial blocks must be performed only in a facility in which all the equipment and drugs needed for intubation, resuscitation, and general anesthesia are immediately available. Regional anesthesia is greatly facilitated by adequate patient premedication. Nonpharmacological patient preparation is also very helpful. The patient should be told what to expect so as to minimize anxiety. This is particularly important in situations in which premedication is not used, as is typically the case in obstetric anesthesia. Supplemental oxygen via a face mask or nasal cannula may be required to avoid hypoxemia when sedation is used. Minimum monitoring requirements include blood pressure and pulse oximetry for labor analgesia. Monitoring for blocks rendered in surgical anesthesia is the same as that in general anesthesia.

**Surface Anatomy**

Spinous processes are usually palpable and help to define the midline. Ultrasound can be used when landmarks are not palpable (Figure 45–10). The spinous processes of the cervical and lumbar spine are nearly horizontal, whereas those in the thoracic spine slant in a caudal direction and can overlap significantly (Figure 45–2). Therefore, when performing a lumbar or cervical epidural block (with maximum spinal flexion), the needle is directed with only a slight cephalad angle, if at all, whereas for a thoracic block, the needle must be angled significantly more cephalad to enter the thoracic epidural space. In the cervical area, the first palpable spinous process is that of C2, but the most prominent one is that of C7 (vertebra prominens). With the arms at the side, the spinous process of T7 is usually at the same level as the inferior angle of the scapulae (Figure 45–11). A line drawn between the highest points of both iliac crests (Tuffier’s line) usually crosses either the body of L4 or the L4–L5 interspace. Counting spinous processes up or down from these reference points identifies other spinal levels. A line connecting the posterior superior iliac spine crosses the S2 posterior foramina. In slender persons, the sacrum is easily palpable, and the sacral hiatus is felt as a depression just above or between the gluteal clefts and above the coccyx, defining the point of entry for caudal blocks.
**Patient Positioning**

**A. Sitting Position**

The anatomic midline is often easier to identify when the patient is sitting than when the patient is in the lateral decubitus position (Figure 45–12). This is particularly true with obese patients. Patients sit with their elbows resting on their thighs or a bedside table, or they can hug a pillow. Flexion of the spine (arching the back “like an angry cat”) maximizes the “target” area between adjacent spinous processes and brings the spine closer to the skin surface (Figure 45–13).

---

**FIGURE 45–11** Surface landmarks for identifying spinal levels.
FIGURE 45–12 Sitting position for neuraxial blockade. Note an assistant helps in obtaining maximal spinal flexion.

B. Lateral Decubitus
Many clinicians prefer the lateral position for neuraxial blocks (Figure 45–14). Patients lie on their side with their knees flexed and pulled high against the abdomen or chest, assuming a “fetal position.” An assistant can help the patient assume and hold this position.
C. Buie’s (Jackknife) Position
This position may be used for anorectal procedures utilizing an isobaric or hypobaric anesthetic solution (see later discussion). The advantage is that the block is done in the same position as the operative procedure, so that the patient does not have to be moved following the block. The disadvantage is that CSF will not freely flow through the needle, so that correct subarachnoid needle tip placement will need to be confirmed by CSF aspiration. A prone position is typically used when fluoroscopic guidance is required.

Anatomic Approach
A. Midline Approach
The spine is palpated, and the patient’s body positioned so that a needle passed parallel to the floor will stay midline as it courses deeper (Figure 45–4). The depression between the spinous processes of the vertebrae above and below the level to be used is palpated; this will be the needle entry site. A sterile field is
established with an appropriate antibacterial solution. A fenestrated sterile drape is applied. After the preparation solution has dried, a skin wheal is raised at the level of the chosen interspace with local anesthetic using a small (25-gauge) needle. A longer needle can be used for deeper local anesthetic infiltration.

Next, the procedure needle is introduced in the midline. Remembering that the spinous processes course caudad from their origin at the spine, the needle will be directed slightly cephalad. The subcutaneous tissues offer little resistance to the needle. As the needle courses deeper, it will enter the supraspinous and interspinous ligaments, felt as an increase in tissue resistance. The needle also feels more firmly implanted in the back (like “an arrow in a target”). If bone is contacted superficially, a midline needle is likely hitting the lower spinous process. Contact with bone at a deeper level usually indicates that the needle is in the midline and hitting the upper spinous process, or that it is lateral to the midline and hitting a lamina. In either case, the needle must be redirected. As the needle penetrates the ligamentum flavum, an obvious increase in resistance is encountered. At this point, the procedures for spinal and epidural anesthesia differ.

For epidural anesthesia, a sudden loss of resistance (to injection of air or saline) is encountered as the needle passes through the ligamentum flavum and enters the epidural space. For spinal anesthesia, the needle is advanced through the epidural space and penetrates the dura–subarachnoid membranes, as signaled by freely flowing CSF.

**B. Paramedian Approach**

The paramedian technique may be selected, particularly if epidural or subarachnoid block is difficult, particularly in patients who cannot be positioned easily (eg, severe arthritis, kyphoscoliosis, or prior spine surgery) (Figure 45–15). Many clinicians routinely use the paramedian approach for thoracic epidural puncture. After skin preparation and sterile draping (as previously described), the skin wheal for a paramedian approach is raised 2 cm lateral to the inferior aspect of the superior spinous process of the desired level. Because this approach is lateral to most of the interspinous ligaments and penetrates the paraspinous muscles, the needle may encounter little resistance initially and may not seem to be in firm tissue. The needle is directed and advanced at a 10° to 25° angle toward the midline. If bone is encountered at a shallow depth with the paramedian approach, the needle is likely in contact with the medial part of the lower lamina and should be redirected mostly upward and perhaps slightly more laterally. On the other hand, if bone is encountered deeply, the needle is usually
in contact with the lateral part of the lower lamina and should be redirected only slightly craniad, more toward the midline (Figure 45–16).

**FIGURE 45–15** Paramedian approach.
FIGURE 45–16 Paramedian approach. A needle that encounters bone at a shallow depth (a) is usually hitting the medial lamina, whereas one that encounters bone deeply (b) is farther lateral from the midline. A: Posterior view. B: Parasagittal view.

C. Assessing Level of Blockade
With knowledge of the sensory dermatomes (see appendix), the extent of sensory block can be assessed by a blunted needle or a piece of ice.
D. Ultrasound-Guided Neuraxial Blockade
Although it has not, as of yet, transformed the practice of neuraxial blockade in the same manner as it has for other procedures, ultrasound guidance can facilitate neuraxial blockade in patients with poorly palpable landmarks. As with other uses of ultrasound, specific training is required for practitioners to identify correctly the landmarks and interspaces necessary for neuraxial blockade.

Spinal Needles
Spinal needles are commercially available in an array of sizes lengths, and bevel and tip designs (Figure 45–17). All should have a tightly fitting, removable stylet that completely occludes the lumen to avoid tracking epithelial cells into the subarachnoid space. Broadly, they can be divided into either sharp (cutting)-tipped or blunt-tipped needles. The Quincke needle is a cutting needle with end injection. The introduction of blunt tip (pencil-point) needles has markedly decreased the incidence of postdural puncture headache. The Whitacre and other pencil-point needles have rounded points and side injection. The Sprotte is a side-injection needle with a long opening. It has the advantage of more vigorous CSF flow compared with similar gauge needles. However, this can lead to a failed block if the distal part of the opening is subarachnoid (with free flow CSF), the proximal part is not past the dura, and the full dose of medication is not delivered. In general, the smaller the gauge needle (along with use of a blunt-tipped needle), the lower will be the incidence of headache.
Spinal Catheters
Larger catheters designed for epidural use are frequently employed for continuous spinal anesthesia following accidental dural puncture during performance of epidural anesthesia. Catheters must be carefully labeled as being subarachnoid, as opposed to epidural, to avoid the potential for inadvertent dosage.

Specific Technique for Spinal Anesthesia
The midline or paramedian approaches, with the patient positioned in the lateral decubitus, sitting, or prone positions, can be used for spinal anesthesia. As previously discussed, the needle is advanced from skin through the deeper structures until two “pops” are felt. The first is penetration of the ligamentum flavum, and the second is penetration of the dura–arachnoid membrane. Successful dural puncture is confirmed by withdrawing the stylet to verify free flow of CSF. With small-gauge needles (<25 gauge), aspiration may be necessary to detect CSF. If free flow occurs initially, but CSF cannot be aspirated after attaching the syringe, the needle likely will have moved. Persistent paresthesias or pain with injection of drugs should prompt the clinician to withdraw and redirect the needle.

Factors Influencing Level of Spinal Block
Table 45–2 lists factors that have been shown to affect the level of neural blockade following spinal anesthesia. The most important determinants are baricity of the local anesthetic solution, position of the patient during and immediately after injection, and drug dosage. In general, the larger the dosage or more cephalad the site of injection, the more cephalad the level of anesthesia that will be obtained. Moreover, migration of the local anesthetic cephalad in CSF depends on its density relative to CSF (baricity). CSF has a specific gravity of 1.003 to 1.008 at 37°C. Table 45–3 lists the specific gravity of anesthetic solutions. A hyperbaric solution of local anesthetic is denser (heavier) than CSF, whereas a hypobaric solution is less dense (lighter) than CSF. The local anesthetic solutions can be made hyperbaric by the addition of glucose or hypobaric by the addition of sterile water or fentanyl. Thus, with the patient in a head-down position, a hyperbaric solution spreads cephalad, and a hypobaric
anesthetic solution moves caudad. A head-up position causes a hyperbaric solution to settle caudad and a hypobaric solution to ascend cephalad. Similarly, when a patient remains in a lateral position, a hyperbaric spinal solution will have a greater effect on the dependent (down) side, whereas a hypobaric solution will achieve a higher level on the nondependent (up) side. An isobaric solution tends to remain at the level of injection. Anesthetic agents lacking glucose may be mixed with CSF (at least 1:1) to make their solutions isobaric. Other factors affecting the level of neural blockade include the level of injection and the patient’s height and vertebral column anatomy. The direction of the needle bevel or injection port may also play a role; higher levels of anesthesia are achieved if the injection is directed cephalad than if the point of injection is oriented laterally or caudal.

**Other factors**

- Age
- Cerebrospinal fluid
- Curvature of the spine
- Drug volume
- Intraabdominal pressure
- Needle direction
- Patient height
- Pregnancy

**TABLE 45–3  Specific gravities of some spinal anesthetic agents.**
Hyperbaric solutions tend to move to the most dependent area of the spine (normally T4–T8 in the supine position).

With normal spinal anatomy, the apex of the thoracolumbar curvature is T4 (Figure 45–18). In the supine position, this should limit a hyperbaric solution to produce a level of anesthesia at or below T4. Abnormal curvatures of the spine, such as scoliosis and kyphoscoliosis, have multiple effects on spinal anesthesia. Placing the block becomes more difficult because of the rotation and angulation of the vertebral bodies and spinous processes. Finding the midline and the interlaminar space may be difficult. The paramedian approach to lumbar puncture may be preferable in patients with severe scoliosis and kyphoscoliosis. Reviewing radiographs of the spine before attempting the block may be useful. Spinal curvature affects the ultimate level by changing the contour of the subarachnoid space. Previous spinal surgery can similarly result in technical difficulties in placing a block. Correctly identifying the interspinous and interlaminar spaces may be difficult at the levels of previous laminectomy or spinal fusion. The paramedian approach may be easier, or a level above the surgical site can be chosen. The block may be incomplete, or the level may be different than anticipated, due to postsurgical anatomic changes.
FIGURE 45–18  The position of the spinal canal in the supine position (A) and lateral decubitus position (B). Note the lowest point is usually between T5 and T7, where a hyperbaric solution tends to settle once the patient is placed supine.

Lumbar CSF volume inversely correlates with the dermatomal spread of spinal anesthesia. Increased intraabdominal pressure or other conditions that cause engorgement of the epidural veins, thus decreasing CSF volume, are associated with greater dermatomal spread for a given volume of injectate. This would include conditions such as pregnancy, ascites, and large abdominal tumors. In these clinical situations, higher levels of anesthesia are achieved with a given dose of local anesthetic than would otherwise be expected. For spinal anesthesia on a term parturient, some clinicians reduce the dosage of anesthetic by one-third compared with a nonpregnant patient, particularly when the block will be initiated with the patient in the lateral position. Age-related decreases in CSF volume are likely responsible for the higher anesthetic levels achieved in the elderly for a given dosage of spinal anesthetic. Severe kyphosis or kyphoscoliosis can also be associated with a decreased volume of CSF and often results in a higher than expected level, particularly with a hypobaric technique or rapid injection.
Spinal Anesthetic Agents

Many local anesthetics have been used for spinal anesthesia in the past, but only a few are currently in use (Table 45–4). Only preservative-free local anesthetic solutions are used. Addition of vasoconstrictors (α-adrenergic agonists, epinephrine [0.1–0.2 mg]) and opioids enhance the quality or prolong the duration of spinal anesthesia, or both. Vasoconstrictors seem to delay the uptake of local anesthetics from CSF and may have weak spinal analgesic properties. Opioids and clonidine can likewise be added to spinal anesthetics to improve both the quality and duration of the subarachnoid block.

1,2
Until very recently in North America, hyperbaric spinal anesthesia was more commonly used than hypobaric or isobaric techniques. The level of anesthesia is then dependent on the patient’s position during and immediately following the injection. In the sitting position, “saddle block” can be achieved by keeping the patient sitting for 3 to 5 min following injection, so that only the lower lumbar nerves and sacral nerves are blocked. If the patient is moved from a sitting position to a supine position immediately after injection, the agent will move more cephalad to the dependent region defined by the thoracolumbar curve.

Hyperbaric anesthetics injected intrathecally with the patient in a lateral decubitus position are useful for unilateral lower extremity procedures. The patient is placed laterally, with the extremity to be operated on in a dependent position. If the patient is kept in this position for about 5 min following injection, the block will tend to be denser and achieve a higher level on the operative dependent side.

If regional anesthesia is chosen for surgical procedures involving hip or lower extremity fracture, hypobaric or isobaric spinal anesthesia can be useful because the patient need not lie on the fractured extremity.

Epidural Anesthesia

Continuous epidural anesthesia is a neuraxial technique offering a range of applications wider than single-dose spinal anesthesia. An epidural block can be performed at the lumbar, thoracic, or cervical level. Sacral epidural anesthesia is
Epidural techniques are widely used for surgical anesthesia, obstetric analgesia, postoperative pain control, and chronic pain management. Epidurals can be used as a single shot technique or with a catheter that allows intermittent boluses or continuous infusion, or both. The motor block can range from none to complete. All of these variables are controlled by the choice of drug, concentration, dosage, and level of injection.

The epidural space surrounds the dura mater posteriorly, laterally, and anteriorly. Nerve roots travel in this space as they exit laterally through the foramen and course outward to become peripheral nerves. Other contents of the lumbar epidural space include fatty connective tissue, lymphatics, and a rich venous (Batson’s) plexus. Fluoroscopic studies have demonstrated the presence of septa or connective tissue bands within the epidural space, possibly explaining the occasional one-sided epidural block. Epidural anesthesia is slower in onset (10–20 min) and may not be as dense as spinal anesthesia, a feature that can be useful clinically. For example, by using relatively dilute concentrations of a local anesthetic combined with an opioid, an epidural provides analgesia without motor block. This is commonly employed for labor and postoperative analgesia. Moreover, a segmental block is possible because the anesthetic can be confined close to the level at which it was injected. A segmental block is characterized by a well-defined band of anesthesia at certain nerve roots; leaving nerve roots above and below unblocked. This can be seen with a thoracic epidural that provides upper abdominal anesthesia while sparing cervical and lumbar nerve roots.

Epidural anesthesia is most often performed in the lumbar region. The midline (Figure 45–4) or paramedian approaches (Figure 45–15) can be used. Lumbar epidural anesthesia can be used for any procedure below the diaphragm. Because the spinal cord typically terminates at the L1 level, there is an extra measure of safety in performing the block in the lower lumbar interspaces, particularly if an accidental dural puncture occurs (see “Complications,” later).

Thoracic epidural blocks are technically more difficult to accomplish than are lumbar blocks because of greater angulation and the overlapping of the spinous processes at the vertebral level (Figure 45–19). Moreover, the potential risk of spinal cord injury with accidental dural puncture, although exceedingly small with good technique, may be greater than that at the lumbar level. Thoracic epidural blocks can be accomplished with either a midline or paramedian approach. The thoracic epidural technique is more commonly used for postoperative analgesia than as a primary anesthetic. Single shot or catheter
techniques are used for the management of chronic pain. Infusions via an epidural catheter are useful for providing prolonged durations of analgesia and may obviate or shorten postoperative ventilation in patients with underlying lung disease and following chest surgery.
FIGURE 45–19  Angulation of the epidural needle at the cervical (A), thoracic (B), and lumbar (C) levels. Note that an acute angulation (30°–50°) is required for a thoracic epidural block, whereas only a slight cephalad orientation is usually required for cervical and lumbar epidural blocks.

Cervical blocks are usually performed with the patient sitting, with the neck flexed, using the midline approach. They are used most often for the management of acute and chronic pain.

**Epidural Needles**

The standard epidural needle is typically 17 to 18 gauge, 3 or 3.5 inches long, and has a blunt bevel with a gentle curve of 15° to 30° at the tip. The Tuohy needle is most commonly used (Figure 45–20). The blunt, curved tip theoretically helps to push away the dura after passing through the ligamentum flavum instead of penetrating it. Straight needles without a curved tip (Crawford needles) may have a greater incidence of dural puncture. Needle modifications include winged tips and introducer devices set into the hub designed for guiding catheter placement.
Epidural Catheters

Placing a catheter into the epidural space allows for continuous infusion or intermittent bolus techniques. In addition to extending the duration of the block, catheter techniques may allow a lower total dose of anesthetic to be used.

Epidural catheters are useful for intraoperative epidural anesthesia and postoperative analgesia. Typically, a 19- or 20-gauge catheter is introduced through a 17- or 18-gauge epidural needle. When using a curved tipped needle, the bevel opening is directed either cephalad or caudad, and the catheter is advanced 2 to 6 cm into the epidural space. The shorter the distance the catheter is advanced, the more likely it is to become dislodged. Conversely, the further the catheter is advanced, the greater the chance of a unilateral block (due to the catheter tip either exiting the epidural space via an intervertebral foramen or coursing into the anterolateral recesses of the epidural space) and the greater chance of penetration of an epidural vein occurring. After advancing the catheter the desired depth, the needle is removed, leaving the catheter in place. The catheter can be taped or otherwise secured along the back. Catheters that will remain in place for prolonged times (eg, >1 week) may be tunneled under the skin. Catheters have either a single port at the distal end or multiple side ports close to a closed tip. Some have a stylet for easier insertion or to help steer the catheter passage in the epidural space with fluoroscopic guidance. Spiral wire-reinforced catheters are very resistant to kinking. The spiral or spring tip is associated with fewer, less intense paresthesias and may be associated with a lower incidence of inadvertent intravascular insertion.

Specific Techniques for Epidural Anesthesia

Using the midline or paramedian approaches detailed previously, the epidural needle is passed through the skin and the ligamentum flavum. The needle must stop short of piercing the dura. Two techniques make it possible to determine when the tip of the needle has entered the potential (epidural) space: the “loss of resistance” and “hanging drop” techniques.

The loss of resistance technique is preferred by most clinicians. The needle is advanced through the subcutaneous tissues with the stylet in place until the interspinous ligament is entered, as noted by an increase in tissue resistance. The stylet or introducer is removed, and a glass syringe filled with saline or air is attached to the hub of the needle. If the tip of the needle is within the ligament,
gentle attempts at injection are met with resistance, and injection is not possible. The needle is then slowly advanced, millimeter by millimeter, with either continuous or rapidly repeating attempts at injection. As the tip of the needle just enters the epidural space, there is a sudden loss of resistance, and injection is easy.

Once the interspinous ligament has been entered and the stylet has been removed, the hanging drop technique requires that the hub of the needle be filled with solution so that a drop hangs from its outside opening. The needle is then slowly advanced deeper. As long as the tip of the needle remains within the ligamentous structures, the drop remains “hanging.” However, as the tip of the needle enters the epidural space, it creates negative pressure, and the drop of fluid is sucked into the needle. If the needle becomes plugged, the drop will not be drawn into the hub of the needle, and accidental dural puncture may occur. Some clinicians prefer to use this technique for the paramedian approach and for cervical epidurals. Skilled “epiduralists” rely on either the loss of resistance or hanging drop as confirmation (rather than as the primary test) that the needle has entered the epidural space. Successful “epiduralists” will generally have sensed the “give” in their hands as the epidural needle tip passes through the ligamentum flavum.

Activating an Epidural

The quantity (volume and concentration) of local anesthetic needed for epidural anesthesia is larger than that needed for spinal anesthesia. Toxic side effects are almost guaranteed if a “full epidural dose” is injected intrathecally or intravascularly. Safeguards against toxic epidural side effects include test dosing and incremental dosing. These safeguards apply whether the injection is through the needle or through an epidural catheter.

A test dose is designed to detect both subarachnoid and intravascular injection. The classic test dose combines local anesthetic and epinephrine, typically 3 mL of 1.5% lidocaine with 1:200,000 epinephrine (0.005 mg/mL). The 45 mg of lidocaine, if injected intrathecally, will produce spinal anesthesia that should be rapidly apparent. Some clinicians have suggested the use of lower doses of local anesthetic, as an unintended injection of 45 mg of intrathecal lidocaine, can be difficult to manage in areas such as labor rooms. The 15 mcg dose of epinephrine, if injected intravascularly, should produce a noticeable increase in heart rate (20% or more), with or without hypertension. Unfortunately, epinephrine as a marker of intravenous injection is not ideal. False positives (a uterine contraction causing pain or an increase in heart rate
coincident to test dosing) and false negatives (bradycardia and exaggerated hypertension in response to epinephrine in patients taking β-blockers) can occur. Simply aspirating prior to injection is insufficient to avoid inadvertent intravenous injection; most experienced practitioners have encountered false-negative aspirations through both a needle and a catheter.

Incremental dosing is a very effective method of avoiding serious complications (“each dose is a test dose”). If aspiration is negative, a fraction of the total intended local anesthetic dose is injected, typically 5 mL. This dose should be large enough for mild symptoms (tinnitus or metallic taste) or signs (slurred speech, altered mentation) of intravascular injection to occur, but small enough to avoid seizure or cardiovascular compromise. This is particularly important for labor epidurals that are to be used for cesarean delivery. If the initial labor epidural bolus was delivered through the needle, and the catheter was then inserted, it may be erroneously assumed that the catheter is well positioned because the patient is still comfortable from the initial bolus. If the catheter was inserted into a blood vessel, or after initial successful placement, has since migrated intravascularly, systemic toxicity will likely result if the full anesthetic dose is injected. Catheters can migrate intrathecally or intravascularly from an initially correct epidural position at any time after placement, but migration is most likely to occur with movement of the patient.

If a clinician uses an initial test dose, is diligent about aspirating prior to each injection, and always uses incremental dosing, major systemic toxic side effects and total spinal anesthesia from accidental intrathecal injections will be rare. Rescue lipid emulsion (20% Intralipid 1.5 mL/kg) must be available whenever epidural blocks are performed, in the event of local anesthetic systemic toxicity.

**Factors Affecting Level of Block**

Factors affecting the level of epidural anesthesia may not be as predictable as with spinal anesthesia. In adults, 1 to 2 mL of local anesthetic per segment to be blocked is a generally accepted guideline. For example, to achieve a T4 sensory level from an L4–L5 injection would require about 12 to 24 mL. For segmental or analgesic blocks, less volume is needed.

The dose required to achieve the same level of anesthesia decreases with age. This is probably a result of age-related decreases in the size or compliance of the epidural space. Although there is little correlation between body weight and epidural dosage requirements, patient height affects the extent of cephalad spread. Thus, shorter patients may require only 1 mL of local anesthetic per
A segment to be blocked, whereas taller patients generally require 2 mL per segment. Although less dramatic than with hyperbaric or hypobaric spinal anesthesia, spread of epidural local anesthetics tends to be partially affected by gravity. The lateral decubitus, Trendelenburg, and reverse Trendelenburg positions can be used to help achieve blockade in the desired dermatomes.

Additives to the local anesthetic, particularly opioids, tend to have a greater effect on the quality of epidural anesthesia than on the duration of the block. Epinephrine in concentrations of 5 mcg/mL prolongs the effect of epidural lidocaine, mepivacaine, and chloroprocaine more than that of bupivacaine, levobupivacaine, or ropivacaine. In addition to prolonging the duration and improving the quality of block, epinephrine delays vascular absorption and reduces peak systemic blood levels of all epidurally administered local anesthetics.

**Epidural Anesthetic Agents**

The epidural agent is chosen based on the desired clinical effect, whether it is to be used as a primary anesthetic, supplementation of general anesthesia, or analgesia. The anticipated duration of the procedure may call for a short- or long-acting single shot anesthetic or the insertion of a catheter (Table 45–5). Commonly used short- to intermediate-acting agents for surgical anesthesia include chloroprocaine, lidocaine, and mepivacaine. Longer acting agents include bupivacaine, levobupivacaine, and ropivacaine.

Following the initial 1 to 2 mL per segment bolus (in fractionated doses), repeat doses delivered through an epidural catheter are done on a fixed time
interval (either as a bolus or continuous infusion), based on the practitioner’s experience with the agent, or only redosed when the block demonstrates some degree of regression. Once some regression in sensory level has occurred, one-third to one-half of the initial activation dose can generally safely be reinjected in incremental doses.

It should be noted that chloroprocaine, an ester with rapid onset, short duration, and extremely low toxicity, may interfere with the analgesic effects of epidural opioids. Previous chloroprocaine formulations with preservatives, specifically bisulfite and ethylenediaminetetraacetic acid (EDTA), produced cauda equine syndrome when accidentally injected in a large volume intrathecally. Bisulfite preparations of chloroprocaine were believed to be associated with neurotoxicity, whereas EDTA formulations were associated with severe back pain (presumably due to localized hypocalcemia). Most current preparations of chloroprocaine are preservative-free and without these complications.

Surgical anesthesia is obtained with a 0.5% bupivacaine formulation. The 0.75% formulation of bupivacaine is no longer used in obstetrics, as its use in cesarean delivery has been associated with reports of cardiac arrest after accidental intravenous injection. Very dilute concentrations of bupivacaine (eg, 0.0625%) are commonly combined with fentanyl and used for analgesia for labor and postoperative pain. Compared with bupivacaine, ropivacaine may produce less motor block at similar concentrations while maintaining a satisfactory sensory block.

Local Anesthetic pH Adjustment

Local anesthetic solutions have an acidic pH for chemical stability and bacteriostasis. Local anesthetic solutions that are formulated with epinephrine by the manufacturer are more acidic than the “plain” solutions that do not contain epinephrine. Because they are weak bases, they exist primarily in the ionic form in commercial preparations. The onset of neural block requires permeation of lipid barriers by the uncharged form of the local anesthetic. Increasing the pH of the solutions increases the fraction of the uncharged form of the local anesthetic. Addition of sodium bicarbonate (1 mEq/10 mL of local anesthetic) immediately before injection may therefore accelerate the onset of the neural blockade. Sodium bicarbonate is typically not added to bupivacaine, which precipitates above a pH of 6.8.
Failed Epidural Blocks

Unlike spinal anesthesia, in which the procedural endpoint is usually very clear (free-flowing CSF), the onset is very fast, and the technique has a very high success rate, epidural anesthesia is dependent on detection of a more subjective loss of resistance (or hanging drop). Also, the onset of epidural anesthesia is slower, and the more variable anatomy of the epidural space and less predictable spread of local anesthetic make epidural anesthesia inherently less predictable than spinal anesthesia.

Misplaced injections of local anesthetic can occur in a number of situations. In some patients, the spinal ligaments are soft, and either good resistance is never appreciated or a false loss of resistance is encountered. Similarly, entry into the paraspinal muscles during an off-center midline approach may cause a false loss of resistance. Other causes of failed epidural anesthesia (such as intrathecal, subdural, and intravenous injection) are discussed in the late section of this chapter on complications.

A unilateral block can occur if the medication is delivered through a catheter that has either exited the epidural space or coursed laterally. The chance of this occurring increases as longer lengths of catheter are threaded into the epidural space. When unilateral block occurs, the problem may be overcome by withdrawing the catheter 1 to 2 cm and reinjecting it with the patient turned with the unblocked side down. Segmental sparing, which may be due to septations within the epidural space, may also be corrected by injecting additional local anesthetic with the unblocked segment positioned down. The large size of the L5, S1, and S2 nerve roots may delay adequate penetration of local anesthetic and is thought to be responsible for sacral sparing. The latter is particularly a problem for surgery on the knee, ankle, or foot; in such cases, elevating the head of the bed and reinjecting the catheter with additional anesthetic solution can sometimes achieve a more intense block of these large nerve roots. Patients may complain of visceral pain despite a seemingly good epidural block. In some cases (eg, traction on the inguinal ligament and spermatic cord), a high thoracic sensory level may alleviate the pain; in other cases (traction on the peritoneum), intravenous supplementation with opioids or other agents may be necessary. Visceral afferent fibers that travel with the vagus nerve may be responsible.

Caudal Anesthesia

Caudal epidural anesthesia is a common regional technique in pediatric
patients. It may also be used for anorectal surgery in adults. The caudal space is the sacral portion of the epidural space. Caudal anesthesia involves needle or catheter penetration of the sacroccocygeal ligament covering the sacral hiatus that is created by the unfused S4 and S5 laminae. The hiatus may be felt as a groove or notch above the coccyx and between two bony prominences, the sacral cornua (Figure 45–3). Its anatomy is very easily appreciated in infants and children (Figure 45–21). The posterior superior iliac spines and the sacral hiatus define an equilateral triangle (Figure 45–14). Calcification of the sacroccocygeal ligament may make caudal anesthesia difficult or impossible in older adults. As previously noted, the dural sac extends to the first sacral vertebra in adults and to about the third sacral vertebra in infants, making accidental intrathecal injection a common concern in infants.

FIGURE 45–21 Positioning an anesthetized child for caudal block and palpation for the sacral hiatus. An assistant gently helps flex the spine.

In children, caudal anesthesia is typically combined with general anesthesia for intraoperative supplementation and postoperative analgesia. It is commonly used for procedures below the diaphragm, including urogenital, rectal, inguinal, and lower extremity surgery. Pediatric caudal blocks are most commonly performed after the induction of general anesthesia. However, regional techniques are increasingly used for surgical anesthesia in infants and young children because of concerns about the possible neurotoxic effects of general anesthesia in that population. The patient is placed in the lateral or prone position with one or both hips flexed, and the sacral hiatus is palpated. After sterile skin preparation, a needle or intravenous catheter (18–23 gauge) is
advanced at a 45° angle cephalad until a pop is felt as the needle pierces the sacroccocygeal ligament. The angle of the needle is then flattened and advanced (Figure 45–22). Aspiration for blood and CSF is performed, and, if negative, injection can proceed. Some clinicians recommend test dosing as with other epidural techniques, although many simply rely on incremental dosing with frequent aspiration. Tachycardia (if epinephrine is used) or increasing size of the T waves on electrocardiography may indicate intravascular injection. Complications are fortunately infrequent but include total spinal and intravenous injection, causing seizure or cardiac arrest. Ultrasound has also been employed in the performance of caudal blocks.

![Figure 45–22](image)

**FIGURE 45–22** Caudal block. Note the sacroccocygeal ligament is penetrated with the needle almost at 90° and then must be angled down and advanced to enter the sacral hiatus.

A dosage of 0.5 to 1.0 mL/kg of 0.125% to 0.25% bupivacaine (or ropivacaine), with or without epinephrine, can be used. Opioids may also be added (eg, 30–40 mcg/kg of morphine). Clonidine is often included, as well. The
analgesic effects of the block may extend for hours into the postoperative period. In adults undergoing anorectal procedures, caudal anesthesia can provide dense sacral sensory blockade with limited cephalad spread. Furthermore, the injection can be given with the patient in the prone jackknife position, which is used for surgery (Figure 45–23). A dose of 15 to 20 mL of 1.5% to 2.0% lidocaine, with or without epinephrine, is usually effective. Fentanyl, 50 to 100 mcg, may also be added. This technique should be avoided in patients with pilonidal cysts because the needle may pass through the cyst track and can potentially introduce bacteria into the caudal epidural space.

![The prone jackknife position often used for anorectal surgery can also be used for caudal anesthesia in adults.](Reproduced with permission from Lambert DH, Covino BG. Hyperbaric, hypobaric, and isobaric spinal anesthesia. Res Staff Phys. 1987 Sep;10(33):79-87.)

**Complications of Neuraxial Blocks**

The complications of epidural, spinal, or caudal anesthetics range from mild to crippling and life-threatening (Table 45–6). Broadly, complications from neuraxial techniques are secondary to excessive physiological effects of an appropriately injected drug, injury from needle or catheter placement, and local anesthetic systemic toxicity.

**TABLE 45–6** Complications of neuraxial anesthesia.
Adverse or exaggerated physiological responses

- Urinary retention
- High block
- Total spinal anesthesia
- Cardiac arrest
- Anterior spinal artery syndrome
- Horner syndrome

Complications related to needle/catheter placement

- Backache
- Dural puncture/leak
  - Postdural puncture headache
  - Diplopia
  - Tinnitus
- Neural injury
  - Nerve root damage
  - Spinal cord damage
  - Cauda equina syndrome
- Bleeding
  - Intraspinal/epidural hematoma
- Misplacement
  - No effect/inadequate anesthesia
  - Subdural block
  - Inadvertent subarachnoid block
  - Inadvertent intravascular injection
- Catheter shearing/retention
- Inflammation
  - Arachnoiditis
- Infection
  - Meningitis
  - Epidural abscess

Drug toxicity

- Systemic local anesthetic toxicity
A very large survey of regional anesthetics provides an indication of the relatively low incidence of serious complications from spinal and epidural anesthesia (Table 45–7). The American Society of Anesthesiologists (ASA) Closed Claims Project helps to identify the most common causes of liability claims involving regional anesthesia in the operating room setting. In a 20-year period (1980–1999), regional anesthesia accounted for 18% of all liability claims. In the majority of these claims, the injuries were judged as temporary or nondisabling (64%). Serious injuries in the remaining claims included death (13%), permanent nerve injury (10%), permanent brain damage (8%), and other permanent injuries (4%). The majority of regional anesthesia claims involved either lumbar epidural anesthesia (42%) or spinal anesthesia (34%) and tended to occur mostly in obstetric patients.

### Complications Associated with Excessive Responses to Appropriately Placed Drug

#### A. High Neural Blockade

Exaggerated dermatomal spread of neural blockade can occur readily with either spinal or epidural anesthesia. Administration of an excessive dose, failure to reduce standard doses in selected patients (eg, the elderly, pregnant, obese, or very short), or unusual sensitivity or spread of local anesthetic may be responsible. Patients may complain of dyspnea and have numbness or weakness in the upper extremities. Nausea often precedes hypotension. Once exaggerated spread of anesthesia is recognized, patients should be reassured, oxygen supplementation may be required, and bradycardia and hypotension should be treated.
Spinal anesthesia ascending into the cervical levels causes severe hypotension, bradycardia, and respiratory insufficiency. Unconsciousness, apnea, and hypotension resulting from high levels of spinal anesthesia are referred to as a “high spinal,” or when the block extends to cranial nerves, as a “total spinal.” These conditions can also occur following attempted epidural or caudal anesthesia if there is accidental intrathecal injection (see later discussion). Apnea is more often the result of severe sustained hypotension and medullary hypoperfusion than a response to phrenic nerve paralysis from anesthesia of C3–C5 roots. Anterior spinal artery syndrome has been reported following neuraxial anesthesia, presumably due to prolonged severe hypotension together with an increase in intraspinal pressure.

Treatment of an excessively high neuraxial block involves maintaining adequate arterial oxygenation and ventilation and supporting the circulation. When respiratory insufficiency becomes evident, in addition to supplemental oxygen and assisted ventilation, intubation and mechanical ventilation may be necessary. Hypotension can be treated with intravenous vasopressors and rapid administration of intravenous fluids. Bradycardia can be treated early with atropine. Ephedrine or epinephrine can also increase heart rate and arterial blood pressure.

B. Cardiac Arrest During Spinal Anesthesia
Examination of data from the ASA Closed Claim Project identified several cases of cardiac arrest during spinal anesthesia. Because many of these cases predated the routine use of pulse oximetry, oversedation and unrecognized hypoventilation and hypoxia may have contributed. However, large prospective studies continue to report a relatively high incidence (perhaps as high as 1:1500) of cardiac arrest in patients having received a spinal anesthetic. Many of these cardiac arrests were preceded by bradycardia, and many occurred in young healthy patients. To prevent this from occurring, hypovolemia should be corrected. Prompt drug treatment of hypotension and bradycardia are recommended.

C. Urinary Retention
Local anesthetic block of S2–S4 root fibers decreases urinary bladder tone and inhibits the voiding reflex. Epidural opioids can also interfere with normal voiding.
Complications Associated with Needle or Catheter Insertion

A. Inadequate Anesthesia or Analgesia
As with other regional anesthesia techniques, neuraxial blocks are associated with a small, but measureable, failure rate that is usually inversely proportional to the clinician’s experience. Failure may still occur, even when CSF is obtained during spinal anesthesia. Movement of the needle during injection, incomplete entry of the needle opening into the subarachnoid space, subdural injection, or injection of the local anesthetic solution into a nerve root sleeve may be responsible. Causes for failed epidural blocks were discussed earlier (see “Failed Epidural Blocks”).

B. Intravascular Injection
Accidental intravascular injection of the local anesthetic for epidural and caudal anesthesia can produce very high serum drug levels, which may affect the central nervous system (seizure and unconsciousness) and the cardiovascular system (hypotension, arrhythmias, and depressed contractility). Because the dosage of medication for spinal anesthesia is relatively small, this complication is seen after epidural and caudal (but not spinal) blocks. Local anesthetic may be injected directly into a vessel through a needle or later through a catheter that has entered a blood vessel (vein). The incidence of intravascular injection can be minimized by carefully aspirating the needle (or catheter) before every injection, using a test dose, always injecting local anesthetic in incremental doses, and close observation for early signs of intravascular injection (tinnitus, lingual sensations). Advanced cardiac life support should be initiated if cardiac arrest occurs. Lipid emulsion, 20% 1.5 mL/kg bolus, should be given followed by a 0.25-mL/kg infusion. Incremental 1 mcg/kg doses of epinephrine should be administered rather than larger 10 mcg/kg doses. Should cardiac function not be restored additional lipid emulsion can be administered up to 10 mL/kg. Cardiopulmonary bypass can be used should the patient fail to respond to resuscitative efforts. A recent review of local anesthetic systemic toxicity (LAST) cases suggests that use of lipid emulsion treatment may be underutilized even when indicated.

Local anesthetics vary in their propensity to produce severe cardiac toxicity. The rank order of local anesthetic potency at producing seizures and cardiac toxicity is the same as the rank order for potency at nerve blocks. Chloroprocaine has relatively low potency and also is metabolized very rapidly;
lidocaine and mepivacaine are intermediate in potency and toxicity; and levobupivacaine, ropivacaine, bupivacaine, and tetracaine are most potent and toxic.

C. Total Spinal Anesthesia
Total spinal anesthesia can occur following attempted epidural or caudal anesthesia if there is accidental intrathecal injection. Onset is usually rapid, because the amount of anesthetic required for epidural and caudal anesthesia is 5 to 10 times that required for spinal anesthesia. Careful aspiration, use of a test dose, and incremental injection techniques (remember, “every dose is a test dose”) during epidural and caudal anesthesia can help avoid this complication.

D. Subdural Injection
Because of the larger amount of local anesthetic administered, accidental subdural injection of local anesthetic during attempted epidural anesthesia is much more serious than during attempted spinal anesthesia. A subdural injection of epidural doses of local anesthetic produces a clinical presentation similar to that of high spinal anesthesia, with the exception that the onset may be delayed for 15 to 30 min and the block may be “patchy.” The spinal subdural space is a potential space between the dura and the arachnoid that extends intracranially, so that anesthetic injected into the spinal subdural space can ascend to higher levels than epidural medications. As with high spinal anesthesia, treatment is supportive and may require intubation, mechanical ventilation, and cardiovascular support. The effects generally last from one to several hours.

E. Backache
As a needle passes through skin, subcutaneous tissues, muscle, and ligaments it causes varying degrees of tissue trauma. Bruising and a localized inflammatory response with or without reflex muscle spasm may be responsible for postoperative backache. One should remember that up to 25% to 30% of patients receiving general anesthesia also complain of backache postoperatively, and a significant percentage of the general population has chronic back pain. Postoperative back soreness or ache is usually mild and self-limited, although it may last for a number of weeks. If treatment is sought, acetaminophen or NSAIDs should suffice. Although backache is usually benign, it may be an important clinical sign of much more serious complications, such as epidural hematoma and abscess (see later discussion).
F. Postdural Puncture Headache

Any breach of the dura may result in a postdural puncture headache (PDPH). This may follow a diagnostic lumbar puncture, a myelogram, a spinal anesthetic, or an epidural “wet tap” in which the epidural needle passed through the epidural space and entered the subarachnoid space. Similarly, an epidural catheter might puncture the dura at any time and result in PDPH. An epidural wet tap is usually immediately recognized as CSF pouring from the epidural needle or aspirated from an epidural catheter. However, PDPH can follow a seemingly uncomplicated epidural anesthetic and may be the result of just the tip of the needle scratching through the dura. Typically, PDPH is bilateral, frontal or retroorbital, or occipital and extends into the neck. It may be throbbing or constant and associated with photophobia and nausea. The hallmark of PDPH is its association with body position. The pain is aggravated by sitting or standing and relieved or decreased by lying down flat. The onset of headache is usually 12 to 72 h following the procedure; however, it may be seen almost immediately.

PDPH is believed to result from leakage of CSF from a dural defect and subsequent intracranial hypotension. Loss of CSF at a rate faster than it can be produced causes traction on structures supporting the brain, particularly the meninges, dura, and tentorium. Increased traction on blood vessels and cranial nerves may also contribute to the pain. Traction on the cranial nerves may occasionally cause diplopia (usually the sixth cranial nerve) and tinnitus. Subdural hematoma can occur following tear of intracerebral veins secondary to intracranial hypotension due to CSF loss. The incidence of PDPH is strongly related to needle size, needle type, and patient population. The larger the needle, the greater the likelihood that PDPH will occur. Cutting-point needles are associated with a higher incidence of PDPH than pencil-point needles of the same gauge. Factors that increase the risk of PDPH include young age, female sex, and pregnancy. The greatest risk, then, would be expected following an accidental wet tap with a large epidural needle in a young woman (perhaps as high as 20% to 50%). The lowest incidence would be expected in an elderly male using a 27-gauge pencil-point needle (<1%). Studies of obstetric patients undergoing spinal anesthesia for cesarean delivery with small-gauge pencil-point needles have shown rates as low as 3% or 4%.

Conservative treatment involves recumbent positioning, analgesics, intravenous or oral fluid administration, and caffeine. Keeping the patient supine will decrease the hydrostatic pressure driving fluid out of the dural hole and minimize the headache. Analgesic medication may range from acetaminophen to NSAIDs and opioids. Hydration and caffeine work to stimulate production of
CSF. Caffeine further helps by vasoconstricting intracranial vessels as cerebral vasodilation is thought to be a response to the intracranial hypotension secondary to the CSF leak. Stool softeners and soft diet are used to minimize Valsalva straining. Headache may persist for days, despite conservative therapy.

An epidural blood patch is an effective treatment for PDPH. It involves injecting 15 to 20 mL of autologous blood into the epidural space at, or one interspace below, the level of the dural puncture. It is believed to stop further leakage of CSF by either mass effect or coagulation. The effect is usually immediate and complete, but may take some hours as CSF production slowly rebuilds intracranial pressure. Approximately 90% of patients will respond to a single blood patch, and 90% of initial nonresponders will obtain relief from a second injection. We do not recommend prophylactic blood patching after a wet tap. Not all patients will develop PDPH following a wet tap, and in any case, prophylaxis has not proven terribly effective. When evaluating patients with presumed PDPH, other sources of headache, including migraine, caffeine withdrawal, meningeal infection, and subarachnoid hemorrhage, should be considered in the differential diagnosis.

G. Neurological Injury
Perhaps no complication is more perplexing or distressing than persistent neurological deficits following an apparently routine neuraxial block. An epidural hematoma or abscess must be ruled out. Either nerve roots or spinal cord may be injured. The latter may be avoided if the neuraxial blockade is performed below the termination of the conus (L1 in adults and L3 in children). Postoperative peripheral neuropathies can be due to direct physical trauma to nerve roots. Although most resolve spontaneously, some are permanent. Any sustained paresthesia during neuraxial anesthesia/analgesia should alert the clinician to redirect the needle. Injections should be immediately stopped and the needle withdrawn, if injection is associated with pain. Direct injection into the spinal cord can cause paraplegia. Damage to the conus medullaris may cause isolated sacral nerve dysfunction. Not all neurological deficits that are reported after a regional anesthetic are the direct result of the block. Postpartum neurological deficits, including lateral femoral cutaneous neuropathy and foot drop, were recognized as complications before the era of routine epidural anesthesia/analgesia.

H. Spinal or Epidural Hematoma
Needle or catheter trauma to epidural veins often causes minor bleeding in the
spinal canal, although this usually has no consequences. The incidence of spinal hematomas has been estimated to be about 1:150,000 for epidural blocks and 1:220,000 for spinal anesthetics. The vast majority of reported cases have occurred in patients with abnormal coagulation secondary to either disease or drugs. Some hematomas have occurred immediately following removal of an epidural catheter. Thus, both insertion and removal of an epidural catheter can lead to epidural hematoma formation.

Diagnosis and treatment must be prompt, if permanent neurological sequelae secondary to neuronal ischemia are to be avoided. The onset of symptoms is typically more sudden than with epidural abscess. **Symptoms include sharp back and leg pain with a motor weakness or sphincter dysfunction, or both.** When hematoma is suspected, imaging (magnetic resonance [MR] or computed tomography [CT]) and neurosurgical consultation must be obtained immediately. In many cases, good neurological recovery has occurred in patients who have undergone prompt surgical decompression.

Neuraxial anesthesia should be avoided in patients with coagulopathy, significant thrombocytopenia, platelet dysfunction, or those who have received fibrinolytic or thrombolytic therapy. Practice guidelines should be reviewed when considering neuraxial anesthesia in such patients, and the risk versus benefit of these techniques should be weighed and delineated in the informed consent process.

I. Meningitis and Arachnoiditis

Infection of the subarachnoid space can follow neuraxial blocks as the result of contamination of the equipment or injected solutions, or as a result of organisms tracked in from the skin. Indwelling catheters may become colonized with skin organisms.

Strict sterile technique should be employed. Careful attention is particularly warranted in the labor room, where family members are often curious to see what is being done to mitigate the parturient’s pain. If hospital policy permits their presence during epidural placement, such individuals should be advised to avoid contaminating the tray. Family members should also wear a mask to prevent contamination of the epidural tray with oral flora.

J. Epidural Abscess

Spinal epidural abscess (EA) is a rare but potentially devastating complication of neuraxial anesthesia. The reported incidence varies widely, from 1:6500 to 1:500,000 epidurals. Most reported anesthesia-related cases involve epidural
catheters. In one reported series, there was a mean of 5 days from catheter insertion to the development of symptoms, although presentation can be delayed for weeks.

There are four classic clinical stages of EA, although progression and time course can vary. Initially, symptoms include back pain that is intensified by percussion over the spine. Second, nerve root or radicular pain develops. The third stage is marked by motor or sensory deficits, or sphincter dysfunction. Paraplegia or paralysis marks the fourth stage. Ideally, the diagnosis is made in the early stages. Prognosis has consistently been shown to correlate to the degree of neurological dysfunction at the time the diagnosis is made. Back pain and fever after epidural anesthesia should alert the clinician to consider EA. Radicular pain or neurological deficit heightens the urgency to investigate. Once EA is suspected, the catheter should be removed (if still present) and the tip cultured. The injection site is examined for evidence of infection; if pus is expressed, it is sent for culture. Blood cultures should be obtained. If suspicion is high and cultures have been obtained, anti-\textit{Staphylococcus} coverage can be instituted, as the most common organisms causing EA are \textit{Staphylococcus aureus} and \textit{Staphylococcus epidermidis}. MR or CT imaging should be performed to confirm or rule out the diagnosis. We recommend prompt consultation with specialists in neurosurgical and infectious disease. In addition to antibiotics, treatment of EA usually involves decompression (laminectomy), although percutaneous drainage with fluoroscopic or CT guidance has been used. Suggested strategies for guarding against the occurrence of EA include (1) minimizing catheter manipulations and maintaining a closed system when possible; (2) using a micropore (0.22-μm) bacterial filter; and (3) removing an epidural catheter or at least changing the catheter, filter, and solution after a defined time interval (eg, some clinicians replace or remove all epidurals after 4 days).

\textbf{K. Sheering of an Epidural Catheter}

There is a risk of neuraxial catheters sheering and breaking off inside of tissues if they are withdrawn through the needle. If a catheter must be withdrawn while the needle remains in situ, both must be carefully withdrawn \textit{together}. If a catheter breaks off within the epidural space, many experts suggest leaving it and observing the patient. If, however, the breakage occurs in superficial tissues, the catheter should be surgically removed.

\textbf{Complications Associated with Drug Toxicity}
A. Local Anesthetic Systemic Toxicity
Absorption of excessive amounts of local anesthetics can produce toxic blood levels (see “Intravascular Injection”). Excessive absorption from epidural or caudal blocks is rare when appropriate doses of local anesthetic are used.

B. Transient Neurological Symptoms
First described in 1993, transient neurological symptoms (TNS), also referred to as transient radicular irritation, are characterized by back pain radiating to the legs without sensory or motor deficits, occurring after the resolution of spinal anesthesia and resolving spontaneously within several days. It is most commonly associated with hyperbaric lidocaine (incidence up to 12%), but has also been reported with tetracaine (2%), bupivacaine (1%), mepivacaine, prilocaine, procaine, and subarachnoid ropivacaine. There are also case reports of TNS following epidural anesthesia. The incidence of this syndrome is greatest among outpatients, particularly males undergoing surgery in the lithotomy position, and least among inpatients undergoing surgery in positions other than lithotomy. The pathogenesis of TNS is believed to represent concentration-dependent neurotoxicity of local anesthetics.

CASE DISCUSSION

Neuraxial Anesthesia for Cystoscopy & Ureteral Stent Placement
A 56-year-old man presents for cystoscopy and stent placement for a large kidney stone. The patient has a long history of spinal problems and has undergone fusion of the cervical spine (C3–C6) and laminectomy with fusion of the lower lumbar spine (L3–L5). On examination, he has no neck flexion or extension and has a Mallampati class IV airway.

What types of anesthesia are appropriate for this patient?
Cystoscopy and stent placement usually require general or neuraxial anesthesia. Selection of the type of anesthesia, as always, should be based on patient preference after informed consent. This patient presents potential difficulties for both general and regional anesthesia. The limited excursion
of the cervical spine, together with the anatomy of a class IV airway, makes difficulty in intubation and possibly ventilation almost certain. Induction of general anesthesia would be safest after the airway is secured with an awake fiberoptic intubation.

Regional anesthesia also presents a problem in that the patient has had previous back surgery in the lumbar area, where neuraxial anesthesia is most commonly performed. Postoperative distortion of the anatomy makes the block technically challenging and may increase the likelihood of a failure, inadvertent dural puncture during epidural anesthesia, paresthesias, and unpredictable spread of the local anesthetics.

If the patient chooses to have neuraxial anesthesia, would spinal or epidural anesthesia be more appropriate?

The associated sympathectomy and subsequent drop in blood pressure are more gradual after epidural anesthesia than that following spinal anesthesia. With either type of anesthesia, significant hypotension should be treated with vasoconstrictors and fluids, and bradycardia should be treated with anticholinergics.

After an explanation of the options, the patient seems to understand the risks of both types of anesthesia and desires epidural anesthesia. Placement of an epidural catheter is attempted at the L1–L2 interspace, but accidental dural puncture occurs. What options are now available?

Options include injecting a spinal dose of local anesthetic through the epidural needle to induce spinal anesthesia, passing an epidural catheter into the subarachnoid space to perform a continuous spinal anesthetic, or proceeding with an awake fiberoptic intubation in advance of general anesthesia. If a spinal dose of local anesthetic is to be injected, the syringe and needle should be kept in place for a few moments to prevent significant back leakage of anesthetic through the large dural hole. Threading an epidural catheter through the needle into the subarachnoid space allows subsequent redosing and may reduce the incidence of dural puncture headache. When a catheter is advanced in the subarachnoid space well below L2, it should not be advanced more than 2 to 3 cm to avoid injury to the cauda equina.

How might a dural puncture affect subsequent epidural or
spinal anesthesia?

A potential hazard of epidural anesthesia at a level adjacent to a large dural puncture is the possibility that some local anesthetic might pass through the dural puncture into the subarachnoid space. This could result in a higher than expected level of sensory and motor blockade.

GUIDELINES

SUGGESTED READINGS

Peripheral Nerve Blocks

Sarah J. Madison, MD and Brian M. Ilfeld, MD, MS (Clinical Investigation)

KEY CONCEPTS

1. In addition to potent analgesia, regional anesthesia may lead to reductions in the stress response, systemic analgesic requirements, opioid-related side effects, general anesthesia requirements, and, possibly, the development of chronic postoperative pain.

2. Regional anesthetics must be administered in an area where standard anesthetic monitors, supplemental oxygen, and resuscitative medications and equipment are immediately available.

3. Local anesthetic may be deposited at any point along the brachial plexus, depending on the desired block effects: interscalene for shoulder and proximal humerus surgical procedures; and supraclavicular, infraclavicular, and axillary for surgeries distal to the mid-humerus.

4. A properly performed interscalene block almost invariably blocks the ipsilateral phrenic nerve, so careful consideration must be given to patients with severe pulmonary disease or preexisting contralateral phrenic nerve palsy.

5. Brachial plexus block at the level of the cords provides excellent anesthesia for procedures at or distal to the elbow. The upper arm and shoulder are not anesthetized with this approach. As with other brachial plexus blocks, the intercostobrachial nerve (T2 dermatome) is spared.

6. The axillary, musculocutaneous, and medial brachial cutaneous nerves branch from the brachial plexus proximal to where local anesthetic is deposited for an axillary brachial plexus block, and thus are usually spared.

7. Often it is necessary to anesthetize a single terminal nerve, either for
minor surgical procedures with a limited field or as a supplement to an incomplete brachial plexus block. Terminal nerves may be anesthetized anywhere along their course, but the elbow and the wrist are the two most favored sites.

Intravenous regional anesthesia, also called a Bier block, can provide intense surgical anesthesia for relatively short (45–60 min) surgical procedures on an extremity.

A femoral nerve block alone will seldom provide adequate surgical anesthesia, but it is often used to provide postoperative analgesia for hip, thigh, knee, and ankle procedures.

*Posterior lumbar plexus blocks* are useful for surgical procedures involving areas innervated by the femoral, lateral femoral cutaneous, and obturator nerves. Complete anesthesia of the knee can be attained with a proximal sciatic nerve block.

Blockade of the sciatic nerve may occur anywhere along its course and is indicated for surgical procedures involving the hip, thigh, knee, lower leg, and foot.

Popliteal nerve blocks provide excellent coverage for foot and ankle surgery, while sparing much of the hamstring muscles, allowing lifting of the foot with knee flexion, thus facilitating ambulation. All sciatic nerve blocks fail to provide complete anesthesia for the cutaneous medial leg and ankle joint capsule, but when a saphenous (or femoral) block is added, complete anesthesia below the knee is provided.

A complete ankle block requires a series of five nerve blocks, but the process may be streamlined to minimize needle insertions. All five injections are required to anesthetize the entire foot; however, surgical procedures rarely require that all terminal nerves be blocked.

Intercostal blocks result in the highest blood levels of local anesthetic per local anesthetic dose injected of any nerve block procedure, and if multiple blocks will be performed care must be taken to avoid toxic levels of local anesthetic.

The thoracic paravertebral space is defined posteriorly by the superior costotransverse ligament, anterolaterally by the parietal pleura, medially by the vertebrae and the intervertebral foramina, and inferiorly and superiorly by the heads of the ribs.

The subcostal (T12), ilioinguinal (L1), and iliohypogastric (L1) nerves are targeted in the transversus abdominus plane (TAP) block, providing anesthesia to the ipsilateral lower abdomen below the umbilicus.
An understanding of regional anesthesia anatomy and techniques is required of the well-rounded anesthesiologist. Although anatomic relationships have not changed over time, our ability to identify them has improved. From the paresthesia-seeking techniques described by Winnie, to the popularization of the nerve stimulator, to the introduction of ultrasound guidance, anesthesiologists and their patients have benefitted from evolving and improving techniques. The field of regional anesthesia has accordingly expanded to one that addresses not only the intraoperative concerns of the anesthesiologist, but also longer term perioperative pain management and acceleration of convalescence. In addition to potent analgesia, regional anesthesia may lead to reductions in the stress response, systemic analgesic requirements, opioid-related side effects, general anesthesia requirements, and, possibly, the development of chronic postoperative pain.

PATIENT SELECTION

The selection of a regional anesthetic technique is a process that begins with a thorough history and physical examination. As with any medical procedure a risk–benefit analysis must be performed. The risk–benefit ratio often favors regional anesthesia in patients with multiple comorbidities for whom a general anesthetic carries a greater risk. In addition, patients intolerant of opioids (eg, those with obstructive sleep apnea or at high risk for nausea) may benefit from the opioid-sparing effects of a regional analgesic. Patients with chronic pain and opioid tolerance may receive optimal analgesia with a continuous peripheral nerve block (perineural local anesthetic infusion).

A comprehensive knowledge of regional anatomy and an understanding of the planned surgical procedure are important for selection of the appropriate regional anesthetic technique. If possible, review of various considerations (tourniquet placement, bone grafting, projected surgical duration) should be undertaken with the surgeon. Also, knowing the anticipated course of recovery and anticipated level of postoperative pain will often influence specific decisions regarding a regional anesthetic technique (eg, a single injection versus continuous peripheral nerve block).

RISKS & CONTRAINDICATIONS

Patient cooperation is key to the success and safety of every regional anesthetic
procedure; patients who cannot remain still for a procedure may be at increased risk. Examples include younger pediatric patients and some developmentally delayed individuals, as well as patients with dementia or movement disorders. Bleeding disorders and pharmacological anticoagulation heighten the risk of local hematoma or hemorrhage, and this risk must be balanced against the possible benefits of regional blockade. Specific peripheral nerve block locations warranting the most concern are posterior lumbar plexus and paravertebral blocks owing to their relative proximity to the retroperitoneal space and neuraxis, respectively.

Placement of a block needle through a site of infection can theoretically track infectious material into the body, where it poses a risk to the target nerve tissue and surrounding structures. Therefore, the presence of a local infection is a relative contraindication to performing a peripheral nerve block. Indwelling perineural catheters can serve as a nidus of infection; however, the risk in patients with systemic infection remains unknown.

Although nerve injury is always a possibility with a regional anesthetic, some patients are at increased risk. Individuals with a preexisting condition (eg, peripheral neuropathy or previous nerve injury) may have a higher incidence of complications, including prolonged or permanent sensorimotor block. The precise mechanisms have yet to be clearly defined but may involve local ischemia from high injection pressure or vasoconstrictors, neurotoxic effect of local anesthetics, or direct trauma to nerve tissue.

Other risks associated with regional anesthesia include systemic local anesthetic toxicity from intravascular injection or perivascular absorption. In the event of a systemic local anesthetic toxic reaction, seizure activity and cardiovascular collapse may occur. Supportive measures should begin immediately. In the case of cardiovascular collapse, one should call for assistance (perhaps by a “code blue”), initiate cardiopulmonary resuscitation, administer incremental doses of epinephrine, infuse intravenous lipid emulsion, and, if all else fails, prepare for cardiopulmonary bypass.

Site-specific risks should also be considered for each individual patient. In a patient with severe pulmonary compromise or hemidiaphragmatic paralysis, for example, a contralateral interscalene or deep cervical plexus block with resultant phrenic nerve block could be catastrophic.

**CHOICE OF LOCAL ANESTHETIC**

The decision about which local anesthetic to employ for a particular nerve block
depends on the desired onset, duration, and relative blockade of sensory and motor fibers. Potential for systemic toxicity should be considered, as well as site-specific risks. A detailed discussion of local anesthetics is provided elsewhere (see Chapter 16).

**PREPARATION**

Regional anesthetics must be administered in an area where standard anesthetic monitors, supplemental oxygen, and resuscitative medications and equipment are immediately available. Patients should be monitored with pulse oximetry, noninvasive blood pressure, and electrocardiography; measurement of end-tidal CO₂ and fraction of inspired oxygen (FiO₂) should also be available. Positioning should be ergonomically favorable for the practitioner and comfortable for the patient. Intravenous premedication may be employed to allay anxiety and minimize discomfort. A relatively short-acting benzodiazepine and opioid are most often used and should be titrated for comfort while ensuring that patients can respond to verbal cues. Sterile technique should be strictly observed.

**BLOCK TECHNIQUES**

**Field Block Technique**

A field block is a local anesthetic injection that targets terminal cutaneous nerves (Figure 46–1). Field blocks are used commonly by surgeons to minimize incisional pain and may be used as a supplementary technique or as a sole anesthetic for minor, superficial procedures. Anesthesiologists often use field blocks to anesthetize the superficial cervical plexus for procedures involving the neck or shoulder; the intercostobrachial nerve for surgery involving the medial upper extremity proximal to the elbow (in combination with a brachial plexus nerve block); and the saphenous nerve for surgery involving the medial leg or ankle joint (in combination with a sciatic nerve block). Field blocks may be undesirable in cases where they obscure or distort the operative anatomy or where local tissue acidosis from infection prevents effective local anesthetic function.
FIGURE 46–1 A field block targets terminal cutaneous nerves, such as the intercostobrachial nerve.

**Paresthesia Technique**

Formerly the mainstay of regional anesthesia, this technique is now rarely used for nerve localization. Using known anatomic relationships and surface landmarks as a guide, a block needle is advanced toward the target nerve or plexus. When a needle makes direct contact with a sensory nerve, a paresthesia (abnormal sensation) is elicited in its area of sensory distribution.

**Nerve Stimulation Technique**

For this technique, an insulated needle concentrates electrical current at the needle tip, while a wire attached to the needle hub connects to a nerve stimulator—a battery-powered machine that emits a small amount (0–5 mA) of electric current at a set frequency (usually 1 or 2 Hz). A grounding electrode is attached to the patient to complete the circuit (Figure 46–2). When the insulated needle tip is placed in proximity to a motor nerve, specific muscle contractions are induced, and local anesthetic is injected. Although it is common to redirect the
block needle until muscle contractions occur at a current less than 0.5 mA, there is scant evidence to support this specific current in all cases. Similarly, although some have suggested that muscle contraction with current less than 0.2 mA implies intraneural needle placement, there is little evidence to support this specific cutoff. Nonetheless, most practitioners inject local anesthetic when current between 0.2 and 0.5 mA results in a muscle response. For most blocks using this technique in adults, 30 to 40 mL of anesthetic is usually injected with gentle aspiration between divided doses.

**FIGURE 46–2** A nerve stimulator delivers a small amount of electrical current to the block needle to facilitate nerve localization.

**Ultrasound Technique**

Ultrasound for peripheral nerve localization is becoming increasingly popular, and it may be used either alone or combined with other modalities such as nerve stimulation. Ultrasound uses high-frequency (1–20 MHz) sound waves emitted from piezoelectric crystals that travel at different rates through tissues of different densities, returning a signal to the transducer. Depending on the amplitude of signal received, the crystals deform to create an electronic voltage that is converted into a two-dimensional grayscale image. The degree of efficiency with which sound passes through a substance determines its echogenicity. Structures and substances through which sound passes easily are described as *hypoechoic* and appear dark or black on the ultrasound screen. In contrast, structures reflecting more sound waves appear brighter—or white—on the ultrasound screen, and are termed *hyperechoic*. 
The optimal transducer varies depending upon the depth of the target nerve and approach angle of the needle relative to the transducer (Figure 46–3). High-frequency transducers provide a high-resolution picture with a relatively clear image but offer poor tissue penetration and are therefore used predominantly for more superficial nerves. Low-frequency transducers provide an image of poorer quality but have better tissue penetration and are therefore used for deeper structures. Transducers with a linear array offer an undistorted image and are therefore often the first choice among practitioners. However, for deeper target nerves that require a more acute angle between the needle and long-axis of the transducer, a curved array (curvilinear) transducer will maximize returning ultrasound waves, providing the optimal needle image (Figure 46–3). Nerves are best imaged in cross-section, where they have a characteristic honeycomb appearance (short-axis). Needle insertion can pass either parallel (in-plane) or not parallel (out-of-plane) to the plane of the ultrasound waves (Figure 46–4). Unlike nerve stimulation alone, ultrasound guidance allows for a variable volume of local anesthetic to be injected, with the final amount determined by what is observed under direct ultrasound vision. This technique usually results in a far smaller injected volume (10–30 mL) of local anesthetic.

**FIGURE 46–3** A linear probe offers higher resolution with less penetration. A curvilinear probe provides better penetration with lower resolution.
Continuous Peripheral Nerve Blocks

Also termed *perineural local anesthetic infusion*, continuous peripheral nerve blocks involve the placement of a percutaneous catheter adjacent to a peripheral nerve, followed by local anesthetic administration to prolong a nerve block (Figure 46–5). Potential advantages appear to depend on successfully improving analgesia and include reductions in resting and dynamic pain, supplemental analgesic requirements, opioid-related side effects, and sleep disturbance. In some cases, patient satisfaction, ambulation, and functioning may be improved, accelerated resumption of passive joint range-of-motion realized, and reduced time until discharge-readiness as well as actual discharge from the hospital or rehabilitation center achieved. Recent evidence suggests that continuous sciatic, femoral, and paravertebral perineural local anesthetic infusions in the immediate postoperative period may decrease the risk of persistent (“chronic”) postsurgical pain.
There are many types of perineural catheters, including nonstimulating and stimulating, flexible and relatively rigid, through-the-needle and over-the-needle. Currently, there is little evidence that a single design results in superior effects. Long-acting local anesthetics (eg, ropivacaine) are more commonly used, as they provide a more favorable sensory-to-motor block ratio (maximizing analgesia while minimizing motor block). In an attempt to further minimize any induced motor block, dilute local anesthetic (0.1–0.2%) is often infused; however, recent evidence suggests that it is the total mass of drug, and not concentration alone, that determines the majority of block effects. Unlike single-injection peripheral nerve blocks, no adjuvant added to a perineural local anesthetic infusion has been demonstrated to be of benefit. The local anesthetic may be administered exclusively as repeated bolus doses or a basal infusion, or as a combination of the two methods. Using a small, portable infusion pump (Figure 46–6), continuous peripheral nerve blocks may be provided on an ambulatory basis.
As with all medical procedures, there are potential risks associated with continuous peripheral nerve blocks. Therefore, these infusions are usually reserved for patients having procedures expected to result in postoperative pain that is difficult to control with oral analgesics and will not resolve in less time than the duration of a single-injection peripheral nerve block. Serious complications, which are relatively rare, include systemic local anesthetic toxicity, catheter retention, nerve injury, infection, and retroperitoneal hematoma formation. In addition, a perineural infusion affecting the femoral nerve increases the risk of falling, although to what degree and by what specific mechanism (eg, sensory, motor, or proprioception deficits) remain unknown.

**UPPER EXTREMITY PERIPHERAL NERVE BLOCKS**

**Brachial Plexus Anatomy**

The brachial plexus is formed by the union of the anterior primary divisions (ventral rami) of the fifth through the eighth cervical nerves and the first thoracic nerve. Contributions from C4 and T2 are often minor or absent. As the
nerve roots leave the intervertebral foramina, they converge, successively forming trunks, divisions, cords, branches, and then finally terminal nerves. The three distinct trunks formed between the anterior and middle scalene muscles are termed superior, middle, and inferior based on their vertical orientation. As the trunks pass over the lateral border of the first rib and under the clavicle, each trunk divides into anterior and posterior divisions. As the brachial plexus emerges below the clavicle, the fibers combine again to form three cords that are named according to their relationship to the axillary artery: lateral, medial, and posterior. At the lateral border of the pectoralis minor muscle, each cord gives off a large branch before ending as a major terminal nerve. The lateral cord gives off the lateral branch of the median nerve and terminates as the musculocutaneous nerve; the medial cord gives off the medial branch of the median nerve and terminates as the ulnar nerve; and the posterior cord gives off the axillary nerve and terminates as the radial nerve. Local anesthetic may be deposited at any point along the brachial plexus, depending on the desired block effects (Figure 46–7): interscalene for shoulder and proximal humerus surgical procedures; and supravacicular, infraclavicular, and axillary for surgeries distal to the mid-humerus.

**FIGURE 46–7** The location of local anesthetic deposition along the brachial
plexus depends on the desired effects of the block.

**Interscalene Block**

An interscalene brachial plexus block is indicated for procedures involving the shoulder and upper arm (Figure 46–8). Roots C5–7 are most densely blocked with this approach; and the ulnar nerve originating from C8 and T1 may be spared. Therefore, interscalene blocks are not ideal for surgery at or distal to the elbow. For complete surgical anesthesia of the shoulder, the C3 and C4 cutaneous branches may need to be supplemented with a superficial cervical plexus block or local infiltration.
An interscalene block is appropriate for shoulder and proximal humerus procedures. The ventral rami of C5–C8 and T1 form the brachial plexus.

Contraindications to an interscalene block include local infection, severe coagulopathy, local anesthetic allergy, and patient refusal. A properly performed interscalene block almost invariably blocks the ipsilateral phrenic nerve (completely for nerve stimulation techniques, but less so with certain low-volume ultrasound techniques), so careful consideration must be given to patients with severe pulmonary disease or preexisting contralateral phrenic nerve...
palsy. The hemidiaphragmatic paresis may result in dyspnea, hypercapnia, and hypoxemia. A Horner syndrome (myosis, ptosis, and anhidrosis) frequently results from proximal tracking of local anesthetic and blockade of sympathetic fibers to the cervicothoracic ganglion. Recurrent laryngeal nerve involvement often induces hoarseness. In a patient with contralateral vocal cord paralysis, respiratory distress may ensue. Other site-specific risks include vertebral artery injection (suspect if immediate seizure activity is observed), spinal or epidural injection, and pneumothorax. As little as 1 mL of local anesthetic delivered into the vertebral artery may induce a seizure. Similarly, intrathecal, subdural, and epidural local anesthetic spread is possible. Lastly, pneumothorax is possible due to the close proximity of the apical pleura.

The brachial plexus passes between the anterior and middle scalene muscles at the level of the cricoid cartilage, or C6 (Figure 46–9). Palpation of the interscalene groove is usually accomplished with the patient supine and the head rotated 30° or less to the contralateral side. The external jugular vein often crosses the interscalene groove at the level of the cricoid cartilage. The interscalene groove should not be confused with the groove between the sternocleidomastoid and the anterior scalene muscle, which lies further anterior. Having the patient lift and turn the head against resistance often helps delineate the anatomy. If surgical anesthesia is desired for the entire shoulder, the intercostobrachial nerve must usually be targeted separately with a field block since it originates from T2 and is not affected with an interscalene block. Interscalene perineural infusions provide potent analgesia following shoulder surgery.
FIGURE 46–9  The brachial plexus passes between the anterior and middle scalene muscles at the level of the cricoid cartilage, or C6.

A. Nerve Stimulation
A relatively short (5-cm) insulated needle is usually employed. The interscalene groove is palpated using the nondominant hand, pressing firmly to stabilize the skin against the underlying structures (Figure 46–10). After the skin is anesthetized, the block needle is inserted at a slightly medial and caudad angle and advanced to optimally elicit a motor response of the deltoid or biceps muscles (suggesting stimulation of the superior trunk). A motor response of the diaphragm indicates that the needle is placed in too anterior a direction; a motor response of the trapezius or serratus anterior muscles indicates that the needle is placed in too posterior a direction. If bone (transverse process) is contacted, the needle should be redirected more anteriorly. Aspiration of arterial blood should raise concern for vertebral or carotid artery puncture; the needle should be withdrawn, pressure held for 3 to 5 min, and landmarks reassessed.
B. Ultrasound

A needle in-plane or out-of-plane technique may be used, and an insulated needle attached to a nerve stimulator can be used to confirm the accuracy of the targeted structure. For both techniques, after identification of the sternocleidomastoid muscle and interscalene groove at the approximate level of C6, a high-frequency linear transducer is placed perpendicular to the course of the interscalene muscles (short axis; Figure 46–11). The brachial plexus and anterior and middle scalene muscles should be visualized in cross-section (Figure 46–12). The brachial plexus at this level appears as three to five hypoechoic circles. The carotid artery and internal jugular vein may be seen lying anterior to the anterior scalene muscle; the sternocleidomastoid is visible superficially as it tapers to form its lateral edge.
For an out-of-plane technique, the block needle is inserted just cephalad to the
transducer and advanced in a caudal direction toward the visualized plexus. After careful aspiration for nonappearance of blood, local anesthetic (hypoechoic) spread should be noted adjacent to, and usually surrounding, the plexus.

For an in-plane technique, the needle is inserted just posterior to the ultrasound transducer in a direction exactly parallel to the ultrasound beam. A longer block needle (8 cm) is usually necessary. It may be helpful to have the patient turn slightly laterally with the affected side up to facilitate manipulation of the needle. The needle is advanced through the middle scalene muscle until it has passed through the fascia anteriorly into the interscalene groove. The needle tip and shaft should be visualized during the entire block performance. Depending on visualized spread relative to the target nerve(s), a lower volume (10 mL) may be employed for postoperative analgesia, whereas a larger volume (20–30 mL) is commonly used for surgical anesthesia.

**Supraclavicular Block**

Once described as the “spinal of the arm” due to its relatively rapid onset and reliability, a supraclavicular block offers dense anesthesia of the brachial plexus for surgical procedures at or distal to the elbow (Figure 46–13). Historically, the supraclavicular block fell out of favor due to the relatively increased incidence of complications (namely, pneumothorax) that occurred with paresthesia and nerve stimulator techniques. It has seen a resurgence in recent years with the use of ultrasound guidance. The supraclavicular block does not reliably anesthetize the axillary and suprascapular nerves, and thus is not ideal for shoulder surgery. Sparing of distal branches, particularly the ulnar nerve, may occur. Supraclavicular perineural catheters provide inferior analgesia compared with infraclavicular perineural catheter infusion and are more often displaced with movement.
FIGURE 46–13 A supraclavicular block can provide dense anesthesia for procedures at or distal to the elbow. Light blue shading indicates regions of variable blockade; purple shading indicates regions of more reliable blockade.

Many of the same precautions that are taken with patient selection for an interscalene block should be exercised with a supraclavicular block. Nearly half of patients undergoing supraclavicular block will experience ipsilateral phrenic nerve palsy, although ultrasound guidance may decrease this incidence by allowing use of minimal local anesthetic volume. Horner syndrome and recurrent laryngeal nerve palsy may also occur. Risks of pneumothorax and
subclavian artery puncture remain, although they are theoretically less likely with ultrasound guidance.

**Ultrasound**

The patient should lie supine with the head turned 30° toward the contralateral side. A linear, high-frequency transducer is placed in the supraclavicular fossa superior to the clavicle and angled slightly toward the thorax (Figure 46–14). The subclavian artery should be easily identified. The brachial plexus appears as multiple hypoechoic disks just superficial and lateral to the subclavian artery (Figure 46–15). The first rib should also be identified as a hyperechoic line just deep to the artery. Pleura may be identified adjacent to the rib and can be distinguished from bone by its movement with breathing.

**FIGURE 46–14** Ultrasound probe placement for supraclavicular block (in-plane technique).
Supraclavicular block. Ultrasound image of the brachial plexus in the supraclavicular fossa. SA, subclavian artery; R, rib; N, brachial plexus in cross-section.

For an out-of-plane technique, a short, 22-gauge blunt-tipped needle is used. The skin is anesthetized, and the needle inserted just cephalad to the ultrasound transducer in a posterior and caudad direction. After careful aspiration for the nonappearance of blood, 30 to 40 mL of local anesthetic is injected in 5-mL increments while visualizing local anesthetic spread around the brachial plexus.

For an in-plane technique, a longer needle may be necessary. The needle is inserted lateral to the transducer in a direction parallel to the ultrasound beam. The needle is advanced medially toward the subclavian artery until the tip is visualized near the brachial plexus just lateral and superficial to the artery. Local anesthetic spread should be visualized surrounding the plexus after careful aspiration and incremental injection, which often requires injections in multiple locations with a highly variable volume (20–30 mL).

Infraclavicular Block

Brachial plexus block at the level of the cords provides excellent anesthesia for procedures at or distal to the elbow (Figure 46–16). The upper arm and shoulder are not anesthetized with this approach. As with other brachial plexus blocks, the intercostobrachial nerve (T2 dermatome) is spared. Site-specific risks of the infraclavicular approach include vascular puncture and pneumothorax, although less common than with supraclavicular block. It is often prudent to use
an alternative approach for patients with an indwelling vascular catheter in the subclavian region, or for patients with an ipsilateral transvenous pacemaker.

![Image](image_url)

**FIGURE 46–16** Infraclavicular block coverage and anatomy. Light blue shading indicates regions of variable blockade; purple shading indicates regions of more reliable blockade.

As the brachial plexus traverses beyond the first rib and into the axilla, the cords are arranged around the axillary artery according to their anatomic position: *medial, lateral, and posterior*.
A. Nerve Stimulation
The patient is positioned supine with the head turned to the contralateral side, and the coracoid process is identified (a bony prominence of the scapula that can be palpated between the acromioclavicular joint and the deltopectoral groove). The subclavian artery and brachial plexus run deep to the coracoid process and can be found approximately 2 cm medial and 2 cm caudal to it, about 4 to 5 cm deep in the average patient (Figure 46–17). A relatively long (8-cm) insulated needle is placed perpendicular to the skin and advanced directly posterior until a motor response is elicited. An acceptable motor response is finger flexion or extension at a current less than 0.5 mA, but not elbow flexion/extension.

FIGURE 46–17 Infraclavicular block using nerve stimulation: coracoid technique.

B. Ultrasound
With the patient in the supine position, a small curvilinear transducer is placed in the parasagittal plane over the point 2 cm medial and 2 cm caudal to the coracoid process (Figure 46–18A). (Abducting the arm 90° improves axillary artery imaging.) A high-frequency linear transducer may be used but will often provide inadequate needle visualization due to the relatively acute needle-to-transducer angle. The axillary artery and vein are identified in cross-section (Figure 46–18B). The medial, lateral, and posterior cords appear as hyperechoic bundles positioned caudal, cephalad, and posterior to the artery, respectively. A long (10-cm) needle is inserted 2 to 3 cm cephalad to the transducer. Optimal needle positioning is between the axillary artery and the posterior cord, where a single 30-mL injection is as effective as individual cord injections. Insertion of a perineural catheter should be in the same location posterior to the axillary artery.
Infraclavicular perineural infusion has been shown to provide superior analgesia to both supraclavicular and axillary infusions.
FIGURE 46–18 Infraclavicular block. A: Use a small curvilinear probe in a parasagittal plane to visualize the brachial plexus. B: Ultrasound image of the brachial plexus surrounding the axillary artery. AA, axillary artery; N, medial, lateral, and posterior cords of the brachial plexus; AV, axillary vein; PMa, pectoralis major muscle; PMi, pectoralis minor muscle. The red dot indicates the location of local anesthetic deposition.

### Axillary Block

At the lateral border of the pectoralis minor muscle, the cords of the brachial plexus form large terminal branches. The axillary, musculocutaneous, and medial brachial cutaneous nerves branch from the brachial plexus proximal to where local anesthetic is deposited for an axillary brachial plexus block, and thus are usually spared (Figure 46–19). At this level, the major terminal nerves often are separated by fascia; therefore, multiple injections (10-mL each) may be required to reliably produce anesthesia of the entire arm distal to the elbow (Figure 46–20).
FIGURE 46–19 Axillary block. The axillary, musculocutaneous, and medial brachial cutaneous nerves are usually spared with an axillary approach.

FIGURE 46–20 A: Patient positioning and needle angle for axillary brachial plexus block. B: A multiple injection technique is more effective because of fascial separation between nerves.

There are few contraindications to axillary brachial plexus blocks. Local infection, neuropathy, and bleeding risk must be considered. Because the axilla is highly vascularized, there is a risk of local anesthetic uptake through small
veins traumatized by needle placement. The axilla is also a suboptimal site for perineural catheter placement because of greatly inferior analgesia versus an infraclavicular infusion, as well as theoretically increased risks of infection and catheter dislodgement.

All of the numerous axillary block techniques require the patient to be positioned supine, with the arm abducted 90° and the head turned toward the contralateral side (Figure 46–20). The axillary artery pulse should be palpated and its location marked as a reference point.

A. Transarterial Technique

This technique has fallen out of favor due to the trauma of twice purposefully penetrating the axillary artery along with a theoretically increased risk of inadvertent intravascular local anesthetic injection. The nondominant hand is used to palpate and immobilize the axillary artery, and a 22-gauge needle is inserted high in the axilla (Figure 46–20) until bright red blood is aspirated. The needle is then slightly advanced until blood aspiration ceases. Injection can be performed both posterior and anterior to the artery. A total of 30 to 40 mL of local anesthetic is typically used.

B. Nerve Stimulation

The nondominant hand is used to palpate and immobilize the axillary artery. With the patient’s arm abducted and externally rotated, the terminal nerves usually lie in the following positions relative to the artery (Figure 46–21, although variations are common): median nerve superior (wrist flexion, thumb opposition, forearm pronation); ulnar nerve inferior (wrist flexion, thumb adduction, fourth/fifth digit flexion); and radial nerve inferior–posterior (digit/wrist/elbow extension, forearm supination). The musculocutaneous nerve (elbow flexion) is most often separate and deep within the coracobrachialis muscle, which is more superior (lateral) in this position and, as a consequence, is generally not anesthetized unless specifically targeted (Figure 46–21). A 2-in., 22-gauge insulated needle is inserted proximal to the palpating fingers to elicit muscle twitches in the hand. Once an appropriate muscle response is identified, and after reducing the stimulation current to less than 0.5 mA, careful aspiration is performed and local anesthetic is injected. Although a single injection of 40 mL may be used, greater success will be achieved with multiple nerve stimulations (ie, two or three nerves) and divided doses of local anesthetic.
FIGURE 46–21 Positioning of terminal nerves about the axillary artery (variations are common).

C. Ultrasound
Using a high-frequency linear array ultrasound transducer, the axillary artery and vein are visualized in cross-section. The brachial plexus can be identified surrounding the artery (Figure 46–22). The needle is inserted superior (lateral) to the transducer and advanced inferiorly (medially) toward the plexus under direct visualization. Ten milliliters of local anesthetic is then injected around each nerve (including the musculocutaneous nerve, if indicated).

FIGURE 46–22 Ultrasound image of axillary brachial plexus block. AA, Axillary artery; AV, axillary vein; U, ulnar nerve; M, median nerve; MC, musculocutaneous nerve; R, radial nerve; CB, coracobrachialis muscle; TM, triceps muscle; BM, biceps muscle.
Blocks of the Terminal Nerves

Often it is necessary to anesthetize a single terminal nerve, either for minor surgical procedures with a limited field or as a supplement to an incomplete brachial plexus block. Terminal nerves may be anesthetized anywhere along their course, but the elbow and the wrist are the two most favored sites.

A. Median Nerve Block

The median nerve is derived from the lateral and medial cords of the brachial plexus. It enters the arm and runs just medial to the brachial artery (Figure 46–23). As it enters the antecubital space, it lies medial to the brachial artery near the insertion of the biceps tendon. Just distal to this point, it gives off numerous motor branches to the wrist and finger flexors and follows the interosseous membrane to the wrist. At the level of the proximal wrist flexion crease, it lies directly behind the palmaris longus tendon in the carpal tunnel.
To block the median nerve at the elbow, the brachial artery is identified in the antecubital crease just medial to the biceps insertion. A short 22-gauge insulated needle is inserted just medial to the artery and directed toward the medial epicondyle until wrist flexion or thumb opposition is elicited (Figure 46–24); 3 to 5 mL of local anesthetic is then injected. If ultrasound is used, the median nerve may be identified in cross-section just medial to the brachial artery and local anesthetic injected to surround it (Figure 46–25).
FIGURE 46–25 Cross-sectional anatomy of median nerve at the elbow.

To block the median nerve at the wrist, the palmaris longus tendon is first identified by asking the patient to flex the wrist against resistance. A short 22-gauge needle is inserted adjacent to the palmaris longus tendon and advanced about 0.5 cm (a “pop” can usually be felt as the needle traverses the flexor retinaculum), and 3 to 5 mL of local anesthetic is injected (Figure 46–26). With ultrasound, the median nerve may be identified at the level of the mid-forearm between the muscle bellies of the flexor digitorum profundus, flexor digitorum superficialis, and flexor pollicis longus (transducer faces perpendicular to the trajectory of the nerves).
B. Ulnar Nerve Block

The ulnar nerve is the continuation of the medial cord of the brachial plexus and maintains a position medial to the axillary and brachial arteries in the upper arm (Figure 46–27). At the distal third of the humerus, the nerve moves more medially and passes under the arcuate ligament of the medial epicondyle. The nerve is frequently palpable just proximal to the medial epicondyle. In the mid-forearm, the nerve lies between the flexor digitorum profundus and the flexor carpi ulnaris. At the wrist, it is lateral to the flexor carpi ulnaris tendon and medial to the ulnar artery.
FIGURE 46–27 Ulnar nerve course.

To block the ulnar nerve at the level of the elbow, an insulated 22-gauge needle is inserted approximately one fingerbreadth proximal to the arcuate ligament (Figure 46–28), and advanced until fourth/fifth digit flexion or thumb adduction is elicited; 3 to 5 mL of local anesthetic is then injected. To block the ulnar nerve at the wrist, the ulnar artery pulse is palpated just lateral to the flexor carpi ulnaris tendon. The needle is inserted just medial to the artery (Figure 46–
and 3 to 5 mL of local anesthetic is injected. If ultrasound is used, the ulnar nerve may be identified just medial to the ulnar artery.

**FIGURE 46–28** Ulnar nerve block at the elbow with region of anesthesia illustrated on the hand.
C. Radial Nerve Block

The radial nerve—the terminal branch of the posterior cord of the brachial plexus—courses posterior to the humerus, innervating the triceps muscle, and enters the spiral groove of the humerus before it moves laterally at the elbow (Figure 46–30). Terminal sensory branches include the lateral cutaneous nerve of the arm and the posterior cutaneous nerve of the forearm. After exiting the spiral groove as it approaches the lateral epicondyle, the radial nerve separates into superficial and deep branches. The deep branch remains close to the periosteum and innervates the postaxial extensor group of the forearm. The superficial branch becomes superficial and follows the radial artery across the “anatomic snuff box” to innervate the radial aspects of the dorsal wrist and the dorsal aspect of the lateral three digits and half of the fourth.
FIGURE 46–30 Radial nerve course.

To block the radial nerve at the elbow, the biceps tendon is identified in the antecubital fossa. A short 22-gauge insulated needle is inserted just lateral to the tendon and directed toward the lateral epicondyle (Figure 46–31) until wrist or finger extension is elicited; 5 mL of local anesthetic is then injected. With ultrasound, the radial nerve can be identified in cross-section just proximal to the antecubital fossa between the biceps and brachioradialis muscles.
FIGURE 46–31 Radial nerve block at the elbow.

At the wrist, the superficial branch of the radial nerve lies just lateral to the radial artery, which can be easily palpated lateral to the flexor carpi radialis tendon (Figure 46–32). Using a short 22-gauge needle, 3 to 5 mL of local anesthetic is injected lateral to the artery. Ultrasound may be used at the level of the wrist or mid-forearm to identify the radial nerve just lateral to the radial artery. Alternatively, the local anesthetic can be injected as a field block in the dorsal subcutaneous tissue proximal to the base of the thumb and index finger.
D. Musculocutaneous Nerve Block

A musculocutaneous nerve block is essential to complete the anesthesia for the forearm and wrist and is commonly included when performing an axillary brachial plexus block. The musculocutaneous nerve is the terminal branch of the lateral cord and the most proximal of the major nerves to emerge from the brachial plexus (Figure 46–33). This nerve innervates the biceps and brachialis muscles and distally terminates as the lateral antebrachial cutaneous nerve, supplying sensory input to the lateral aspect of the forearm and wrist.
To target the musculocutaneous nerve following an axillary block, the needle is redirected superior and proximal to the artery (see Figure 46–21), the coracobrachialis muscle is pierced, and 5 to 10 mL of local anesthetic is injected after nerve-stimulated elbow flexion. (Alternatively, simple infiltration may be used, although the success rate using this technique is questionable.) Ultrasound may be used to confirm the location of the musculocutaneous nerve in the coracobrachialis muscle or between this muscle and the biceps (see Figure 46–22). Alternatively, the block can be performed at the elbow as the nerve courses superficially at the interepicondylar line. The insertion of the biceps tendon is identified, and a short 22-gauge needle is inserted 1 to 2 cm laterally; 5 to 10 mL of local anesthetic is then injected as a field block.

E. Digital Nerve Blocks

Digital nerve blocks are used for minor operations on the fingers and to supplement incomplete brachial plexus and terminal nerve blocks. Sensory innervation of each finger is provided by four small digital nerves that enter each digit at its base in each of the four corners (Figure 46–34). A small-gauge needle is inserted at the medial and lateral aspects of the base of the selected digit, and 2 to 3 mL of local anesthetic is injected. Addition of a vasoconstrictor (epinephrine) to local anesthetics reduces blood flow to the digit; however, there
are no case reports of necrosis following use of epinephrine with lidocaine or other modern local anesthetics. Nevertheless, it seems prudent to include epinephrine only as a surgical decision to avoid the need for a tourniquet.

**FIGURE 46–34** Sensory innervation of the fingers is provided by the digital nerves.

**F. Intercostobrachial Nerve Block**
The intercostobrachial nerve originates in the upper thorax (T2) and becomes superficial on the medial upper arm. It supplies cutaneous innervation to the medial aspect of the proximal arm and is not anesthetized with a brachial plexus block (**Figure 46–35**). The patient should be supine with the arm abducted and externally rotated. Starting at the deltoid prominence and proceeding inferiorly, a field block is performed in a linear fashion using 5 mL of local anesthetic, extending to the most inferior aspect of the medial arm (**Figure 46–36**).
FIGURE 46–35 Intercostobrachial nerve cutaneous innervation.
Intravenous Regional Anesthesia

Intravenous regional anesthesia, also called a Bier block, can provide surgical anesthesia for relatively short (45–60 min) surgical procedures on an extremity (eg, carpal tunnel release). An intravenous catheter is usually inserted on the dorsum of the hand (or foot) and a double pneumatic tourniquet is placed on the forearm or arm, or below the knee or on the thigh. The extremity is elevated and exsanguinated by tightly wrapping an Esmarch elastic bandage from a distal to proximal direction. The proximal tourniquet is inflated, the Esmarch bandage removed, and 0.5% lidocaine (25 mL for a forearm or ankle, 50 mL for an arm or below the knee, and 100 mL for a thigh tourniquet) injected over 2 to 3 min through the catheter, which is subsequently removed (Figure 46–37). Anesthesia is usually established after 5 to 10 min. Tourniquet pain usually develops after 20 to 30 min, at which time the distal tourniquet is inflated and the proximal tourniquet subsequently deflated. Patients usually tolerate the distal tourniquet for an additional 15 to 20 min because it is inflated over an anesthetized area. Even for surgical procedures of a very short duration, the tourniquet must be left inflated for a total of at least 15 to 20 min to avoid a rapid intravenous bolus of local anesthetic resulting in systemic toxicity. Slow deflation is also recommended to provide an additional margin of safety.

FIGURE 46–36 Intercostobrachial nerve block.

FIGURE 46–37 Intravenous regional anesthesia provides surgical anesthesia for procedures of short duration.

LOWER EXTREMITY PERIPHERAL NERVE
The lumbosacral plexus provides innervation to the lower extremities (Figure 46–38). The lumbar plexus is formed by the ventral rami of L1–4, with occasional contribution from T12. It lies within the psoas muscle with branches descending into the proximal thigh. Three major nerves from the lumbar plexus make contributions to the lower limb: the femoral (L2–4), lateral femoral cutaneous (L1–3), and obturator (L2–4). These provide motor and sensory innervation to the anterior portion of the thigh and sensory innervation to the medial leg. The sacral plexus arises from L4–5 and S1–4. The posterior thigh and most of the leg and foot are supplied by the tibial and peroneal portions of the sciatic nerve. The posterior femoral cutaneous nerve (S1–3), and not the sciatic nerve, provides sensory innervation to the posterior thigh; it travels with the sciatic nerve as it emerges around the piriformis muscle.
FIGURE 46–38 The ventral rami of L1–5 and S1–4 form the lumbosacral plexus, which provides innervation to the lower extremities.

**Femoral Nerve Block**

The femoral nerve innervates the main hip flexors and knee extensors, and provides much of the sensory innervation of the hip and thigh (Figure 46–39). Its most medial branch is the saphenous nerve, which innervates much of the skin of the medial leg and ankle joint. The term 3-in-1 block refers to anesthetizing the femoral, lateral femoral cutaneous, and obturator nerves with a single injection below the inguinal ligament; this term has largely been abandoned as evidence accumulated demonstrating the failure of most single injections to consistently affect all three nerves. A femoral nerve block alone will seldom provide adequate surgical anesthesia, but it is often used to provide postoperative analgesia for hip, thigh, knee, and ankle (via the saphenous nerve)
procedures. Femoral nerve blocks have a relatively low rate of complications and few contraindications. Local infection, previous vascular grafting, and local adenopathy should be carefully considered in patient selection.

**FIGURE 46–39** The femoral nerve provides sensory innervation to the hip and thigh, and to the medial leg via its terminal branch, the saphenous nerve.

**A. Nerve Stimulation**

With the patient positioned supine, the femoral artery pulse is palpated at the level of the inguinal ligament. A short (5-cm) insulated needle is inserted at a 45° angle to the skin in a cephalad direction (**Figure 46–40**) until a distinct quadriceps twitch is elicited with a current less than 0.5 mA (look for patella motion).
FIGURE 46–40 Femoral block using nerve stimulation.

B. Ultrasound
A high-frequency linear ultrasound transducer is placed over the area of the inguinal crease parallel to the crease itself, or slightly more transverse (Figure 46–41). The femoral artery and femoral vein are visualized in cross-section, with the overlying fascia iliaca. Just lateral to the artery and deep to the fascia iliaca, the femoral nerve appears in cross-section as a spindle-shaped structure with a “honeycomb” texture (Figure 46–42).
FIGURE 46–41 Ultrasound-guided femoral nerve block (in-plane technique).
For an out-of-plane technique, the block needle is inserted just lateral to where the femoral nerve is seen, and directed cephalad at an angle approximately 45° to the skin. The needle is advanced until it is seen penetrating the fascia iliaca or (if using concurrent electrical stimulation) until an appropriate motor response is elicited. Following careful aspiration for the nonappearance of blood, 30 to 40 mL of local anesthetic is injected.

For an in-plane technique, a longer needle may be used. The needle is inserted parallel to the ultrasound transducer just lateral to the outer edge. The needle is advanced through the sartorius muscle, deep to the fascia iliaca, until it is visualized just lateral to the femoral nerve. Local anesthetic is injected while observing its hypoechoic spread deep to the fascia iliaca and around the nerve.

C. Fascia Iliaca Technique
The goal of a fascia iliaca block is similar to that of a femoral nerve block, but the approach is slightly different. A relatively reliable level of anesthesia may be attained simply with anatomic landmarks and tactile sensation, although ultrasound may be used to facilitate proper needle placement. Once the inguinal ligament and femoral artery pulse are identified, the length of the inguinal ligament is divided into thirds (Figure 46–43). Two centimeters distal to the junction of the middle and outer thirds, a short, blunt-tipped needle is inserted in a slightly cephalad direction. As the needle passes through the two layers of
fascia in this region (fascia lata and fascia iliaca), two “pops” will be felt. Once the needle has passed through the fascia iliaca, careful aspiration is performed and 30 to 40 mL of local anesthetic is injected. This block usually anesthetizes both the femoral nerve and lateral femoral cutaneous nerves, since the local anesthetic is deposited under the fascia iliaca between the two nerves that run in the same plane between the fascia and underlying muscle.

**FIGURE 46–43** Fascia iliaca block.

**Lateral Femoral Cutaneous Nerve Block**

The *lateral femoral cutaneous nerve* provides sensory innervation to the lateral thigh (see Figure 46–39). It may be anesthetized as a supplement to a femoral nerve block or as an isolated block for limited anesthesia of the lateral thigh. As there are few vital structures in proximity to the lateral femoral cutaneous nerve, complications with this block are exceedingly rare. The lateral femoral
cutaneous nerve (L2–3) departs from the lumbar plexus, traverses laterally from the psoas muscle, and courses anterolaterally along the iliacus muscle (see Figure 46–38). It emerges inferior and medial to the anterior superior iliac spine (ASIS) to supply the cutaneous sensory innervation of the lateral thigh.

The patient is positioned supine or lateral, and the point 2 cm medial and 2 cm distal to the ASIS is identified. A short 22-gauge block needle is inserted and directed laterally, observing for a “pop” as it passes through the fascia lata. A field block is performed with 10 to 15 mL of local anesthetic, which is deposited above and below the fascia (Figure 46–44). Ultrasound may be used to guide needle placement.

**FIGURE 46–44** Lateral femoral cutaneous nerve block.

**Obturator Nerve Block**

A block of the obturator nerve is usually required for complete anesthesia of the knee and is most often performed in combination with femoral and sciatic nerve
blocks for this purpose. The obturator nerve contributes sensory branches to the hip and knee joints, a variable degree of sensation to the medial thigh, and innervates the adductors of the hip (Figure 46–45). This nerve exits the pelvis and enters the medial thigh through the obturator foramen, which lies beneath the superior pubic ramus. After identification of the pubic tubercle, a long (10-cm) block needle is inserted 1.5 cm inferior and 1.5 cm lateral to the tubercle. The needle is advanced posteriorly until bone is contacted (Figure 46–46). Redirecting laterally and caudally, the needle is advanced an additional 2 to 4 cm until a motor response (thigh adduction) is elicited and maintained below 0.5 mA. Following careful aspiration for the nonappearance of blood, 15 to 20 mL of local anesthetic is injected.

FIGURE 46–45 Obturator nerve innervation.
Obturator nerve block. Contact pubic tubercle (1), then redirect laterally and caudally (2) until a motor response is elicited.

**Posterior Lumbar Plexus (Psoas Compartment) Block**

Posterior lumbar plexus blocks are useful for surgical procedures involving areas innervated by the femoral, lateral femoral cutaneous, and obturator nerves (Figure 46–47). These include procedures on the hip, knee, and anterior thigh. Complete anesthesia of the knee can be attained with a proximal sciatic nerve block. The lumbar plexus is relatively close to multiple sensitive structures (Figure 46–48) and reaching it requires a very long needle. Hence, the posterior lumbar plexus block has one of the highest complication rates of any peripheral nerve block; these include retroperitoneal hematoma, intravascular local anesthetic injection with toxicity, intrathecal and epidural injections, and renal capsular puncture with subsequent hematoma.
FIGURE 46–47 Lumbar plexus blocks provide anesthesia to the femoral, lateral femoral cutaneous, and obturator nerves.
The lumbar plexus lies in close proximity to several important structures. Lumbar nerve roots emerge into the body of the psoas muscle and travel within the muscle compartment before exiting as terminal nerves (see Figure 46–38). Modern posterior lumbar plexus blocks deposit local anesthetic within the body of the psoas muscle. The patient is positioned in lateral decubitus with the side to be blocked in the nondependent position (Figure 46–49). The midline is palpated, identifying the spinous processes if possible. A line is first drawn through the lumbar spinous processes, and both iliac crests are identified and connected with a line to approximate the level of L4. The posterior superior iliac
spine is then palpated and a line is drawn cephalad, parallel to the first line. If available, ultrasound imaging of the transverse process may be helpful to estimate lumbar plexus depth. A long (10- to 15-cm) insulated needle is inserted at the point of intersection between the transverse (intercristal) line and the intersection of the lateral and middle thirds of the two sagittal lines. The needle is advanced in an anterior direction until a femoral motor response is elicited (quadriceps contraction). If the transverse process is contacted, the needle should be withdrawn slightly and “walked off” the transverse process in a caudal direction, maintaining the needle in the parasagittal plane. The needle should never be inserted more than 3 cm past the depth at which the transverse process was contacted. Local anesthetic volumes greater than 20 mL will increase the risk of bilateral spread and contralateral limb involvement.
Adductor Canal Block

The *adductor canal block* is used for analgesia of the knee and medial leg; single injection or continuous techniques can be used. The quadriceps muscles are
affected to a lesser degree by an adductor canal block than by a femoral block, which may facilitate ambulation following knee surgery. Bounded by the sartorius muscle and vasto-adductor membrane medially, the vastus medialis anteriorly, and the adductor muscles posteriorly, the adductor canal contains several nerves that provide sensory innervation to the knee. Most notable is the saphenous nerve, and a block within the adductor canal will likely affect the posterior division of the obturator nerve and the nerve to the vastus medialis as well.

A. Ultrasound

The patient is positioned supine with the knee slightly bent and the leg externally rotated. A high-frequency linear transducer is positioned in a transverse orientation over the medial thigh, halfway between the ASIS and the superior patellar pole (Figure 46–50). The femoral artery and vein are visualized deep to the sartorius muscle, and the saphenous nerve lies just lateral to the artery (Figure 46–51). A long (10-cm) block needle is placed 2 to 3 cm lateral to the transducer and advanced in-plane to the triangular space deep to the sartorius muscle and vasto-adductor membrane and lateral to the artery. After careful aspiration for nonappearance of blood, 15 to 20 mL of local anesthetic is injected.

FIGURE 46–50 Positioning for adductor canal block. The patient is positioned supine with the leg externally rotated. A high-frequency linear transducer is placed in a transverse orientation at the mid-thigh.
FIGURE 46–51 Ultrasound image of adductor canal block. Femoral artery (A) and vein (V) lie deep to sartorius muscle (SM) with saphenous nerve (SN) just lateral to the artery.

Saphenous Nerve Block
The saphenous nerve is the most medial branch of the femoral nerve and innervates the skin over the medial leg and the ankle joint (see Figure 46–39). Therefore, this block is used mainly in conjunction with a sciatic nerve block to provide complete anesthesia/analgesia below the knee.

A. Trans-Sartorial Technique
The saphenous nerve may be accessed proximal to the knee, just deep to the sartorius muscle. A high-frequency linear probe is used to identify the junction between the sartorius, vastus medialis, and adductor muscles in cross-section just distal to the adductor canal. A long needle is inserted from medial to lateral (in-plane) or angled cephalad (out-of-plane) and 5 to 10 mL of local anesthetic deposited within this fascial plane.
B. Proximal Saphenous Technique
A short block needle is inserted 2 cm distal to the tibial tuberosity and directed medially, infiltrating 5 to 10 mL of local anesthetic as the needle passes toward the posterior aspect of the leg (Figure 46–52). Ultrasound may be used to identify the saphenous vein near the tibial tuberosity and facilitate a perivascular technique, with infiltration about the vein.

![Proximal saphenous nerve block](Figure 46–52)

C. Distal Saphenous Technique
The medial malleolus is identified, infiltrating 5 mL of local anesthetic in a line running anteriorly around the ankle (see “Ankle Block,” below).

Sciatic Nerve Block
The sciatic nerve originates from the lumbosacral trunk and is composed of nerve roots L4–5 and S1–3 (see Figure 46–38). Blockade of the sciatic nerve may occur anywhere along its course and is indicated for surgical procedures involving the hip, thigh, knee, lower leg, and foot. The posterior femoral cutaneous nerve is variably anesthetized as well, depending on the approach. If sacral plexus or posterior femoral cutaneous nerve anesthesia is required, the
parasacral approach is used (a technique that is beyond the scope of this chapter).

**A. Posterior (Classic or Labat) Approach**

The patient is positioned laterally with the side to be blocked in the nondependent position. The patient is asked to bend the knee of the affected leg and tilt the pelvis slightly forward (Sim’s position; Figure 46–53). The greater trochanter, posterior superior iliac spine (PSIS), and sacral hiatus are then identified. A line is drawn from the greater trochanter to the PSIS, its midpoint identified, and a perpendicular line extended in a caudal direction. Next, a line is drawn from the greater trochanter to the sacral hiatus and the intersection point is marked; this is the initial needle insertion point. A long (10-cm) insulated needle is inserted at an angle perpendicular to all planes to the skin (Figure 46–53). The needle is advanced through the gluteal muscles (a motor response of these muscles may be encountered) until plantar- or dorsiflexion is elicited (plantarflexion or foot inversion is preferred for surgical anesthesia). A local anesthetic volume of 25 mL provides surgical anesthesia.
FIGURE 46–53 Patient positioning, surface landmarks, and needle positioning for proximal sciatic nerve block (classic approach).

B. Anterior Approach

After leaving the sciatic notch, the sciatic nerve descends behind the lesser trochanter to a position posterior to the femur. It can be accessed from the anterior thigh just medial to the lesser trochanter. Lateral or prone positioning may present a challenge for some patients requiring a sciatic nerve block (ie, elderly patients, pediatric patients under general anesthesia). An anterior approach can be technically challenging but offers an alternative path to the sciatic nerve. Before proceeding with this block, which carries a risk of vascular puncture (femoral artery and vein), patient-specific risks should be considered (eg, coagulopathy and vascular grafting). In addition, if combining this block with the femoral nerve block in an unanesthetized patient, performing the sciatic
block first is recommended to avoid passing the block needle through a previously anesthetized femoral nerve. A local anesthetic volume of 25 mL provides surgical anesthesia.

1. **Nerve stimulation**—With the patient positioned supine, a line is drawn along the inguinal ligament, from the ASIS to the pubic tubercle (Figure 46–54). A second line is drawn parallel to the first that traverses the greater trochanter (intertrochanteric line). Next, these two lines are connected with a third line drawn from the point between the medial one-third and lateral two-thirds of the first line, at a 90° angle, and extended caudally to intersect with the intertrochanteric line. A long (10- to 15-cm) needle is inserted through this intersection and directly posterior until foot inversion or plantarflexion is elicited (dorsiflexion is acceptable for postoperative analgesia). Often with this approach, the femur is contacted before the needle reaches the sciatic nerve. When this occurs, the needle should be withdrawn 2 to 3 cm, the patient should be asked to internally rotate the leg, and then the needle should be advanced. If the femur is contacted again, the landmarks may require reassessment. A local anesthetic volume of 25 mL provides surgical anesthesia.

![Figure 46–54](image-url) **FIGURE 46–54** Anatomy and surface landmarks for anterior sciatic nerve block.

2. **Ultrasound**—With the patient positioned supine and the leg externally rotated, a low-frequency curvilinear transducer is placed transversely over the medial thigh, approximately at the level of the lesser trochanter. The femur,
femoral vessels, adductor muscles, and gluteus maximus are identified in cross-section. The elliptical, hyperechoic sciatic nerve is found in the fascial plane between adductors and gluteus muscles, posterior to the femur. Using a long (10-cm) needle, the nerve is approached in-plane (anterior to posterior) or out-of-plane (cephalad to caudad), taking care to avoid femoral vessels, until the needle tip lies in this muscle plane and a local anesthetic injection can be observed as hypoechoic spread surrounding the sciatic nerve.

C. Subgluteal Approach
A subgluteal approach to the sciatic nerve is a useful alternative to the traditional posterior approach because the landmarks are often more easily identified and less tissue is traversed. With the sciatic nerve at a more superficial location, the exclusive use of ultrasound becomes far more practical, as well. If sciatic nerve block is being combined with a femoral block and ambulation is desired within the local anesthetic duration, consider a popliteal approach (see next section) that will not affect the hamstring muscles to the same degree, allowing knee flexion to lift the foot with the use of crutches.

1. Nerve stimulation—With the patient in the Sim’s position, the greater trochanter and ischial tuberosity are identified and a line drawn between them (Figure 46–55). From the midpoint of this line, a second line is drawn perpendicularly and extended caudally 4 cm. Through this point a long (10-cm) insulated needle is inserted directly slightly cephalad until foot plantarflexion or inversion is elicited (dorsiflexion is acceptable for analgesia). A local anesthetic volume of 25 mL provides surgical anesthesia.

![Figure 46–55](image)

**FIGURE 46–55** Patient positioning and surface landmarks for subgluteal sciatic block.

2. Ultrasound—Using the same positioning and landmarks (Figure 46–55), a linear or low-frequency curvilinear (best) ultrasound transducer is placed over
the midpoint between the ischial tuberosity and the greater trochanter in a transverse orientation. Both bony structures should be visible in the ultrasound field simultaneously. Gluteal muscles are identified superficially, along with the fascial layer defining their deep border. The triangular sciatic nerve should be visible in cross-section just deep to this layer in a location approximately midway between the ischial tuberosity and the greater trochanter, superficial to the quadratus femoris muscle.

For an out-of-plane ultrasound-guided sciatic block, the block needle is inserted just caudal to the ultrasound transducer and advanced in an anterior and cephalad direction. Once the needle passes through the gluteus muscles with the tip next to sciatic nerve, careful aspiration for the nonappearance of blood is performed and local anesthetic is injected, visualizing spread around the nerve.

For an in-plane technique, the block needle is inserted just lateral to the ultrasound transducer near the greater trochanter. It is advanced through the field of the ultrasound beam until the tip is visible deep to the gluteus maximus, next to the sciatic nerve. Again, local anesthetic spread around the nerve should be observed.

**D. Popliteal Approach**

*Popliteal nerve blocks* provide excellent coverage for foot and ankle surgery, while sparing much of the hamstring muscles, allowing lifting of the foot with knee flexion, thus facilitating ambulation. All sciatic nerve blocks fail to provide complete anesthesia for the cutaneous medial leg and ankle joint capsule, but when a saphenous (or femoral) block is added, complete anesthesia below the knee is provided. The major site-specific risk of a popliteal block is vascular puncture, owing to the sciatic nerve’s proximity to the popliteal vessels at this location.

The sciatic nerve divides into the tibial and common peroneal nerves within or just proximal to the popliteal fossa (*Figure 46–56*). The upper popliteal fossa is bounded laterally by the biceps femoris tendon and medially by the semitendinosus and semimembranosus tendons. Cephalad to the flexion crease of the knee, the popliteal artery is immediately lateral to the semitendinosus tendon. The popliteal vein is lateral to the artery, and the tibial and common peroneal nerves are just lateral to the vein and medial to the biceps tendon, 2 to 6 cm deep to the skin. The tibial nerve continues deep behind the gastrocnemius muscle, and the common peroneal nerve exits the popliteal fossa between the head and neck of the fibula to supply the lower leg. The sciatic nerve is approached by either a posterior or a lateral approach. For posterior approaches,
the patient is usually positioned prone with the knee slightly flexed by propping the ankle on pillows or towels. For lateral approaches, the patient may be in the lateral or supine position.

**FIGURE 46–56** The sciatic nerve divides into tibial and peroneal branches just proximal to the popliteal fossa and provides sensory innervation to much of the lower leg.

1. **Nerve stimulation (posterior approach)**—With the patient in the prone position, the apex of the popliteal fossa is identified. The hamstring muscles are palpated to locate the point where the biceps femoris (lateral) and the semimembranosus/semitendinosus complex (medial) join (Figure 46–57). Having the patient flex the knee against resistance facilitates recognition of these structures. The needle entry point is 1 cm caudal from the apex. An insulated needle (5–10 cm) is advanced until foot plantarflexion or inversion is elicited (dorsiflexion is acceptable for analgesia). A volume of 30 to 40 mL of local anesthetic is often required for single-injection popliteal–sciatic nerve block.
FIGURE 46–57 Anatomy and sonoanatomy of the sciatic nerve in the popliteal fossa. PA, popliteal artery; PV, popliteal vein; N, sciatic nerve; BFM, biceps femoris muscle; F, femur.
2. **Nerve stimulation (lateral approach)**—With the patient in the supine position and the knee fully extended, the intertendinous groove is palpated between the vastus lateralis and biceps femoris muscles approximately 10 cm proximal to the superior notch of the patella. A long (10-cm) insulated needle is inserted at this point and advanced at a 30° angle posteriorly until an appropriate motor response is elicited. If bone (femur) is contacted, the needle is withdrawn and redirected slightly posteriorly until an acceptable motor response is encountered.

3. **Ultrasound**—With the patient positioned prone, the apex of the popliteal fossa is identified, as previously described. Using a high-frequency linear ultrasound transducer placed in a transverse orientation, the femur, biceps femoris muscle, popliteal vessels, and sciatic nerve or branches are identified in cross-section (Figure 46–57). The nerve is usually posterior and lateral (or immediately posterior) to the vessels and is often located in close relationship to the biceps femoris muscle, just deep to its medial edge.

   For an out-of-plane technique, the needle is inserted just caudad to the ultrasound transducer and directed anteriorly and slightly cephalad. When the needle is positioned in proximity to the sciatic nerve, and following careful aspiration, local anesthetic is injected, observing for spread around the nerve.

   For an in-plane technique, the block needle is inserted lateral to the ultrasound transducer, traversing—or just anterior to—the biceps femoris muscle (Figure 46–58). The needle is advanced in the ultrasound plane, while visualizing its approach either deep or superficial to the nerve.
If surgical anesthesia is desired, local anesthetic should be seen surrounding all sides of the nerve, which usually requires multiple needle tip placements with incremental injections. For analgesia alone, a single injection of local anesthetic
is acceptable. Injection into the nerve or within the paraneural sheath hastens onset and prolongs duration, but may place the nerve at risk for injury. Ultrasound-guided popliteal sciatic blocks may be performed with the patient in the lateral or supine positions (the latter with leg up-raised on several pillows). These maneuvers are often more technically challenging.

**Ankle Block**

For surgical procedures of the foot, an ankle block is a fast, low-technology, low-risk means of providing anesthesia. Excessive injectate volume and use of vasoconstrictors such as epinephrine must be avoided to minimize the risk of ischemic complications. Since this block includes five separate injections, it is often uncomfortable for patients, and adequate sedation and analgesia premedication is advised.

Five nerves supply sensation to the foot (Figure 46–59). The *saphenous nerve* is a terminal branch of the femoral nerve and the only innervation of the foot that is not a part of the sciatic system. It supplies superficial sensation to the anteromedial foot and is most constantly located just anterior to the medial malleolus. The *deep peroneal nerve* runs in the anterior leg after branching off the common peroneal nerve, entering the ankle between the extensor hallucis longus and the extensor digitorum longus tendons (Figure 46–60), just lateral to the dorsalis pedis artery. It provides innervation to the toe extensors and sensation to the first dorsal webspace. The *superficial peroneal nerve*, also a branch of the common peroneal nerve, descends toward the ankle in the lateral compartment, giving motor branches to the muscles of eversion. It enters the ankle just lateral to the extensor digitorum longus and provides cutaneous sensation to the dorsum of the foot and toes. The *posterior tibial nerve* is a direct continuation of the tibial nerve and enters the foot posterior to the medial malleolus, branching into calcaneal, lateral plantar, and medial plantar nerves. It is located behind the posterior tibial artery at the level of the medial malleolus and provides sensory innervation to the heel, the medial sole, and part of the lateral sole of the foot, as well as the tips of the toes. The *sural nerve* is a branch of the tibial nerve and enters the foot between the Achilles tendon and the lateral malleolus to provide sensation to the lateral foot.
A complete ankle block requires a series of five nerve blocks, but the
process may be streamlined to minimize needle insertions (Figure 46–61). All five injections are required to anesthetize the entire foot; however, surgical procedures rarely require that all terminal nerves be blocked. In addition, unlike a sciatic nerve block, an ankle block provides no analgesia for (below-the-knee) tourniquet pain, nor does it allow for perineural catheter insertion. To block the deep peroneal nerve, the groove between the extensor hallucis longus and extensor digitorum longus tendons is identified. The dorsalis pedis pulse is often palpable here. A short, small-gauge block needle is inserted perpendicular to the skin just lateral to the pulse, bone is contacted, and 5 mL of local anesthetic is infiltrated as the needle is withdrawn. Continuing from this insertion site, a subcutaneous wheal of 5 mL of local anesthetic is extended toward the lateral malleolus to target the superficial peroneal nerve. The needle is withdrawn and redirected from the same location in a medial direction, infiltrating 5 mL of local anesthetic toward the medial malleolus to target the saphenous nerve. The posterior tibial nerve may be located by identifying the posterior tibial artery pulse behind the medial malleolus. A short, small-gauge block needle is inserted just posterior to the artery and 5 mL of local anesthetic is distributed in the pocket deep to the flexor retinaculum. To target the sural nerve, 5 mL of local anesthetic is injected subcutaneously posterior to the lateral malleolus.

FIGURE 46–61 Needle placement for ankle block.

PERIPHERAL NERVE BLOCKS OF THE TRUNK

Superficial Cervical Plexus Block

The superficial cervical plexus block provides cutaneous analgesia for surgical
procedures on the neck, anterior shoulder, and clavicle. The cervical plexus is formed from the anterior rami of C1–4, which emerge from the platysma muscle posterior to the sternocleidomastoid (Figure 46–62). It supplies sensation to the jaw, neck, occiput, and areas of the chest and shoulder.

**FIGURE 46–62** Distribution of the superficial cervical plexus.

The patient is positioned supine with the head turned away from the side to be blocked. It is helpful to identify and avoid the external jugular vein. The sternocleidomastoid muscle is identified and its lateral edge marked. Typically, the nerve passes over the sternocleidomastoid very near to where the external jugular vein crosses the muscle, and this can be the starting point for injection of local anesthetic. Alternatively, at the junction of the upper and middle thirds, a short (5-cm) block needle is inserted, directed cephalad toward the mastoid process, and 10 mL of local anesthetic is injected in a subcutaneous plane. The needle is turned to advance it in a caudad direction, maintaining a path along the posterior border of sternocleidomastoid. An additional 10 mL of local anesthetic is infiltrated subcutaneously. A dilute concentration of local anesthetic (eg, 0.25% bupivacaine) is appropriate, as this is essentially a field block.

**Intercostal Block**

*Intercostal blocks* provide analgesia following thoracic and upper abdominal surgery, and relief of pain associated with rib fractures, herpes zoster, and cancer. These blocks require individual injections delivered at the intercostal nerves that innervate the area of body wall to be anesthetized. **Intercostal blocks result in the highest blood levels of local anesthetic per local anesthetic dose**
injected of any nerve block procedure, and if multiple blocks will be performed care must be taken to avoid toxic levels of local anesthetic. The intercostal block has one of the highest complication rates of any peripheral nerve block due to the close proximity of the intercostal artery and vein (intravascular local anesthetic injection), as well as underlying pleura (pneumothorax). In addition, duration is impressively short due to the high vascular flow, and placement of a perineural catheter is tenuous, at best. With the advent of ultrasound guidance, the paravertebral approach is rapidly replacing the intercostal approach, with exception of specific indications such as providing anesthesia prior to placement of a chest tube.

The intercostal nerves arise from the dorsal and ventral rami of the thoracic spinal nerves. They exit from the spine at the intervertebral foramen and enter a groove on the underside of the corresponding rib, running with the intercostal artery and vein; the nerve is generally the most inferior structure in the neurovascular bundle (Figure 46–63). Branches are given off for sensation in a single dermatome from the midline dorsally all the way to across the midline ventrally.

![Image of intercostal nerve block](image)

**FIGURE 46–63** Anatomy and needle positioning for intercostal nerve block.

With the patient in the lateral decubitus or supine position, the level of each rib in the mid and posterior axillary line is palpated and marked. A small-gauge needle is inserted at the inferior edge of each of the selected ribs, bone is contacted, and the needle is then “walked off” inferiorly (Figure 46–62). The needle is advanced approximately 0.25 cm. Following aspiration, observing for
blood or air, 3 to 5 mL of local anesthetic is injected at each desired level.

**Paravertebral Block**

*Paravertebral blocks* provide surgical anesthesia or postoperative analgesia for procedures involving the thoracic or abdominal wall, mastectomy, inguinal or abdominal hernia repair, and more invasive unilateral procedures such as open nephrectomy. Paravertebral blocks usually require individual injections delivered at the various vertebral levels that correspond to the area of body wall to be anesthetized. For example, a simple mastectomy would require blocks at levels T3–6; for axillary node dissection, additional injections should be made from C7 through T2. For inguinal hernia repair, blocks should be performed at T10 through L2. Ventral hernias require bilateral injections corresponding to the level of the surgical site. The major complication of thoracic injections is pneumothorax, whereas retroperitoneal structures may be at risk with lumbar-level injections. Hypotension secondary to sympathectomy can be observed with multilevel thoracic blocks. Unlike the intercostal approach, long-acting local anesthetic will have a nearly 24-hour duration, and perineural catheter insertion is an option (although local anesthetic spread from a single catheter to multiple levels is variable).

Each spinal nerve emerges from the intervertebral foramina and divides into two rami: a larger *anterior ramus*, which innervates the muscles and skin over the anterolateral body wall and limbs, and a smaller *posterior ramus*, which reflects posteriorly and innervates the skin and muscles of the back and neck (*Figure 46–64*). The thoracic paravertebral space is defined posteriorly by the superior costotransverse ligament, anterolaterally by the parietal pleura, medially by the vertebrae and the intervertebral foramina, and inferiorly and superiorly by the heads of the ribs.
FIGURE 46–64 Paravertebral anatomy and traditional approach. Surface anatomy: spinous processes are identified by circles and needle insertion sites for transverse processes are identified by dots. Needle is first inserted perpendicular to the plane of the skin to contact the transverse process (1), then redirected caudally (2) and advanced 1 cm.

With the patient seated and vertebral column flexed, each spinous process is palpated, counting from the prominent C7 for thoracic blocks, and the iliac crests as a reference for lumbar levels. From the midpoint of the superior aspect of each spinous process, a point 2.5 cm laterally is measured and marked. In the thorax, the target nerve is located lateral to the spinous process above it, due to the steep angulation of thoracic spinous processes (eg, the T4 nerve root is located lateral to the spinous process of T3).

A. Traditional Technique
A 20-gauge Tuohy needle is inserted at each point and advanced perpendicular to the skin (Figure 46–64). Upon contact with the transverse process, the needle is withdrawn slightly and redirected caudally an additional 1 cm (0.5 cm for lumbar placement). A “pop” or loss of resistance may be felt as the needle passes
through the costotransverse ligament. Some practitioners use a loss-of-resistance syringe to guide placement; others prefer use of a nerve stimulator with chest wall motion for the end point. Inject 5 mL of local anesthetic at each level. The difficulty with this technique is that the depth of the transverse process is simply estimated; thus, the risk of pneumothorax is relatively high. Using ultrasound to gauge transverse process depth prior to needle insertion theoretically decreases the risk of pneumothorax.

B. Ultrasound
An ultrasound transducer with a curvilinear array is used, with the beam oriented in a parasagittal or transverse plane. The transverse process, head of the rib, costotransverse ligament, and pleura are identified. The paravertebral space may be approached from a caudal-to-cephalad direction (parasagittal) or a lateral-to-medial direction (transverse). It is helpful to visualize the needle in-plane as it passes through the costotransverse ligament and observe a downward displacement of the pleura as local anesthetic is injected. At each level 5 mL of local anesthetic is injected.

“Pecs” Block
The Pecs block is emerging as a useful alternative to paravertebral block for surgery involving the chest wall. It provides analgesia to the anterior chest wall via the medial and lateral pectoral nerves and is administered further from the neuraxis—an important consideration in the coagulopathic patient. A Pecs block can be achieved by depositing local anesthetic in the plane between the pectoralis major and pectoralis minor muscles at the level of the third rib. In addition, local anesthetic can be deposited between the pectoralis minor and around the serratus anterior, which targets the T2–4 spinal nerves as well as the long thoracic nerve.

A. Ultrasound
A high-frequency linear transducer is placed at the mid-clavicular line and angled inferolaterally. The pectoralis major, pectoralis minor, and axillary vessels are identified. Tracing the muscles toward their insertion, the serratus anterior muscle may then be identified deep to the pectoralis muscles and superficial to the third and fourth ribs (Figure 46–65). A long (10-cm) needle is inserted lateral to the transducer and advanced in plane to target the interfascial plane between the pectoralis major and minor muscles. An additional injection
may be performed after advancing the needle through the pectoralis minor muscle to surround the serratus anterior.

**FIGURE 46–65** Ultrasound image of Pecs block. Pectoralis major (PMM) and pectoralis minor (PmM) overlie serratus anterior (SAM). Local anesthetic may be injected between the pectoralis major and minor, deep to the pectoralis minor, or around the serratus anterior.

**Transversus Abdominis Plane Block**

The *transversus abdominis plane* (TAP) block is most often used to provide surgical anesthesia for minor, superficial procedures on the lower abdominal wall, or postoperative analgesia for procedures below the umbilicus. For hernia surgeries, intravenous or local supplementation may be necessary to provide anesthesia during peritoneal traction. Potential complications include violation of the peritoneum with or without bowel perforation, and the use of ultrasound is highly recommended to minimize this risk.

The *subcostal* (T12), *ilioinguinal* (L1), and *iliohypogastric* (L1) nerves are targeted in the TAP block, providing anesthesia to the ipsilateral lower abdomen below the umbilicus (Figure 46–66). For part of their course, these three nerves travel in the muscle plane between the internal oblique and transversus abdominis muscles. Needle placement should be between the two fascial layers of these muscles, with local anesthetic filling the transversus abdominis plane. The patient is ideally positioned in lateral decubitus, but if mobility is limited the block may be performed in the supine position.
A. Ultrasound

With a linear or curvilinear array transducer oriented parallel to the inguinal ligament, the layers of the external oblique, internal oblique, and transversus abdominis muscles are identified just superior to the ASIS (Figure 46–67). Muscles appear as striated hypoechoic structures with hyperechoic layers of fascia at their borders. A long (10-cm) needle is inserted in-plane just lateral (posterior) to the transducer and advanced, noting tactile feedback from fascial planes, to the hyperechoic effacement of the deep border of internal oblique and the superficial border of transversus abdominis. Following careful aspiration for the nonappearance of blood, 20 mL of local anesthetic is injected, observing for an elliptical separation between the two fascial layers (Figure 46–67).

SUGGESTED READINGS

Chronic Pain Management

Bruce M. Vrooman, MD, MS, FIPP and Richard W. Rosenquist, MD

KEY CONCEPTS

1. Pain may be classified according to pathophysiology (eg, nociceptive or neuropathic pain), etiology (eg, arthritis or cancer pain), or the affected area (eg, headache or low back pain).

2. *Nociceptive* pain is caused by activation or sensitization of peripheral nociceptors, specialized receptors that transduce noxious stimuli. *Neuropathic* pain is the result of injury or acquired abnormalities of peripheral or central neural structures.

3. *Acute pain* is caused by noxious stimulation due to injury, a disease process, or the abnormal function of muscle or viscera. It is almost always nociceptive.

4. *Chronic pain* is pain that persists beyond the usual course of an acute disease or after a reasonable time for healing to occur, typically 1 to 6 months. Chronic pain may be nociceptive, neuropathic, or mixed.

5. *Modulation* of pain occurs peripherally at the nociceptor, in the spinal cord, or in supraspinal structures. This modulation can either inhibit (suppress) or facilitate (intensify) pain.

6. At least three mechanisms are responsible for *central sensitization* in the spinal cord: (1) wind-up and sensitization of second-order wide dynamic range neurons; (2) dorsal horn neuron receptor field expansion; and (3) hyperexitability of flexion reflexes.

7. Chronic pain may be caused by a combination of peripheral, central, and psychological mechanisms.

8. Moderate to severe acute pain, regardless of site, can affect the function of nearly every organ and may adversely influence perioperative morbidity, mortality, and convalescence.
The evaluation of any patient with pain should include several key components. Information about location, onset, and quality of pain, as well as alleviating and exacerbating factors, should be obtained along with a pain history that includes previous therapies and changes in symptoms over time.

Psychosocial evaluation is useful whenever medical evaluation fails to reveal an apparent cause for pain, pain intensity is disproportionate to disease or injury, or when psychological or social issues are apparent.

Myofascial pain syndromes are common disorders characterized by aching muscle pain, muscle spasm, stiffness, weakness, and, occasionally, autonomic dysfunction.

Ninety percent of disc herniations occur at L5–S1 or L4–L5. Symptoms usually develop following flexion injuries or heavy lifting and may be associated with bulging, protrusion, or extrusion of the disc.

Back pain caused by spinal stenosis usually radiates into the buttocks, thighs, and legs. Termed pseudoclaudication or neurogenic claudication, this pain is characteristically worse with exercise and relieved by rest, particularly sitting with the spine flexed.

Diabetic neuropathy is the most common type of neuropathic pain.

Complex regional pain syndrome (CRPS) is a neuropathic pain disorder with significant autonomic features that is usually subdivided into two variants: CRPS 1, formerly known as reflex sympathetic dystrophy (RSD), and CRPS 2, formerly known as causalgia. The major difference between the two is the absence or presence, respectively, of documented nerve injury.

Trigeminal neuralgia (tic douloureux) is classically unilateral and usually located in the V2 or V3 distribution of the trigeminal nerve. It has an electric shock quality, with episodes lasting from seconds to minutes, and is often provoked by contact with a discrete trigger.

Antidepressants are most useful for patients with neuropathic pain and demonstrate an analgesic effect that occurs at a dose lower than needed for antidepressant activity.

Anticonvulsant medications are useful for patients with neuropathic pain, especially trigeminal neuralgia and diabetic neuropathy.

Patients who experience opioid tolerance require escalating doses of opioid to maintain the same analgesic effect. Physical dependence manifests in opioid withdrawal when the opioid medication is either abruptly discontinued or the dose is abruptly and significantly
decreased. *Psychological dependence*, characterized by behavioral changes focusing on drug craving, is rare in cancer patients.

Complications of stellate block include intravascular and subarachnoid injection, hematoma, pneumothorax, epidural anesthesia, brachial plexus block, hoarseness due to blockade of the recurrent laryngeal nerve, and, rarely, osteomyelitis or mediastinitis. *Ganglion impar block* is effective for patients with visceral or sympathetically maintained pain in the perineal area.

Neurolytic blocks are indicated for patients with severe, intractable cancer pain in whom more conventional therapy proves inadequate or conventional analgesic modalities are accompanied by unacceptable side effects.

Spinal cord stimulation may be most effective for neuropathic pain; accepted indications include sympathetically mediated pain, spinal cord lesions with localized segmental pain, phantom limb pain, ischemic lower extremity pain due to peripheral vascular disease, adhesive arachnoiditis, peripheral neuropathies, post-thoracotomy pain, intercostal neuralgia, postherpetic neuralgia, angina, visceral abdominal pain, and visceral pelvic pain.

Patients with pathological or osteoporotic vertebral compression fracture may benefit from vertebral augmentation with polymethylmethacrylate cement. *Vertebroplasty* involves injection of the cement through the trocar needle. *Kyphoplasty* involves inflation of a balloon inserted through a percutaneously placed trocar needle, with subsequent injection of cement.

Acupuncture can be a useful adjunct for patients with chronic pain, particularly that associated with chronic musculoskeletal disorders and headaches.

Pain is the most common symptom that brings patients to see a physician, and the symptom may have a wide variety of causes ranging from relatively benign conditions to acute injury, myocardial ischemia, degenerative changes, or malignancy. In most cases, after a diagnosis is made, conservative measures are prescribed and the patient responds successfully. In others, referral to a pain medicine specialist for evaluation and treatment improves outcomes and conserves health care resources. In still other situations, pain persists and patients develop chronic pain, the cause of which remains obscure after
preliminary investigations have excluded serious and life-threatening illnesses and, if warranted, surgical intervention has either failed to relieve pain or has produced a new pain syndrome.

The term *pain management* in a general sense applies to the entire discipline of anesthesiology, but its modern usage more specifically involves management of pain throughout the perioperative period as well as nonsurgical pain in both inpatient and outpatient settings. Pain medicine practice may be broadly divided into *acute* and *chronic* pain management. The former primarily deals with patients recovering from surgery or with acute medical conditions in a hospital or ambulatory surgery center setting (see Chapter 48), whereas the latter includes diverse groups of patients almost always seen in the outpatient setting. Unfortunately, this distinction is artificial and considerable overlap exists; a good example is the patient with cancer who frequently requires short- and long-term pain management in both inpatient and outpatient settings.

The contemporary practice of pain management is not limited to anesthesiologists but is often team based and includes other physicians (physiatrists, surgeons, internists, oncologists, psychiatrists, and neurologists) and nonphysicians (psychologists, physical therapists, acupuncturists, and hypnotists). The most effective approaches are multidisciplinary, in which the patient is evaluated by one or more physicians who conduct an initial examination, make a diagnosis, and formulate a treatment plan, and where subsequent evaluation and use of the services and resources of other health care providers is typical.

Anesthesiologists trained in pain management are in a unique position to coordinate multidisciplinary pain management centers because of their broad training in dealing with a wide variety of patients from surgical, obstetric, pediatric, and medical subspecialties and their expertise in clinical pharmacology and applied neuroanatomy, including the use of peripheral and central nerve blocks.

**DEFINITIONS & CLASSIFICATION OF PAIN**

Like other conscious sensations, normal pain perception depends on specialized neurons that function as receptors, detecting a noxious stimulus and then transducing and conducting it to the central nervous system. Sensation is often described as either *protopathic* (noxious) or *epicritic* (nonnoxious). Epicritic sensations (light touch, pressure, proprioception, and temperature discrimination) are characterized by low-threshold receptors and are generally
conducted by large myelinated nerve fibers. In contrast, protopathic sensations (pain) are detected by high-threshold receptors and conducted by smaller myelinated (Aδ) and unmyelinated (C) nerve fibers.

**What Is Pain?**

Pain is not just a sensory modality but an experience. The International Association for the Study of Pain defines pain as **an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage**. This definition recognizes the interplay between the objective, physiological sensory aspects of pain and its subjective, emotional, and psychological components.

The response to pain can be highly variable among different individuals as well as in the same person at different times. There are differences in pain perception, experiences, and coping strategies related to both gender and age. Brain activation and brain imaging patterns differ between genders, with some of these differences decreasing with age and disappearing entirely after age 40.

The term *nociception* is derived from *noci* (Latin for harm or injury) and is used to describe neural responses to traumatic or noxious stimuli. All nociception produces pain, but not all pain results from nociception. Many patients experience pain in the absence of noxious stimuli. It is therefore clinically useful to divide pain into one of two categories: (1) acute pain, which is primarily due to nociception, and (2) chronic pain, which may be due to nociception, but in which psychological and behavioral factors often play a major role. **Table 47–1** lists terms frequently used in describing pain.

Pain may also be classified according to pathophysiology (eg, nociceptive or neuropathic pain), etiology (eg, arthritis or cancer pain), or the affected area (eg, headache or low back pain). Such classifications are useful in the selection of treatment modalities and drug therapy. Nociceptive pain is caused by activation or sensitization of peripheral nociceptors, specialized receptors that transduce noxious stimuli. Neuropathic pain is the result of injury or acquired abnormalities of peripheral or central neural structures.

A. Acute Pain

Acute pain is caused by noxious stimulation due to injury, a disease process, or the abnormal function of muscle or viscera. It is almost always nociceptive. Nociceptive pain serves to detect, localize, and limit tissue damage. Four physiological processes are involved: transduction, transmission, modulation, and perception. This type of pain is typically associated with a systemic neuroendocrine stress response that is proportional to the pain’s intensity. The most common forms of acute pain include post-traumatic, postoperative, and obstetric pain as well as pain associated with acute medical illnesses, such as myocardial infarction, pancreatitis, and renal calculi. Most forms of acute pain are self-limited or resolve with treatment in a few days or weeks. When pain fails to resolve because of either abnormal healing or inadequate treatment, it becomes chronic. Two types of acute (nociceptive) pain—somatic and visceral—are differentiated based on origin and features.

1. Somatic pain—Somatic pain can be further classified as superficial or deep. Superficial somatic pain is due to nociceptive input from skin, subcutaneous tissues, and mucous membranes. It is characteristically well-localized and described as a sharp, pricking, throbbing, or burning sensation.

   Deep somatic pain arises from muscles, tendons, joints, or bones. In contrast to superficial somatic pain, it usually has a dull, aching quality and is less well localized. An additional feature is that both the intensity and duration of the stimulus affect the degree of localization. For example, pain following brief minor trauma to the elbow joint is localized to the elbow, but severe or sustained trauma often causes pain in the whole arm.

2. Visceral pain—Visceral acute pain is due to a disease process or abnormal function involving an internal organ or its covering (eg, parietal pleura, pericardium, or peritoneum). Four subtypes are described: (1) true localized visceral pain, (2) localized parietal pain, (3) referred visceral pain, and (4) referred parietal pain. True visceral pain is dull, diffuse, and usually midline. It is
frequently associated with abnormal sympathetic or parasympathetic activity causing nausea, vomiting, sweating, and changes in blood pressure and heart rate. Parietal pain is typically sharp and often described as a stabbing sensation that is either localized to the area around the organ or referred to a distant site (Table 47–2). The phenomenon of visceral or parietal pain referred to cutaneous areas results from patterns of embryological development and migration of tissues, and the convergence of visceral and somatic afferent input into the central nervous system. Thus, pain associated with disease processes involving the peritoneum or pleura over the central diaphragm is frequently referred to the neck and shoulder, whereas pain from disease processes affecting the parietal surfaces of the peripheral diaphragm is referred to the chest or upper abdominal wall.

**TABLE 47–2 Patterns of referred pain.**
B. Chronic Pain

Chronic pain persists beyond the usual course of an acute disease or after a reasonable time for healing to occur, typically 1 to 6 months. Chronic pain may be nociceptive, neuropathic, or mixed, and psychological mechanisms or environmental factors, or both, frequently play a major role. Patients with chronic pain often have attenuated or absent neuroendocrine stress responses and have prominent sleep and affective (mood) disturbances. Neuropathic pain is classically paroxysmal and lancinating, has a burning quality, and is associated with hyperpathia. When it is also associated with loss of sensory input (eg,
amputation) into the central nervous system, it is termed *deafferentation pain*. When the sympathetic system plays a major role, it is often termed *sympathetically maintained pain*.

The most common forms of chronic pain include those associated with musculoskeletal disorders, chronic visceral disorders, lesions of peripheral nerves, nerve roots, or dorsal root ganglia (including diabetic neuropathy, causalgia, phantom limb pain, and postherpetic neuralgia), lesions of the central nervous system (stroke, spinal cord injury, and multiple sclerosis), and cancer pain. The pain of most musculoskeletal disorders (eg, rheumatoid arthritis and osteoarthritis) is primarily nociceptive, whereas pain associated with peripheral or central neural disorders is primarily neuropathic. The pain associated with some disorders, eg, cancer and chronic back pain (particularly after surgery), is often mixed.

---

**Anatomy & Physiology of Nociception**

**PAIN PATHWAYS**

Pain is conducted along three neuronal pathways that transmit noxious stimuli from the periphery to the cerebral cortex (*Figure 47–1*). The cell bodies of primary afferent neurons are located in the dorsal root ganglia, which lie in the vertebral foramina at each spinal cord level. Each neuron has a single axon that bifurcates, sending one end to the peripheral tissues it innervates and the other into the dorsal horn of the spinal cord. In the dorsal horn, the primary afferent neuron synapses with a second-order neuron whose axon crosses the midline and ascends in the contralateral spinothalamic tract to reach the thalamus. Second-order neurons synapse in thalamic nuclei with third-order neurons, which in turn send projections through the internal capsule and corona radiata to the postcentral gyrus of the cerebral cortex (*Figure 47–2*).
FIGURE 47–1 Pain pathways. DC, dorsal column; STT, spinothalamic tracts.

FIGURE 47–2 Lateral (A) and coronal (B) views of the brain show the location of the primary sensory cortex. Note the cortical representation of body parts, the sensory homunculus (B).
First-Order Neurons

The majority of first-order neurons send the proximal end of their axons into the spinal cord via the dorsal (sensory) spinal root at each cervical, thoracic, lumbar, and sacral level. Some unmyelinated afferent (C) fibers have been shown to enter the spinal cord via the ventral nerve (motor) root, accounting for observations that some patients continue to feel pain even after transection of the dorsal nerve root (rhizotomy) and report pain following ventral root stimulation. Once in the dorsal horn, in addition to synapsing with second-order neurons, the axons of first-order neurons may synapse with interneurons, sympathetic neurons, and ventral horn motor neurons.

Pain fibers originating from the head are carried by the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagal (X) nerves. The gasserian ganglion contains the cell bodies of sensory fibers in the ophthalmic, maxillary, and mandibular divisions of the trigeminal nerve. Cell bodies of first-order afferent neurons of the facial nerve are located in the geniculate ganglion; those of the glossopharyngeal nerve lie in its superior and petrosal ganglia; and those of the vagal nerve are located in the jugular ganglion (somatic) and the ganglion nodosum (visceral). The proximal axonal processes of the first-order neurons in these ganglia reach the brainstem nuclei via their respective cranial nerves, where they synapse with second-order neurons in brainstem nuclei.

SECOND-ORDER NEURONS

As afferent fibers enter the spinal cord, they segregate according to size, with large, myelinated fibers becoming medial, and small, unmyelinated fibers becoming lateral. Pain fibers may ascend or descend one to three spinal cord segments in Lissauer’s tract before synapsing with second-order neurons in the gray matter of the ipsilateral dorsal horn. In many instances, they communicate with second-order neurons through interneurons.

Spinal cord gray matter was divided by Rexed into ten laminae (Figure 47–3 and Table 47–3). The first six laminae, which make up the dorsal horn, receive all afferent neural activity and represent the principal site of modulation of pain by ascending and descending neural pathways. Second-order neurons are either nociceptive-specific or wide dynamic range (WDR) neurons. Nociceptive-specific neurons serve only noxious stimuli, but WDR neurons also receive nonnoxious afferent input from Aβ, Aδ, and C fibers. Nociceptive-specific neurons are arranged somatotopically in lamina I and have discrete, somatic receptive fields; they are normally silent and respond only to high-threshold
noxious stimulation, poorly encoding stimulus intensity. WDR neurons are the most prevalent cell type in the dorsal horn. Although they are found throughout the dorsal horn, WDR neurons are most abundant in lamina V. During repeated stimulation, WDR neurons characteristically increase their firing rate exponentially in a graded fashion (wind-up), even with the same stimulus intensity. They have large receptive fields compared with nociceptive-specific neurons.

**FIGURE 47–3** Rexed’s spinal cord laminae. Note the termination of the different types of primary afferent neurons.
Most nociceptive C fibers send collaterals to, or terminate on, second-order neurons in laminae I and II, and, to a lesser extent, in lamina V. In contrast, nociceptive Aδ fibers synapse mainly in laminae I and V, and, to a lesser degree, in lamina X. Lamina I responds primarily to noxious (nociceptive) stimuli from cutaneous and deep somatic tissues. Lamina II, also called the substantia gelatinosa, contains many interneurons and plays a major role in processing and modulating nociceptive input from cutaneous nociceptors. It is a major site of action for opioids. Laminae III and IV primarily receive nonnociceptive sensory input. Laminae VIII and IX make up the anterior (motor) horn. Lamina VII is the intermediolateral column and contains the cell bodies of preganglionic sympathetic neurons.

Visceral afferents terminate primarily in lamina V, and, to a lesser extent, in lamina I. These two laminae represent points of central convergence between somatic and visceral inputs. Lamina V responds to both noxious and nonnoxious sensory input and receives both visceral and somatic pain afferents. The phenomenon of convergence between visceral and somatic sensory input is manifested clinically as referred pain (see Table 47–2). Compared with somatic fibers, visceral nociceptive fibers are fewer in number, more widely distributed, proportionately activate a larger number of spinal neurons, and are not organized somatotopically.

### A. The Spinothalamic Tract

The axons of most second-order neurons cross the midline close to their dermatomal level of origin (at the anterior commissure) to the contralateral side of the spinal cord before they form the spinothalamic tract and send their fibers to the thalamus, the reticular formation, the nucleus raphe magnus, and the

\(^1\)WDR, wide dynamic range.
periaqueductal gray. The spinothalamic tract, which is classically considered the major pain pathway, lies anterolaterally in the white matter of the spinal cord (Figure 47–4). This ascending tract can be divided into a lateral and a medial tract. The lateral spinothalamic (neospinothalamic) tract projects mainly to the ventral posterolateral nucleus of the thalamus and carries discriminative aspects of pain, such as location, intensity, and duration. The medial spinothalamic (paleospinothalamic) tract projects to the medial thalamus and is responsible for mediating the autonomic and unpleasant emotional perceptions of pain. Some spinothalamic fibers also project to the periaqueductal gray and thus may be an important link between the ascending and descending pathways. Collateral fibers also project to the reticular activating system and the hypothalamus; these are likely responsible for the arousal response to pain.

FIGURE 47–4 A cross section of the spinal cord showing the spinothalamic and other ascending sensory pathways. Note the spatial distribution of fibers from different spinal levels: cervical (C), thoracic (T), lumbar (L), and sacral (S).
B. Alternate Pain Pathways
As with epicritic sensation, pain fibers ascend diffusely, ipsilaterally, and contralaterally; some patients continue to perceive pain following ablation of the contralateral spinothalamic tract, and therefore other ascending pain pathways are also important. The spinoreticular tract is thought to mediate arousal and autonomic responses to pain. The spinomesencephalic tract may be important in activating antinociceptive, descending pathways, because it has some projections to the periaqueductal gray. The spinohypothalamic and spinotelencephalic tracts activate the hypothalamus and evoke emotional behavior. The spinocervical tract ascends uncrossed to the lateral cervical nucleus, which relays the fibers to the contralateral thalamus; this tract is likely a major alternative pathway for pain. Lastly, some fibers in the dorsal columns (which mainly carry light touch and proprioception) are responsive to pain; they ascend medially and ipsilaterally.

C. Integration with the Sympathetic and Motor Systems
Somatic and visceral afferents are fully integrated with the skeletal motor and sympathetic systems in the spinal cord, brainstem, and higher centers. Afferent dorsal horn neurons synapse both directly and indirectly with anterior horn motor neurons. These synapses are responsible for the reflex muscle activity—whether normal or abnormal—that is associated with pain. In a similar fashion, synapses between afferent nociceptive neurons and sympathetic neurons in the intermediolateral column result in reflex sympathetically mediated vasoconstriction, smooth muscle spasm, and the release of catecholamines, both locally and from the adrenal medulla.

Third-Order Neurons
Third-order neurons are located in the thalamus and send fibers to somatosensory areas I and II in the postcentral gyrus of the parietal cortex and the superior wall of the sylvian fissure, respectively. Perception and discrete localization of pain take place in these cortical areas. Although most neurons from the lateral thalamic nuclei project to the primary somatosensory cortex, neurons from the intralaminar and medial nuclei project to the anterior cingulate gyrus and are likely involved in mediating the suffering and emotional components of pain.

PHYSIOLOGY OF NOCICEPTION
1. Nociceptors

Nociceptors are characterized by a high threshold for activation and encode the intensity of stimulation by increasing their discharge rates in a graded fashion. Following repeated stimulation, they characteristically display delayed adaptation, sensitization, and afterdischarges.

Noxious sensations can often be broken down into two components: a fast, sharp, and well-localized sensation (“first pain”), which is conducted with a short latency (0.1 s) by Aδ fibers (tested by pinprick); and a slower onset, duller, and often poorly localized sensation (“second pain”), which is conducted by C fibers. In contrast to well-localized epicritic sensation, which may be transduced by specialized end organs on the afferent neuron (eg, pacinian corpuscle for touch), less well-localized protopathic sensation is transduced mainly by free nerve endings nociceptors that sense heat and mechanical and chemical tissue damage. Nociceptor types include (1) mechanonociceptors, which respond to pinch and pinprick, (2) silent nociceptors, which respond only in the presence of inflammation, and (3) polymodal mechanohot nociceptors. The last are most prevalent and respond to excessive pressure, extremes of temperature (>42°C and <40°C), and noxious substances such as bradykinin, histamine, serotonin (5-hydroxytryptamine or 5-HT), H⁺, K⁺, some prostaglandins, capsaicin, and possibly adenosine triphosphate. At least two nociceptor receptors (containing ion channels in nerve endings) have been identified, TRPV1 and TRPV2. Both respond to high temperatures. Capsaicin stimulates the TRPV1 receptor. Polymodal nociceptors are slow to adapt to strong pressure and display heat sensitization.

Cutaneous Nociceptors

Nociceptors are present in both somatic and visceral tissues. Primary afferent neurons reach tissues by traveling along spinal somatic, sympathetic, or parasympathetic nerves. Somatic nociceptors include those in skin (cutaneous) and deep tissues (muscle, tendons, fascia, and bone), whereas visceral nociceptors include those in internal organs. The cornea and tooth pulp are unique in that they are almost exclusively innervated by nociceptive Aδ and C fibers.

Deep Somatic Nociceptors

Deep somatic nociceptors are less sensitive to noxious stimuli than cutaneous
nociceptors but are easily sensitized by inflammation. The pain arising from them is characteristically dull and poorly localized. Specific nociceptors exist in muscles and joint capsules, and they respond to mechanical, thermal, and chemical stimuli.

**Visceral Nociceptors**

Visceral organs are generally insensitive tissues that mostly contain silent nociceptors. Some organs appear to have specific nociceptors, such as the heart, lung, testis, and bile ducts. Most other organs, such as the intestines, are innervated by polymodal nociceptors that respond to smooth muscle spasm, ischemia, and inflammation. These receptors generally do not respond to the cutting, burning, or crushing that occurs during surgery. A few organs, such as the brain, lack nociceptors altogether; however, the brain’s meningeal coverings do contain nociceptors.

Like somatic nociceptors, those in the viscera are the free nerve endings of primary afferent neurons whose cell bodies lie in the dorsal horn. These afferent nerve fibers, however, frequently travel with efferent sympathetic nerve fibers to reach the viscera. Afferent activity from these neurons enters the spinal cord between T1 and L2. Nociceptive C fibers from the esophagus, larynx, and trachea travel with the vagus nerve to enter the nucleus solitarius in the brainstem. Afferent pain fibers from the bladder, prostate, rectum, cervix and urethra, and genitalia are transmitted into the spinal cord via parasympathetic nerves at the level of the S2–S4 nerve roots. Though relatively few compared with somatic pain fibers, fibers from primary visceral afferent neurons enter the cord and synapse more diffusely with single fibers, often synapsing with multiple dermatomal levels and often crossing to the contralateral dorsal horn.

**2. Chemical Mediators of Pain**

Several neuropeptides and excitatory amino acids function as neurotransmitters for afferent neurons subserving pain (Table 47–4). Many, if not most, of these neurons contain more than one neurotransmitter, which are simultaneously released. The most important of these peptides are *substance P* and *calcitonin gene-related peptide* (CGRP). Glutamate is the most important excitatory amino acid.

$^1$NMDA, N-methyl-D-aspartate; AMPA, 2-(aminomethyl)phenylacetic acid; 5-HT, 5-hydroxytryptamine.

Substance P is an 11-amino-acid peptide that is synthesized and released by first-order neurons both peripherally and in the dorsal horn. Also found in other
parts of the nervous system and the intestines, it facilitates transmission in pain pathways via neurokinin-1 receptor activation. In the periphery, substance P neurons send collaterals that are closely associated with blood vessels, sweat glands, hair follicles, and mast cells in the dermis. Substance P sensitizes nociceptors, degranulates histamine from mast cells and 5-HT from platelets, and is a potent vasodilator and chemoattractant for leukocytes. Substance P–releasing neurons also innervate the viscera and send collateral fibers to paravertebral sympathetic ganglia; intense stimulation of viscera, therefore, can cause direct postganglionic sympathetic discharge.

Both opioid and α2-adrenergic receptors have been described on or near the terminals of unmyelinated peripheral nerves. Although their physiological role is not clear, the latter may explain the observed analgesia of peripherally applied opioids, particularly in the presence of inflammation.

3. Modulation of Pain

Modulation of pain occurs peripherally at the nociceptor, in the spinal cord, and in supraspinal structures. This modulation can either inhibit (suppress) or facilitate (intensify) pain.

Peripheral Modulation of Pain

Nociceptors and their neurons display sensitization following repeated stimulation. Sensitization may be manifested as an enhanced response to noxious stimulation or a newly acquired responsiveness to a wider range of stimuli, including nonnoxious stimuli.

A. Primary Hyperalgesia

Sensitization of nociceptors results in a decrease in threshold, an increase in the frequency response to the same stimulus intensity, a decrease in response latency, and spontaneous firing even after cessation of the stimulus (afterdischarges). Such sensitization, termed primary hyperalgesia, commonly occurs with injury and following application of heat and is mediated by the release of noxious substances from damaged tissues. Histamine is released from mast cells, basophils, and platelets, whereas serotonin is released from mast cells and platelets. Bradykinin is released from tissues following activation of factor XII. Bradykinin activates free nerve endings via specific B1 and B2 receptors.

Prostaglandins are produced following tissue damage by the action of
phospholipase A$_2$ on phospholipids released from cell membranes to form arachidonic acid (Figure 47–5). The cyclooxygenase (COX) pathway then converts the latter into endoperoxides, which in turn are transformed into prostacyclin, prostaglandins and thromboxanes. The lipoxygenase pathway converts arachidonic acid into hydroperoxy compounds, which are subsequently converted into leukotrienes. Acetylsalicylic acid (aspirin), nonsteroidal antiinflammatory drugs (NSAIDs), and likely also acetaminophen produce analgesia by inhibition of COX. The analgesic effect of corticosteroids is likely the result of inhibition of prostaglandin production through blockade of phospholipase A$_2$ activation.

**FIGURE 47–5** Phospholipase C (PLC) catalyzes the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP$_2$) to produce inositol triphosphate (IP$_3$) and diacylglycerol (DAG). Protein kinase C (PKC) is also important. Phospholipase A$_2$ (PLA$_2$) catalyzes the conversion of phosphatidylcholine (PC) to arachidonic acid (AA).

**B. Secondary Hyperalgesia**

*Neurogenic inflammation*, also called *secondary hyperalgesia*, plays an important role in peripheral sensitization following injury. It is manifested by the *triple response of Lewis*: a red flush around the site of injury (*flare*), local tissue edema, and sensitization to noxious stimuli. Secondary hyperalgesia is primarily due to antidromic release of substance P (and probably CGRP). Substance P degranulates histamine and 5-HT, vasodilates blood vessels, causes tissue edema, and induces the formation of leukotrienes. The neural origin of this response is supported by the following findings: (1) it can be produced by electrical stimulation of a sensory nerve, (2) it is not observed in denervated
skin, and (3) it is diminished by injection of a local anesthetic. *Capsaicin* applied topically in a gel, cream, or patch depletes substance P, diminishes neurogenic inflammation, and is useful for some patients with postherpetic neuralgia.

**Central Modulation of Pain**

**A. Facilitation**

At least three mechanisms are responsible for *central sensitization* in the spinal cord:

1. Wind-up and sensitization of second-order neurons. WDR neurons increase their frequency of discharge with the same repetitive stimuli and exhibit prolonged discharge, even after afferent C fiber input has stopped.

2. Receptive field expansion. Dorsal horn neurons increase their receptive fields such that adjacent neurons become responsive to stimuli (whether noxious or not) to which they were previously unresponsive.

3. Hyperexcitability of flexion reflexes. Enhancement of flexion reflexes is observed both ipsilaterally and contralaterally.

   Neurochemical mediators of central sensitization include substance P, CGRP, vasoactive intestinal peptide (VIP), cholecystokinin (CCK), angiotensin, and galanin, as well as the excitatory amino acids L-glutamate and L-aspartate. These substances trigger changes in membrane excitability by interacting with G protein–coupled membrane receptors on neurons (Figure 47–5).

   Glutamate and aspartate play important roles in wind-up, via activation of N-methyl-D-aspartate (NMDA) and other receptor mechanisms, and in the induction and maintenance of central sensitization. Activation of NMDA receptors also induces nitric oxide synthetase, increasing formation of nitric oxide. Both prostaglandins and nitric oxide facilitate the release of excitatory amino acids in the spinal cord. Thus, COX inhibitors such as acetylsalicylic acid (ASA) and NSAIDs have important analgesic actions in the spinal cord.

**B. Inhibition**

Transmission of nociceptive input in the spinal cord can be inhibited by segmental activity in the cord itself, as well as by descending neural activity from supraspinal centers.

1. **Segmental inhibition**—Activation of large afferent fibers subserving
sensation inhibits WDR neuron and spinothalamic tract activity. Moreover, activation of noxious stimuli in noncontiguous parts of the body inhibits WDR neurons at other levels, which may explain why pain in one part of the body inhibits pain in other parts. These two phenomena support a “gate” theory for pain processing in the spinal cord as initially hypothesized by Melzack and Wall.

Glycine and γ-aminobutyric acid (GABA) are amino acids that function as inhibitory neurotransmitters and likely play an important role in segmental inhibition of pain in the spinal cord. Antagonism of glycine and GABA results in powerful facilitation of WDR neurons and produces allodynia and hyperesthesia. There are two subtypes of GABA receptors: GABA$_A$, of which muscimol is an agonist, and GABA$_B$, of which baclofen is an agonist. Segmental inhibition appears to be mediated by GABA$_B$ receptor activity. The GABA$_A$ receptor functions as a Cl⁻ channel, and benzodiazepines activate this channel. Activation of glycine receptors also increases Cl⁻ conductance across neuronal cell membranes. Adenosine also modulates nociceptive activity in the dorsal horn. At least two receptors are known: A$_1$, which inhibits adenyl cyclase, and A$_2$, which stimulates adenyl cyclase. The A$_1$ receptor mediates adenosine’s antinociceptive action.

2. **Supraspinal inhibition**—Several supraspinal structures send fibers down the spinal cord to inhibit pain in the dorsal horn. Important sites of origin for these descending pathways include the periaqueductal gray, reticular formation, and nucleus raphe magnus (NRM). Stimulation of the periaqueductal gray area in the midbrain produces widespread analgesia in humans. Axons from these tracts act presynaptically on primary afferent neurons and postsynaptically on second-order neurons (or interneurons). These pathways mediate their antinociceptive action via $\alpha_2$-adrenergic, serotonergic, and opiate ($\mu$, $\delta$, and $\kappa$) receptor mechanisms. These pathways explain the analgesic efficacy of antidepressants that block reuptake of catecholamines and serotonin.

Inhibitory adrenergic pathways originate primarily from the periaqueductal gray area and the reticular formation. Norepinephrine mediates this action via activation of presynaptic or postsynaptic $\alpha_2$ receptors. At least part of the descending inhibition from the periaqueductal gray is relayed first to the NRM and medullary reticular formation; serotonergic fibers from the NRM then relay the inhibition to dorsal horn neurons via the dorsolateral funiculus.

The *endogenous opiate system* (primarily the NRM and reticular formation) acts via methionine enkephalin, leucine enkephalin, and β-endorphin, all of which are antagonized by naloxone. These opioids act presynaptically to
hyperpolarize primary afferent neurons and inhibit the release of substance P; they also appear to cause some postsynaptic inhibition. Exogenous opioids preferentially act postsynaptically on the second-order neurons or interneurons in the substantia gelatinosa.

PATHOPHYSIOLOGY OF CHRONIC PAIN

Chronic pain may be caused by a combination of peripheral, central, and psychological mechanisms. Sensitization of nociceptors plays a major role in the origin of pain associated with peripheral mechanisms, such as chronic musculoskeletal and visceral disorders.

Neuropathic pain involves peripheral–central and central neural mechanisms that are complex and generally associated with partial or complete lesions of peripheral nerves, dorsal root ganglia, nerve roots, or more central structures (Table 47–5). Peripheral mechanisms include spontaneous discharges, sensitization of receptors (to mechanical, thermal, and chemical stimuli), and upregulation of adrenergic receptors. Neural inflammation may also be present. Systemic administration of local anesthetics and anticonvulsants has been shown to suppress the spontaneous firing of sensitized or traumatized neurons, and this laboratory observation is reinforced by the clinical efficacy of agents such as lidocaine, mexiletine, and carbamazepine in many patients with neuropathic pain. Central mechanisms include loss of segmental inhibition, wind-up of WDR neurons, spontaneous discharges in deafferentated neurons, and reorganization of neural connections.

The sympathetic nervous system appears to play a major role in some patients with chronic pain. The efficacy of sympathetic nerve blocks in some of these patients supports the concept of sympathetically maintained pain. Painful disorders that often respond to sympathetic blocks include complex regional pain syndrome, deafferentation syndromes due to nerve avulsion or amputations, and postherpetic neuralgia. However, the simplistic theory of heightened sympathetic activity resulting in vasoconstriction, edema, and hyperalgesia fails to account for the warm and erythematous phase observed in some patients. Similarly, clinical and experimental observations do not satisfactorily support the theory of ephaptic transmission between pain fibers and demyelinated sympathetic fibers.

Psychological mechanisms or environmental factors are rarely the sole mechanisms for chronic pain but are commonly seen in combination with other mechanisms (Table 47–6).

**SYSTEMIC RESPONSES TO PAIN**

**Systemic Responses to Acute Pain**
Acute pain is typically associated with a systemic neuroendocrine stress response that is proportional to pain intensity. The pain pathways mediating the afferent limb of this response are discussed above. The efferent limb is mediated by the sympathetic nervous and endocrine systems. Sympathetic activation increases efferent sympathetic tone to all viscera and releases catecholamines from the adrenal medulla. The hormonal response results from increased sympathetic tone and from hypothalamically-mediated reflexes. **Moderate to severe acute pain, regardless of site, may adversely affect perioperative morbidity, mortality, and convalescence.**

A. **Cardiovascular Effects**
Cardiovascular effects of acute pain often include hypertension, tachycardia, enhanced myocardial irritability, and increased systemic vascular resistance. Cardiac output increases in most normal patients but may decrease in patients with compromised ventricular function. Because of the increase in myocardial oxygen demand, pain can worsen or precipitate myocardial ischemia.

B. **Respiratory Effects**
An increase in total body oxygen consumption and carbon dioxide production necessitates a concomitant increase in minute ventilation. The latter increases the work of breathing, particularly in patients with underlying lung disease. Pain due to abdominal or thoracic incisions further compromises pulmonary function because of guarding (splinting). Decreased movement of the chest wall reduces tidal volume and functional residual capacity, promoting atelectasis, intrapulmonary shunting, hypoxemia, and, less commonly, hypoventilation. Reductions in vital capacity impair coughing and clearing of secretions.

C. **Gastrointestinal and Urinary Effects**
Enhanced sympathetic tone increases sphincter tone and decreases intestinal and urinary bladder motility, promoting ileus and urinary retention. Hypersecretion of gastric acid can promote stress ulceration. Nausea, vomiting, and constipation are common. In addition, systemic opioids used to treat postoperative pain (and also administered as a component of the operative anesthetic) are a common cause of postoperative ileus and urinary retention.

D. **Endocrine Effects**
Stress increases release of catabolic hormones (catecholamines, cortisol, and glucagon) and inhibits release of anabolic hormones (insulin and testosterone).
Patients develop a negative nitrogen balance, carbohydrate intolerance, and increased lipolysis. The increase in cortisol, renin, angiotensin, aldosterone, and antidiuretic hormone results in sodium retention, water retention, and secondary expansion of the extracellular space.

**E. Hematological Effects**
The neuroendocrine stress response to acute pain may increase platelet adhesiveness, reduce fibrinolysis, and promote a hypercoagulability state.

**F. Immune Effects**
The neuroendocrine stress response produces leukocytosis and may predispose patients to infection. Worsening carbohydrate intolerance with sustained hyperglycemia also increases the risk of infection. Stress-related immunodepression may enhance tumor growth and metastasis.

**G. Psychological Effects**
Anxiety and sleep disturbances are common reactions to acute pain. With prolonged duration of the pain, depression is not unusual. Some patients react with frustration and anger that may be directed at family, friends, and the medical staff.

**Systemic Responses to Chronic Pain**
The neuroendocrine stress response in the setting of chronic pain is generally observed only in patients with severe recurring pain due to peripheral (nociceptive) mechanisms and in patients with prominent central mechanisms such as pain associated with paraplegia. It is attenuated or absent in most patients with chronic pain. Sleep and affective disturbances, particularly depression, are often prominent. Many patients also experience significant decreases or increases in appetite and psychological stress related to social relationships.

**Evaluation of the Patient with Chronic Pain**

- The evaluation of any patient with pain should include several key components. Information about location, onset, and quality of pain, as well as alleviating and exacerbating factors, should be obtained, along with a
pain history that includes previous therapies and changes in symptoms over time. In addition to physical symptoms, chronic pain usually involves a psychological component that should be addressed. Questionnaires, diagrams, and pain scales are useful tools that help patients adequately describe the characteristics of their pain and how it affects their quality of life. Information gathered during the physical examination can help distinguish pain location, type, and systemic sequelae, if any. Imaging studies such as plain radiographs, computed tomography (CT), magnetic resonance imaging (MRI), and bone scans can often help delineate physiological causes. All components are necessary for a comprehensive evaluation of the pain patient prior to determining appropriate treatment options.

PAIN MEASUREMENT

A reliable measurement of pain severity would help determine therapeutic interventions and evaluate the efficacy of treatments. This is a challenge, however, because pain is a subjective experience that is influenced by psychological, social, cultural, and other variables. Clear definitions are necessary, as pain may be described in terms of tissue destruction or bodily or emotional reaction.

The numerical rating scale, Wong-Baker FACES rating scale, visual analog scale (VAS), and McGill Pain Questionnaire (MPQ) are most commonly used. In the numerical scale, 0 corresponds to no pain and 10 is intended to reflect the worst possible pain. The Wong-Baker FACES pain scale, designed for children 3 years of age and older, is useful in patients with whom communication may be difficult. The patient is asked to point to various facial expressions ranging from a smiling face (no pain) to an extremely unhappy one that expresses the worst possible pain. The VAS is a 10-cm horizontal line labeled “no pain” at one end and “worst pain imaginable” on the other end. The patient is asked to mark on this line where the intensity of the pain lies. The distance from “no pain” to the patient’s mark numerically quantifies the pain. The VAS is a simple and efficient method that correlates well with other reliable methods.

The MPQ is a checklist of words describing symptoms. Unlike other pain rating methods that assume pain is one-dimensional and describe intensity but not quality, the MPQ attempts to define the pain in three major dimensions: (1) sensory–discriminative (nociceptive pathways), (2) motivational–affective (reticular and limbic structures), and (3) cognitive–evaluative (cerebral cortex). It contains 20 sets of descriptive words that are divided into four major groups: 10 sensory, 5 affective, 1 evaluative, and 4 miscellaneous. The patient selects the
sets that apply to his or her pain and circles the words in each set that best describe the pain.

**PSYCHOSOCIAL EVALUATION**

Psychosocial evaluation is useful whenever medical evaluation fails to reveal an apparent cause for pain, when pain intensity, characteristics, or duration are disproportionate to disease or injury, or when psychological or social issues, or both, are apparent. These types of evaluations help clarify the role of behavioral factors. The most commonly used psychological tests are the Minnesota Multiphasic Personality Inventory (MMPI) and Beck Depression Inventory. The MMPI is used primarily to confirm clinical impressions about the role of psychological factors; it cannot reliably distinguish between “organic” and “functional” pain. Depression is very common in patients with chronic pain. It is often difficult to determine the relative contribution of depression to the suffering associated with pain. The Beck Depression Inventory is a useful test for identifying patients with major depression.

Several tests have been developed to assess functional limitations or impairment (disability) and quality of life. These include the Multidimensional Pain Inventory (MPI), Medical Outcomes Survey 36-Item Short Form (SF-36), Pain Disability Index (PDI), and Oswestry Disability Index (ODI).

Emotional disorders are commonly associated with complaints of chronic pain, and chronic pain often results in varying degrees of psychological distress. Both the pain and emotional distress need to be treated. Table 47–7 lists emotional disorders in which treatment should be primarily directed at the emotional disorder.

**TABLE 47–7**  Emotional and related disorders commonly associated with chronic pain.
ELECTROMYOGRAPHY & NERVE CONDUCTION STUDIES

Electromyography and nerve conduction studies complement one another and are useful for confirming the diagnosis of entrapment syndromes, radicular syndromes, neural trauma, and polyneuropathies. They can often distinguish between neurogenic and myogenic disorders. Patterns of abnormalities can localize a lesion to the spinal cord, nerve root, limb plexus, or peripheral nerve. In addition, they may also be useful in clarifying the contribution of “organic”
Electromyography employs needle electrodes to record potentials in individual muscles. Muscle potentials are recorded first while the muscle is at rest and then as the patient is asked to move the muscle. Abnormal findings suggestive of denervation include persistent insertion potentials, the presence of positive sharp waves, fibrillar activity, or fasciculation potentials. Abnormalities in muscles produce changes in amplitude and duration as well as polyphasic action potentials. Peripheral nerve conduction studies employ supramaximal stimulations of motor or mixed sensorimotor nerve, whereas muscle potentials are recorded over the appropriate muscle. The time between the onset of the stimulation and the onset of the muscle potential (latency) is a measurement of the fastest conducting motor fibers in the nerve. The amplitude of the recorded potential indicates the number of functional motor units, whereas its duration reflects the range of conduction velocities in the nerve. Conduction velocity can be obtained by stimulating the nerve from two points and comparing the latencies. When a pure sensory nerve is evaluated, the nerve is stimulated while action potentials are recorded either proximally or distally (antidromic conduction).

Nerve conduction studies distinguish between mononeuropathies (due to trauma, compression, or entrapment) and polyneuropathies. The latter includes acute or chronic neuropathies that are widespread and symmetrical (eg, related to diabetes, alcohol abuse, malnutrition, toxins, or drugs such as chemotherapeutic agents), or that are focal but random (eg, mononeuropathy multiplex).

### Selected Pain Syndromes

#### ENTRAPMENT SYNDROMES

Neural compression may occur wherever a nerve courses through an anatomically narrowed passage, and *entrapment neuropathies* can involve sensory, motor, or mixed nerves. Genetic factors and repetitive macrotrauma or microtrauma are likely involved, and adjacent tenosynovitis is often responsible. Table 47–8 lists the most commonly recognized entrapment syndromes. When a sensory nerve is involved, patients complain of pain and numbness in its distribution distal to the site of entrapment; occasionally, a patient may complain of pain referred proximal to the site of entrapment. Entrapment of the sciatic nerve can mimic a herniated intervertebral disc. Entrapment of a motor nerve produces weakness in the muscles it innervates. Even entrapments of “pure”
motor nerves can produce a vague pain that may be mediated by afferent fibers from muscles and joints. The diagnosis can usually be confirmed by electromyography and nerve conduction studies. Neural blockade of the nerve with local anesthetic, with or without corticosteroid, may be diagnostic and may provide temporary pain relief. Treatment is usually symptomatic, with oral analgesics and temporary immobilization, but may eventually include operative decompression. Development of complex regional pain syndrome may respond to sympathetic blocks.

**MYOFASCIAL PAIN**

Myofascial pain syndromes are common disorders characterized by aching muscle pain, muscle spasm, stiffness, weakness, and, occasionally, autonomic dysfunction. Patients have discrete areas (trigger points) of marked tenderness in one or more muscles or the associated connective tissue. Palpation of the involved muscles may reveal tight, ropy bands over trigger points. Signs of autonomic dysfunction (vasoconstriction or piloerection) in the overlying muscles may be present. The pain characteristically radiates in a fixed pattern
that does not follow dermatomes.

Gross trauma or repetitive microtrauma may play a major role in initiating myofascial pain syndromes. Trigger points develop following acute injury; stimulation of these active trigger points produces pain, and the ensuing muscle spasm sustains the pain. When the acute episode subsides, the trigger points become latent (tender, but not pain-producing) only to be reactivated at a later time by subsequent stress. The pathophysiology is poorly understood.

The diagnosis of a myofascial pain syndrome is suggested by the character of the pain and by palpation of discrete trigger points that reproduce it. Common syndromes produce trigger points in the levator scapulae, masseter, quadratus lumborum, and gluteus medius muscles. The latter two syndromes produce low back pain and should be considered in all patients with back pain; moreover, gluteal trigger points can mimic S₁ radiculopathy.

Although myofascial pain may spontaneously resolve without sequelae, many patients continue to have latent trigger points. When trigger points are active, treatment is directed at regaining muscle length and elasticity. Analgesia may be provided utilizing local anesthetic (1–3 mL) trigger point injections. Topical cooling with either an ethyl chloride or fluorocarbon (fluoromethane) spray can also induce reflex muscle relaxation, facilitating massage (“stretch and spray”) and ultrasound therapy. Physical therapy is important in establishing and maintaining normal range of motion for affected muscles, and biofeedback may be helpful.

**FIBROMYALGIA**

The American College of Rheumatology recently identified three criteria that, if met, suggest the diagnosis of *fibromyalgia*:

1. Widespread Pain Index (WPI) score of 7 or higher, and Symptom Severity (SS) scale score of 5 or higher, or WPI of 3 to 6 and SS scale score of 9 or higher.
2. Symptoms present at a similar level for at least 3 months.
3. Absence of another disorder that would otherwise explain the pain.

Treatment of fibromyalgia includes cardiovascular conditioning, strength training, improving sleep hygiene, cognitive–behavioral therapy, patient education, and pharmacotherapy. Medications approved by the U.S. Food and Drug Administration (FDA) for the treatment of fibromyalgia include pregabalin
(Lyrica), duloxetine (Cymbalta), and milnacipran (Savella).

LOW BACK PAIN & RELATED SYNDROMES

Back pain is a common complaint and a major cause of disability. Lumbosacral strain, degenerative disc disease, and myofascial syndromes are the most common causes. Low back pain, with or without associated leg pain, may also have congenital, traumatic, degenerative, inflammatory, infectious, metabolic, psychological, and neoplastic causes. Moreover, back pain can be due to disease processes in the abdomen and pelvis, particularly those affecting retroperitoneal structures (pancreas, kidneys, ureters, and aorta), the uterus and adnexa, the prostate, and the rectosigmoid colon. Disorders of the hip can also mimic back disorders. A positive Patrick’s sign (or Patrick’s test)—ie, the elicitation of pain in the hip or sacroiliac joint when the examiner places the ipsilateral heel of the supine patient on the contralateral knee and presses down on the ipsilateral knee—helps identify back pain due to hip or sacroiliac joint disorders. This sign is also referred to by the acronym FABERE (sign), because the movement of the leg involves flexion, abduction, external rotation, and extension.

1. Applied Anatomy of the Back

The back can be described in terms of anterior and posterior elements. The anterior elements consist of cylindrical vertebral bodies interconnected by intervertebral discs and supported by anterior and posterior longitudinal ligaments. The posterior elements are bony arches extending from each vertebral body, consisting of two pedicles, two transverse processes, two laminae, and a spinous process. The transverse and spinous processes provide points of attachment for the muscles that move and protect the spinal column. Adjacent vertebrae also articulate posteriorly by two gliding facet joints.

Spinal structures are innervated by the sinuvertebral branches and posterior rami of spinal nerves. The sinuvertebral nerve arises before each spinal nerve divides into anterior and posterior rami, and reenters the intervertebral foramen to innervate the posterior longitudinal ligament, the posterior annulus fibrosus, periosteum, dura, and epidural vessels. Paraspinal structures are supplied by the posterior primary ramus. Each facet joint is innervated by the medial branch of the posterior primary rami of the spinal nerves above and below the joint.

As lumbar spinal nerve roots exit the dural sac, they travel down 1 to 2 cm laterally before exiting through their respective intervertebral foramina; thus, for example, the L5 nerve root leaves the dural sac at the level of the L4–L5 disc
(where it is more likely to be compressed) but leaves the spinal canal beneath the L5 pedicle opposite the L5–S1 disc.

2. **Paravertebral Muscle & Lumbosacral Joint Sprain/Strain**

Approximately 80% to 90% of low back pain is due to sprain or strain associated with lifting heavy objects, falls, or sudden abnormal movements of the spine. The term *sprain* is generally used when the pain is related to a well-defined acute injury, whereas *strain* is used when the pain is more chronic and is likely related to repetitive minor injuries.

Injury to paravertebral muscles and ligaments results in reflex muscle spasm, which may or may not be associated with trigger points. The pain is usually dull and aching, and occasionally radiates down the buttocks or hips. Sprain is a self-limited benign process that resolves in 1 to 2 weeks. Symptomatic treatment consists of rest and oral analgesics.

The sacroiliac joint is particularly vulnerable to rotational injuries. It is one of the largest joints in the body and functions to transfer weight from the upper body to the lower extremities. Acute or chronic injury can cause slippage, or *subluxation*, of the joint. Pain originating from this joint is characteristically located along the posterior ilium and radiates down the hips and posterior thigh to the knees. The diagnosis is suggested by tenderness on palpation, particularly on the medial aspect of the posterior superior iliac spine, and by compression of the joints. Pain relief following injection of the joint with local anesthetic (3 mL) is diagnostic and may also be therapeutic. Injection of intraarticular steroid medication may be considered. For potentially longer duration of analgesia, radiofrequency ablation may be performed at the dorsal ramus of L5 as well as the lateral branches of the S1, S2, and S3 nerves if the patient initially responded well to local anesthetic injections of the sacroiliac joint or to diagnostic injections of these nerves.

3. **Buttock Pain**

Buttock pain may be due to several different factors and can be quite debilitating. *Coccydynia* may result from trauma to the coccyx or surrounding ligaments. It may resolve by means of physical therapy, coccygeal nerve blocks to the lateral aspects of the coccyx, or ablative or neuromodulatory techniques. *Piriformis syndrome* presents as pain in the buttock, which can be accompanied
by numbness and tingling in distribution of the sciatic nerve. The nerve may or may not be entrapped. Injection of local anesthetic into the belly of this muscle or into trigger points located at the origin and insertion of the muscle may help relieve the pain.

4. **Degenerative Disc Disease**

Intervertebral discs bear at least one third of the weight of the spinal column. Their central portion, the nucleus pulposus, is composed of gelatinous material early in life. This material degenerates and becomes fibrotic with advancing age and following trauma. The nucleus pulposus is ringed by the annulus fibrosus, which is thinnest posteriorly and bounded superiorly and inferiorly by cartilaginous plates. *Discogenic pain* may be due to one of two major mechanisms: (1) protrusion or extrusion of the nucleus pulposus posteriorly or (2) loss of disc height, resulting in the reactive formation of bony spurs (osteophytes) from the rims of the vertebral bodies above and below the disc. Degenerative disc disease most commonly affects the lumbar spine because it is subjected to the greatest motion and because the posterior longitudinal ligament is thinnest at L2–L5. Factors such as increased body weight and cigarette smoking may play a role in the development of lumbar disc disease. The role of the disc in producing chronic back pain is not clearly understood. In patients with persistent axial low back pain, the history and physical examination may provide clues. If the patient has pain when sitting or standing, or maintaining a certain position for an extended period of time, there may be an element of discogenic pain.

*Discography* is a procedure that is sometimes used to try to provide some objective evidence of the role of a given disc in producing a patient’s back pain. The opening pressure can be assessed via a needle inserted into the disc, and a subsequent injection of radiocontrast material typically produces increased pressure that may reproduce the patient’s pain and may provide radiographic identification of anatomic abnormalities within the disc (eg, a rent or tear). If the pain produced with injection is similar to that which the patient experiences on a daily basis, it is deemed *concordant* pain. If not, it is deemed *discordant*. In some circumstances, the pressure in the disc following injection is not significantly higher than the opening pressure, and this may be due to the presence of a fissure in the disc that tracks to the epidural space. Treatment options for discogenic pain include conservative therapy, steroid injections into the disc, heating the posterior annulus of the disc by way of radiofrequency ablation, and surgical fusion with bone graft or hardware placement; each option
has shown mixed degrees of success. The evaluation and treatment of discogenic pain is an area of significant controversy and ongoing research.

**Herniated (Prolapsed) Intervertebral Disc**

Weakness and degeneration of the annulus fibrosus and posterior longitudinal ligament can cause herniation of the nucleus pulposus posteriorly into the spinal canal. Ninety percent of disc herniations occur at L5–S1 or L4–L5. Symptoms usually develop following flexion injuries or heavy lifting and may be associated with bulging, protrusion, or extrusion of the disc. Disc herniations usually occur posterolaterally and often result in compression of adjacent nerve roots, producing pain that radiates along that dermatome (*radiculopathy*, or *radicular pain*). *Sciatica* describes pain along the sciatic nerve due to compression of the lower lumbar nerve roots. When disc material is extruded through the annulus fibrosus and posterior longitudinal ligament, free fragments can become wedged in the spinal canal or the intervertebral foramina. Less commonly a large disc bulges or large fragments extrude posteriorly, compressing the cauda equina in the dural sac; in these instances, patients can experience bilateral pain, urinary retention, or, less commonly, fecal incontinence.

Pain associated with disc disease is aggravated by bending, lifting, prolonged sitting, or anything that increases intraabdominal pressure, such as sneezing, coughing, or straining. It is usually relieved by lying down. Numbness or weakness is indicative of radiculopathy (Table 47–9). Bulging of the disc through the posterior longitudinal ligament can also produce low back pain that radiates to the hips or buttocks. Straight leg-raising tests may be used to assess nerve root compression. With the patient supine and the knee fully extended, the leg on the affected side is raised and the angle at which the pain develops is noted; dorsiflexion of the ankle with the leg raised typically exacerbates the pain by further stretching the lumbosacral plexus. Pain while raising the contralateral leg is an even more reliable sign of nerve compression.

</table>
Magnetic resonance imaging (MRI) of the spine has increased dramatically in the past decade in association with a severalfold increase in back surgeries, without improved patient outcome. The American Pain Society’s clinical practice guidelines for low back pain do not recommend routine imaging or other diagnostic tests for patients with nonspecific low back pain. Up to 30% to 40% of asymptomatic persons have abnormalities of spinal structures on CT or MRI. In addition, the patient’s awareness of his or her imaging abnormalities may influence self-perception of health and functional ability.

Imaging studies and other tests should be obtained when severe or progressive neurological deficits are present, or when serious underlying conditions are suspected. CT myelography is the most sensitive test for evaluating subtle neural compression. Discography may be considered when the pain pattern does not match the clinical findings. A centrally herniated disc will usually cause pain at the lower level, and a laterally protruded disc will cause pain at the same level as the disc. For example, a centrally located disc herniation at L4–L5 may compress the L5 nerve root whereas a laterally located disc herniation at this level may compress the L4 nerve root.

The natural course of herniated disc disorders is generally benign and the duration of pain is usually less than 2 months. Over 75% of patients treated nonsurgically, even those with radiculopathy, experience complete or near-complete pain relief. The goals of treatment should therefore be to alleviate the pain and to rehabilitate the patient to return to a maximally functional quality of life. Acute back pain due to a herniated disc can be initially managed with modification of activity and with medications such as NSAIDs and acetaminophen. A short course of opioids may be considered for patients with severe pain. After the acute symptoms subside, the patient can be referred to a physical therapist for instruction on exercises to improve lower back health. Patients who smoke tobacco should be advised to stop smoking, not only for the obvious health benefits but also because nicotine further compromises blood flow to the relatively avascular intervertebral disc. Percutaneous disc decompression involving extraction of a small amount of nucleus pulposus may help to decompress the nerve root. For patients with acute-onset weakness correlating with the level of the disc herniation, surgical management should be considered.

When symptoms persist beyond 3 months, the pain may be considered chronic and may require a multidisciplinary approach. Physical therapy continues to be a very important component of rehabilitation. NSAIDs and antidepressants are also helpful, and percutaneous interventions may be
considered. Of note, back supports should be discouraged because they may weaken paraspinal muscles.

**Spinal Stenosis**

*Spinal stenosis* is a disease of advancing age. Degeneration of the nucleus pulposus reduces disc height and leads to osteophyte formation (*spondylosis*) at the endplates of adjoining vertebral bodies. In conjunction with facet joint hypertrophy and with ligamentum flavum hypertrophy and calcification, this process leads to progressive narrowing of the neural foramina and spinal canal. Neural compression may cause radiculopathy that mimics a herniated disc. Extensive osteophyte formation may compress multiple nerve roots and cause bilateral pain. The back pain usually radiates into the buttocks, thighs, and legs. It is characteristically worse with exercise and relieved by rest, particularly sitting with the spine flexed (*shopping cart sign*). The terms *pseudoclaudication* and *neurogenic claudication* are used to describe such pain that develops with prolonged standing or ambulation. The diagnosis is suggested by the clinical presentation and is confirmed by MRI, CT, or myelography. Electromyography and nerve conduction studies may be useful in evaluating the degree of neurological compromise.

Patients with mild to moderate stenosis and radicular symptoms may obtain benefit from epidural steroid injections via a transforaminal, interlaminar, or caudal approach, which may help these individuals tolerate physical therapy. Those with moderate to severe stenosis may be candidates for the minimally invasive lumbar decompression (MILD) procedure, which involves percutaneously sculpting the lamina and ligamentum flavum to reduce central canal compression. Severe, multilevel symptoms may warrant surgical decompression.

**5. Facet Syndrome**

Degenerative changes in the facet (zygapophyseal) joints may also produce back pain. Pain may be near the midline; may radiate to the gluteal region, thigh, and knee; and may be associated with muscle spasm. Hyperextension and lateral rotation of the spine usually exacerbate the pain. The diagnosis may be confirmed if pain relief is obtained following intraarticular injection of local anesthetic solution into affected joints or by blockade of the medial branch of the posterior division (ramus) of the spinal nerves that innervate them. Long-term studies suggest that medial branch nerve blocks are more effective than facet
joint injections. Medial branch rhizotomy may provide long-term analgesia for patients with facet joint disease.

6. Cervical Pain

Although most spine-related pain due to disc disease, spinal stenosis, or degenerative changes in the zygapophyseal joints is felt in the low back and lower extremities, patients may have cervical pain attributed to these processes. A key anatomic difference is that the cervical nerve roots, unlike those in the thoracic and lumbar spine, exit the foramina above the vertebral bodies for which they are named. This occurs until the level of C7, where the extra cervical nerve roots, C8, exit below the pedicles of C7, thus transitioning to the nomenclature of the thoracic- and lumbar-level vertebral bodies and nerve root denominations. The clinical examination may help to identify the nerve root that is affected with confirmation by a selective nerve root block. Risks inherent with percutaneous cervical procedures include accidental intravascular injection of local anesthetic or steroid. Particulate steroid injections in the neck have been associated with devastating outcomes and should be avoided.

For primarily axial pain in the neck with extension into the head or to the shoulders, cervical medial branch blocks may clarify the diagnosis. Long-term analgesia may be obtained with radiofrequency ablation of the medial branches innervating the zygapophyseal joints.

7. Congenital Abnormalities

Congenital abnormalities of the back may be asymptomatic and remain occult for many years. Abnormal spinal mechanics can make the patient prone to back pain, and in some instances, progressive deformities. Relatively common anomalies include sacralization of L5 (the vertebral body is fused to the sacrum), lumbarization of S1 (it functions as a sixth lumbar vertebra), spondylolysis (disruption of the pars interarticularis), spondylolisthesis (displacement anteriorly of one vertebral body on the next due to disruption of the posterior elements, usually the pars interarticularis), and spondyloptosis (subluxation of one vertebral body on another resulting in one body in front of the next). These diagnoses are made with radiographic imaging studies. Spinal fusion may be necessary in patients with progressive symptoms and spinal instability.

8. Tumors
A wide range of benign and malignant tumors may lead to back pain. When diagnosed by imaging these tumors will be managed by neurosurgeons, radiotherapists, and or medical oncologists, not by pain specialists.

9. **Infection**

Bacterial infections of the spine usually begin as a discitis before progressing to osteomyelitis, and can be due to pyogenic as well as tuberculous organisms. Patients may present with chronic back pain without fever or leukocytosis (eg, spinal tuberculosis). Those with acute discitis, osteomyelitis, or epidural abscess present with acute pain, fever, leukocytosis, elevated sedimentation rate, and elevated C-reactive protein, warranting immediate initiation of antibiotics. Urgent surgical intervention is indicated when the patient also suffers from acute weakness.

10. **Arthritides**

*Ankylosing spondylitis* is a familial disorder that is associated with the HLA-B27 antigen. It typically presents as low back pain associated with early morning stiffness in a young male patient. The pain has an insidious onset and may initially improve with activity. After a few months to years, the pain gradually intensifies and is associated with progressively restricted movement of the spine. Diagnosis may be difficult early in the disease, but radiographic evidence of sacroiliitis is usually present. As the disease progresses, the spine develops a characteristic “bamboo-like” radiographic appearance. Some patients develop arthritis of the hips and shoulders, as well as extraarticular inflammatory manifestations. Treatment is primarily directed at functional preservation of posture. NSAIDs are effective analgesics that reduce the early morning stiffness. Anti–tumor necrosis factor-α agents, including infliximab (Remicade), etanercept (Enbrel), adalimumab (Humira), and golimumab (Simponi), decrease the progression of ankylosing spondylitis when administered early in the course of therapy. However, patients treated with these medications may be at increased risk for infection and for the development of lymphoma.

Patients with Reiter syndrome, psoriatic arthritis, or inflammatory bowel disease may also present with low back pain, but extraspinal manifestations are usually more prominent. Rheumatoid arthritis usually spares the spine except for the zygapophyseal joints of the cervical spine.
NEUROPATHIC PAIN

Neuropathic pain tends to be paroxysmal and sometimes lancinating with a burning quality, and is usually accompanied by hyperpathia. It is associated with diabetic neuropathy, causalgia, phantom limbs, postherpetic neuralgia, stroke, spinal cord injury, and multiple sclerosis. Cancer pain and chronic low back pain may also have prominent neuropathic components. Mechanisms of neuropathic pain are reviewed earlier in this chapter.

Neuropathic pain is often difficult to treat, and multiple therapeutic modalities may be needed. Treatment options include anticonvulsants (eg, gabapentin, pregabalin), antidepressants (tricyclic antidepressants or serotonin-norepinephrine reuptake inhibitors), antiarrhythmics (mexiletine), α2-adrenergic agonists (clonidine), topical agents (lidocaine or capsaicin), and analgesics (NSAIDs and opioids). Of note, tricyclic antidepressants may have significant anticholinergic side effects that may limit their tolerability. Secondary amines, such as nortriptyline or desipramine, may have fewer or less severe anticholinergic side effects than tertiary amines such as amitriptyline or imipramine. Sympathetic blocks are effective in selected disorders (see later discussion). Spinal cord stimulation may be effective for patients who do not tolerate or respond to other treatments. Spinal opioids may be effective and appropriate for selected patients.

Diabetic Neuropathy

Diabetic neuropathy is the most common type of neuropathic pain and is a major cause of morbidity and disability. Its pathophysiology may be related to microangiopathy and to abnormal activation of glycation of proteins as a consequence of chronic hyperglycemia. Diabetic neuropathy may be symmetric (generalized), focal, or multifocal, affecting peripheral (sensory or motor), cranial, or autonomic nerves.

The most common diabetic neuropathy syndrome is peripheral polyneuropathy, which results in symmetric numbness (“stocking-and-glove” distribution), paresthesias, dysesthesias, and pain. The pain varies in intensity, may be severe, and is often worst at night. Loss of proprioception may lead to gait disturbances, and sensory deficits can lead to repetitive traumatic injuries. Isolated mononeuropathies affecting individual nerves may lead to wrist or foot drop or to cranial nerve palsy. Mononeuropathies typically have a sudden onset and are self-limiting, lasting a few weeks. Autonomic neuropathy typically affects the gastrointestinal tract, causing diarrhea, delayed gastric emptying, and
esophageal motility disorders. Orthostatic hypotension and other forms of autonomic dysfunction are common.

Treatment of diabetic neuropathy is symptomatic and directed at optimal glycemic control to slow progression. Acetaminophen and NSAIDs are usually ineffective for moderate to severe pain. Risks associated with opioids limit their use. Adjuvant drugs play a major role. The combination of an antiepileptic drug and a tricyclic antidepressant may be particularly effective.

**Sympathetically Maintained & Sympathetically Independent Pain**

*Complex regional pain syndrome* (CRPS) is a neuropathic pain disorder with significant autonomic features that is usually subdivided into two variants: *CRPS 1*, formerly known as *reflex sympathetic dystrophy* (RSD), and *CRPS 2*, formerly known as *causalgia*. The major difference between the two is the absence or presence, respectively, of documented nerve injury. Signs, symptoms, pathophysiology, and response to treatment are quite similar. Previously, this condition was thought to represent sympathetically maintained pain, but there is recent evidence that in some cases the pain may be sympathetically independent.

CRPS is a largely underdiagnosed condition affecting at least 50,000 patients a year in the United States alone. It affects individuals from childhood to late adulthood and may occur more commonly in females. Patients frequently present with burning neuropathic pain accompanied by hyperalgesia and allodynia. The autonomic nervous system may be involved, exemplified by alterations in sweating (sudomotor changes), color, and skin temperature, and by trophic changes in the skin, hair, or nails. Decreases in strength and range of motion in the affected extremity may be present. CRPS may develop after minimal injury, although the most common initiating events are surgery, fractures, crush injuries, and sprains.

The pathophysiology of CRPS 1 and 2 probably involves both the sympathetic nervous system and the central nervous system. There may be changes in the cutaneous innervation after a nerve injury, along with changes in central and peripheral sensitization. Genetic, inflammatory, and psychological factors may all play roles. Causalgia (which means burning pain), first identified by Weir Mitchell in injured veterans of the American Civil War, typically follows gunshot injuries or other major trauma to large nerves. The pain often has an immediate onset and is associated with allodynia, hyperpathia, and vasomotor and sudomotor dysfunction. It is exacerbated by factors that increase
sympathetic tone, such as fear, anxiety, light, noise, or touch. The syndrome has a variable duration that can range from days to months or may be permanent. Causalgia commonly affects the brachial plexus, particularly the median nerve, and the tibial division of the sciatic nerve in the lower extremity.

Patients with CRPS often respond to sympathetic blocks, but a multidisciplinary therapeutic approach must be utilized to avoid long-term functional and psychological disability. Some patients recover spontaneously, but if left untreated other patients can progress to severe and irreversible functional disability. Sympathetic blocks and intravenous regional sympatholytic blockade are equally effective; these blocks should be continued until either a cure is achieved or the response plateaus. The blocks facilitate physical therapy, which plays a central role and which typically consists of active movement without weights and of desensitization therapy. Many patients require a series of three to seven blocks. The likelihood of a cure is high (>90%) if treatment is initiated within 1 month of symptom onset and appears to decrease over time with therapeutic delay.

Some patients benefit from transcutaneous electrical nerve stimulation (TENS) therapy. Spinal cord stimulation can be particularly effective in both acute and chronic settings. In the acute phase of treatment, there is increasing interest in placing tunneled epidural catheters for infusion therapy, or percutaneous electrodes for extended trials of spinal cord stimulation, in order to help patients tolerate physical therapy. Many patients benefit from surgical implantation of peripheral nerve stimulators placed directly on larger injured nerves.

For sympathetically maintained pain, oral α-adrenergic blockers, such as the nonselective phenoxybenzamine or the α₁-selective prazosin, may be beneficial. Orthostatic hypotension may occur with these agents, and dosage should be increased gradually. Anticonvulsant and antidepressant medications may also be beneficial.

Surgical sympathectomy in patients with chronic symptoms frequently results in only transient relief and, in some cases, a new, alternate pain syndrome. Patients with pain refractory to prior medical or procedural therapies may respond to intravenous ketamine infusions in a monitored setting.

**ACUTE HERPES ZOSTER & POSTHERPETIC NEURALGIA**

During an initial childhood chickenpox infection, the varicella-zoster virus
(VZV) infects dorsal root ganglia, where it remains latent until reactivation. Acute herpes zoster, which represents VZV reactivation, manifests as an erythematous vesicular rash in a dermatomal distribution that is usually associated with severe pain. Dermatomes T3–L3 are most commonly affected. The pain often precedes the rash by 48 to 72 h, and the rash usually lasts 1 to 2 weeks. Herpes zoster is most common in elderly and immunocompromised patients but may occur at any age. It is typically a self-limited disorder in younger, healthy patients (<50 years old). Treatment is primarily supportive, consisting of oral analgesics and oral acyclovir, famciclovir, ganciclovir, or valacyclovir. Antiviral therapy reduces the duration of the rash and speeds healing. Immunocompromised patients with disseminated infection (nondermatomal distribution of vesicles) require intravenous acyclovir therapy.

The incidence of severe, radicular pain following resolution of acute herpes zoster, a condition termed postherpetic neuralgia (PHN), is estimated to be 50% in patients older than 50 years of age. PHN is often very difficult to treat. An oral course of corticosteroids during acute zoster may decrease the incidence of PHN but remains controversial and may increase the likelihood of viral dissemination in immunocompromised patients. Sympathetic blocks performed during the acute episode of herpes zoster often produce excellent analgesia and may decrease the incidence of PHN, although this is controversial. Some studies suggest that when sympathetic blocks are initiated within 2 months of the rash, PHN resolves in up to 80% of patients. Once the neuralgia is well established, however, sympathetic blocks, like other treatments, are generally ineffective. Antidepressants, anticonvulsants, and TENS may be useful in some patients. Tricyclic antidepressants may be particularly effective, though their use is often limited by anticholinergic side effects. Application of a transdermal lidocaine 5% patch (Lidoderm) over the most painful area may help relieve symptoms, presumably by decreasing peripheral sensitization of nerve endings and receptors. Application of capsaicin cream or a transdermal capsaicin 8% patch (Qutenza) may be helpful; however, Qutenza must be administered in a monitored setting. Administration of EMLA (eutectic mixture of local anesthetic) cream 1 h before application of the transdermal capsaicin patch may decrease the incidence and severity of pain from the capsaicin in the patch. Epidural steroid injections have not been proven to prevent postherpetic neuralgia.

**HEADACHE**

Headache is a common complaint that affects nearly everyone at some time in
life. In the vast majority of cases, headaches are not of sufficient severity or frequency for the individual to seek medical attention and do not reflect a serious underlying disorder. However, as with other complaints of pain, the possibility of a clinically significant underlying disorder should always be considered. The practitioner should solicit other associated symptoms or clinical findings that suggest serious underlying pathology. Table 47–10 lists important causes of headache. Disorders in which the primary complaint is headache are considered in the following discussion. As will become apparent, there is significant variability in clinical presentation and overlap in the symptoms of the major headache syndromes, particularly between tension and migraine headaches.

Tension Headache

Tension headaches are classically described as tight, bandlike pain or discomfort that is often associated with neck muscle tightness. The headache may be frontal, temporal, or occipital, and is more often bilateral than unilateral. Intensity typically builds gradually and fluctuates, lasting hours to days. They may be associated with emotional stress or depression. Treatment is symptomatic and most commonly consists of NSAIDs or acetaminophen, or both, with caffeine often combined with both of these agents in a single medication.

Migraine Headache

Migraine headaches are typically described as throbbing or pounding and are often associated with photophobia, scotoma, nausea and vomiting, and localized transient neurological dysfunction (aura). The latter may be sensory, motor, visual, or olfactory. Classic migraines by definition are preceded by an aura, whereas common migraines are not. The pain lasts 4 to 72 h and is usually unilateral, but can be bilateral with a frontotemporal location. Migraines primarily affect children (both sexes equally) and young adults (predominantly
females). A family history is often present. Provocation by odors, certain foods (eg, red wine), menses, and sleep deprivation is common. Sleep characteristically relieves the headache. The pathophysiology is complex and may include vasomotor, autonomic (serotonergic brainstem systems), and trigeminal nucleus dysfunction. Treatment is both abortive and prophylactic. Rapid abortive treatment includes oxygen, sumatriptan (6 mg subcutaneously), dihydroergotamine (1 mg intramuscularly or subcutaneously), intravenous lidocaine (100 mg), nasal butorphanol (1–2 mg), and sphenopalatine ganglion block. Other abortive options include zolmitriptan nasal spray, dihydroergotamine nasal spray, or an oral serotonin 5-HT_{1B/1D}-receptor agonist (almotriptan, frovatriptan, naratriptan, rizatriptan, eletriptan, or sumatriptan). Prophylactic treatment may include β-adrenergic blockers, calcium channel blockers, valproic acid, amitriptyline, and onabotulinumtoxinA (Botox) injections.

**Cluster Headache**

Cluster headaches are classically unilateral and periorbital, occurring in clusters of one to three attacks a day over a 4- to 8-week period. The pain is described as a burning or drilling sensation that may awaken the patient from sleep. Each episode lasts 30 to 120 min. Remissions lasting a year at a time are common. Red eye, tearing, nasal stuffiness, ptosis, and Horner syndrome are classic findings. The headaches are typically episodic but can become chronic without remissions. Cluster headaches primarily affect males (90%). Abortive treatments include oxygen and sphenopalatine block. Lithium, a short course of steroid medication, and verapamil may be used for prophylaxis.

**Temporal Arteritis**

Temporal arteritis is an inflammatory disorder of extracranial arteries. The headache can be bilateral or unilateral and is located in the temporal area in at least 50% of patients. The pain develops over a few hours, is usually dull in quality but may be lancinating at times, and is often worse at night and in cold weather. Scalp tenderness is usually present. Temporal arteritis is often accompanied by polymyalgia rheumatica, fever, and weight loss. It is a relatively common disorder of older patients (>55 years), with an incidence of about 1 in 10,000 per year and a slight female predominance. Early diagnosis and treatment with steroids is important because progression can lead to blindness through involvement of the ophthalmic artery.
Trigeminal Neuralgia

Trigeminal neuralgia (or tic douloureux) is classically unilateral and usually located in the V2 or V3 distribution of the trigeminal nerve. It has an electric shock quality, with episodes lasting from seconds to minutes at a time and is often provoked by contact with a discrete trigger. Facial muscle spasm may be present. Patients are middle-aged and elderly, with a 2:1 female-to-male ratio. Common causes of trigeminal neuralgia include compression of the nerve by the superior cerebellar artery as it exits the brainstem, multiple sclerosis, and cerebellopontine angle tumor. The drug of choice for treatment is carbamazepine, although it carries a risk of agranulocytosis. Phenytoin or baclofen may be added, particularly if patients do not tolerate the required doses of carbamazepine. More invasive treatments for patients who do not respond to drug therapy include glycerol injection, radiofrequency ablation, balloon compression of the gasserian ganglion, and microvascular decompression of the trigeminal nerve.

ABDOMINAL PAIN

Chronic abdominal pain has a variety of causes, and it is useful to distinguish between somatosensory, visceral, and centralized pain origins. A differential epidural block may help in elucidating the primary source but is time consuming and may be difficult to interpret. A transversus abdominis plane (TAP) blockade with ultrasound guidance may help treat somatosensory pain and thus may be potentially both diagnostic and therapeutic (see Chapter 46). The patient with pain of visceral origin may benefit from a celiac or splanchnic block.

CANCER-RELATED PAIN

Cancer-related pain may be due to the primary cancer lesion itself, metastatic disease, complications such as neural compression or infection, or treatment such as surgery, chemotherapy, or radiation therapy. In addition, the cancer patient may have acute or chronic pain that is entirely unrelated to the cancer. The pain manager must therefore have a thorough understanding of the nature of the cancer, its stage, the presence of metastatic disease, and treatments.

Cancer pain can be managed with oral analgesics in most patients. The World Health Organization recommends a progressive, three-step approach: (1) nonopioid analgesics such as aspirin, acetaminophen, or an NSAID for mild pain, (2) “weak” oral opioids such as codeine or oxycodone for moderate pain,
and (3) stronger opioids such as morphine or hydromorphone for severe pain (Tables 47–11 and 47–12). Parenteral therapy is necessary when patients have refractory pain, cannot take medication orally, or have poor enteral absorption. Regardless of the agent selected, in most instances drug therapy should be provided on a fixed time schedule rather than as needed. Adjuvant drug therapy, including antidepressants and anticonvulsants, may be used to both increase analgesia quality and decrease opioid-related side effects (Tables 47–13 and 47–14). Intrathecal drug delivery systems may improve analgesia and, via a drug-sparing effect, also help decrease side effects associated with oral or intravenous agents. Numerous intrathecal agents have been studied, and opioids have been utilized both alone and in combination with other medications. Ziconotide is a direct-acting N-type calcium-channel blocker that may be helpful for refractory pain or as a first-line agent. It acts by decreasing the release of substance P from the presynaptic nerve terminal in the dorsal horn of the spinal cord. Dose-dependent side effects include auditory hallucinations and worsening of preexisting depression or psychosis. It does not lead to significant withdrawal symptoms if abruptly discontinued.

1Efficacy in pain management may not correlate with blood level.

Surgery, radiation therapy, chemotherapy, and comprehensive palliative care may prolong survivorship for patients with cancer. However, survivorship may be accompanied by therapy-related acute or chronic pain, including radiation fibrosis or chemotherapy-induced peripheral neuropathy, or both.

**Interventional Therapies**

Interventional pain therapy options include pharmacological treatment, nerve blocks with local anesthetics and steroid or a neurolytic solution, radiofrequency
ablation, neuromodulatory techniques, or multidisciplinary treatment (psychological interventions, physical or occupational therapy, or modalities such as acupuncture).

**PHARMACOLOGICAL INTERVENTIONS**

Pharmacological interventions in pain management include acetaminophen, cyclooxygenase (COX) inhibitors, antidepressants, neuroleptic agents, anticonvulsants, corticosteroids, systemic administration of local anesthetics, and opioids.

**Acetaminophen**

Acetaminophen (paracetamol) is an oral analgesic and antipyretic agent that is also available as an intravenous preparation (Ofirmev). It inhibits prostaglandin synthesis but lacks significant antiinflammatory activity. Acetaminophen has few side effects but is hepatotoxic at high doses. The recommended adult maximum daily limit is 3000 mg/d, reduced from a previously recommended limit of 4000 mg/d. Isoniazid, zidovudine, and barbiturates may potentiate acetaminophen toxicity.

**Nonsteroidal Antiinflammatory Drugs (NSAIDs)**

Nonopiod oral analgesics include salicylates, acetaminophen, and NSAIDs (see Table 47–11). NSAIDs inhibit prostaglandin synthesis by inhibiting COX activity. Prostaglandins sensitize and amplify nociceptive input, and blockade of their synthesis results in the analgesic, antipyretic, and antiinflammatory properties characteristic of NSAIDs. At least two types of COX are recognized. COX-1 is found throughout body tissues, with functions including promotion of gastric mucus production, which protects the stomach lining, and stimulation of thromboxane A₂ production in platelets, which induces platelet aggregation.

COX-2 is induced primarily with inflammation. COX inhibitors likely have important peripheral and central nervous system actions. Their analgesic action is limited by side effects and toxicity at higher doses, especially peptic ulceration and kidney failure. Selective COX-2 inhibitors, such as celecoxib, have a lower risk of peptic ulceration but are associated with an increased risk of thrombotic events, including myocardial infarction. The COX-2 inhibitor rofecoxib (Vioxx) has been taken off the market in the United States for this reason. Some types of pain, particularly pain that follows orthopedic and gynecological surgery,
respond very well to COX inhibitors.

All of the nonopioid oral analgesic agents are well absorbed enterally. Food delays absorption but otherwise has no effect on bioavailability. Because most of these agents are highly protein bound (>80%), they can displace other highly bound drugs such as warfarin. All undergo hepatic metabolism and are excreted by the kidney. Dosages should therefore be reduced, or alternative medications selected, in patients with hepatic or kidney impairment.

The most common side effects of aspirin (acetylsalicylic acid, ASA) and other NSAIDs are stomach upset, heartburn, nausea, and ulceration of the gastric mucosa. Diclofenac is available as both an oral preparation and a topical gel or patch that may be less likely to contribute to gastric distress.

Other side effects of NSAIDs include dizziness, headache, and drowsiness. With the exception of selective COX-2 inhibitors, all COX inhibitors decrease platelet aggregation. Aspirin irreversibly inhibits platelet aggregation for 1 to 2 weeks, whereas the antiplatelet effect of other NSAIDs is reversible and lasts approximately five elimination half-lives (24–96 h). This inhibition of platelet aggregation does not appreciably increase the incidence of postoperative hemorrhage following most outpatient procedures. NSAIDs may exacerbate bronchospasm in patients with the triad of nasal polyps, rhinitis, and asthma. ASA should not be used in children with varicella or influenza infections because it may precipitate Reye syndrome. NSAIDs may cause acute kidney injury, particularly in patients with underlying kidney dysfunction.

**Antidepressants**

Antidepressants are most useful for patients with neuropathic pain and demonstrate an analgesic effect that occurs at a dose lower than that needed for antidepressant activity. Both of these actions are due to blockade of presynaptic reuptake of serotonin, norepinephrine, or both. Older tricyclic agents appear to be more effective analgesics than selective serotonin reuptake inhibitors (SSRIs). Serotonin and norepinephrine reuptake inhibitors (SNRIs) may provide the most favorable balance between analgesic efficacy and side effects. Antidepressants potentiate the action of opioids and frequently help normalize sleep patterns.

All antidepressant medications undergo extensive first-pass hepatic metabolism and are highly protein bound. Most are highly lipophilic and have large volumes of distribution. Elimination half-lives of most of these medications vary between 1 and 4 days, and many have active metabolites. Available agents differ in their side effects (see Table 47–13), which include
antimuscarinic effects (dry mouth, impaired visual accommodation, urinary retention, and constipation), antihistaminic effects (sedation and increased gastric pH), α-adrenergic blockade (orthostatic hypotension), and a quinidine-like effect (atrioventricular block, QT prolongation, torsades de pointes).

**Serotonin and Norepinephrine Reuptake Inhibitors**

The SNRIs milnacipran (Ixel, Savella, Dalcipran, Toledomin) and duloxetine (Cymbalta) have been approved in the United States for the treatment of fibromyalgia. Milnacipran has an elimination half-life of 8 h, is minimally metabolized by the liver, and is primarily excreted unchanged in the urine. Duloxetine (Cymbalta) is also useful in the treatment of neuropathic pain and depression. It has a half-life of 12 h and is metabolized by the liver, and most of its metabolites are excreted in the urine.

Absolute and relative contraindications for the use of SNRIs include known hypersensitivity, usage of other drugs that act on the central nervous system (including monoamine oxidase inhibitors), hepatic and kidney impairment, uncontrolled narrow-angle glaucoma, and suicidal ideation. Common side effects include nausea, headache, dizziness, constipation, insomnia, hyperhydrosis, hot flashes, vomiting, palpitations, dry mouth, and hypertension.

**Neuroleptics**

Neuroleptic medications may occasionally be useful for patients with refractory neuropathic pain, and may be most helpful in patients with marked agitation or psychotic symptoms. The most commonly used agents are fluphenazine (Prolixin), haloperidol (Haldol), chlorpromazine (Thorazine, Largactil), and perphenazine (Trilafon). Their therapeutic action appears to be due to blockade of dopaminergic receptors in mesolimbic sites. Unfortunately, the same action in nigrostriatal pathways can produce undesirable extrapyramidal side effects, such as masklike facies, a festinating gait, cogwheel rigidity, and bradykinesia. Some patients also develop acute dystonic reactions such as oculogyric crisis and torticollis. Long-term side effects include akathisia (extreme restlessness) and tardive dyskinesia (involuntary choreoathetoid movements of the tongue, lip smacking, and truncal instability). Like antidepressants, many of these drugs also have antihistaminic, antimuscarinic, and α-adrenergic–blocking effects.

**Antispasmodics & Muscle Relaxants**
Antispasmodics may be helpful for patients with musculoskeletal sprain and pain associated with spasm or contractures. Tizanidine (Zanaflex) is a centrally acting $\alpha_2$-adrenergic agonist used in the treatment of muscle spasm in conditions such as multiple sclerosis, low back pain, and spastic diplegia. Cyclobenzaprine (Flexeril) also may be effective for these conditions. Its precise mechanism of action is unknown.

Baclofen (Gablofen, Lioresal), a GABA$_B$ agonist, is particularly effective in the treatment of muscle spasm associated with multiple sclerosis or spinal cord injury when administered by continuous intrathecal drug infusion. Abrupt discontinuation of this medication has been associated with fever, altered mental status, pronounced muscle spasticity or rigidity, rhabdomyolysis, and death.

**Corticosteroids**

Glucocorticoids are extensively used in pain management for their antiinflammatory and possibly analgesic actions. They may be given topically, orally, or parenterally (intravenously, subcutaneously, intrabursally, intraarticularly, or epidurally). Table 47–15 lists the most commonly used agents, which differ in potency, relative glucocorticoid and mineralocorticoid activities, and duration of action. Large doses or prolonged administration result in significant side effects. Excess glucocorticoid activity can produce hypertension, hyperglycemia, increased susceptibility to infection, peptic ulcers, osteoporosis, aseptic necrosis of the femoral head, proximal myopathy, cataracts, and, rarely, psychosis. Patients with diabetes may have elevated blood glucose levels after corticosteroid injections. Patients can also develop the physical features characteristic of Cushing syndrome. Excess mineralocorticoid activity causes sodium retention and hypokalemia, and may precipitate congestive heart failure.

**TABLE 47–15 Selected corticosteroids.**

1
Many corticosteroid preparations are suspensions, rather than solutions, and the relative particulate size of a given glucocorticoid suspension may affect the risk of neural damage due to arterial occlusion when accidental arterial injection occurs. Because of the relatively small size of its suspension particles, dexamethasone is becoming the preferred corticosteroid for injection procedures involving relatively vascular areas, such as the head and neck region.

### Anticonvulsants

Anticonvulsant medications are useful for patients with neuropathic pain, especially trigeminal neuralgia and diabetic neuropathy. These agents can suppress the spontaneous neural discharges that play a major role in these disorders. The most commonly utilized agents are phenytoin (Dilantin), carbamazepine (Tegretol), valproic acid (Depakene, Stavzor), clonazepam (Klonopin), and gabapentin (Neurontin) (see Table 47–14). Pregabalin (Lyrica) has been approved for the treatment of diabetic peripheral neuropathy and fibromyalgia, but is widely prescribed for all forms of neuropathic pain. Lamotrigine (Lamictal) and topiramate (Topamax) may also be effective. All are highly protein-bound and have relatively long half-lives. Carbamazepine (Carbatrol, Equetro, Tegretol) has a slow and unpredictable absorption, which requires monitoring of blood levels for optimal efficacy. Phenytoin may be effective, but is associated with the side effect of gum hyperplasia. Levetiracetam (Keppra) and oxcarbazepine (Trileptal) have been used as adjuvant pain therapies. Gabapentin and pregabalin may also be effective adjuvants for the treatment of acute postoperative pain.

### Local Anesthetics
Systemic infusion of local anesthetic medication produces sedation and central analgesia and is occasionally used in the treatment of patients with neuropathic pain. The resultant analgesia may outlast the pharmacokinetic profile of the local anesthetic and break the so-called pain cycle. Lidocaine and procaine are the most commonly used agents. They are given either as a slow bolus or by continuous infusion. Lidocaine is given by infusion over 5 to 30 min for a total of 1 to 5 mg/kg. Procaine, 200 to 400 mg, can be given intravenously over the course of 1 to 2 h. Monitoring by qualified medical personnel should include electrocardiography, blood pressure, respiration, pulse oximetry, and mental status, and full resuscitation equipment must be immediately available. Signs of toxicity, such as tinnitus, slurring of speech, excessive sedation, or nystagmus, necessitate slowing or discontinuing the infusion to avoid the progression to seizures. Patients who do not respond satisfactorily to anticonvulsants but respond to intravenous local anesthetics may benefit from chronic oral antiarrhythmic therapy. Mexiletine (Mexitil, 150–300 mg every 6–8 h) is a class 1B antiarrhythmic that is commonly used and generally well tolerated.

Topical lidocaine preparations, in concentrations up to 5%, may be helpful in the treatment of some neuropathic pain conditions. A 5% lidocaine transdermal patch (Lidoderm) containing 700 mg of lidocaine has been approved for the treatment of PHN. One to three patches may be applied to dry, intact skin, alternating 12 h on, then 12 h off.

**α₂-Adrenergic Agonists**

The primary effect of α₂-adrenergic agonists is activation of descending inhibitory pathways in the spinal cord dorsal horn. Epidural and intrathecal α₂-adrenergic agonists are particularly effective in the treatment of neuropathic pain and opioid tolerance. Clonidine (Catapres), a direct-acting α₂-adrenergic agonist, is effective as an adjunctive medication in the treatment of severe pain. The oral dosage is 0.1 to 0.3 mg twice daily; a transdermal patch (0.1–0.3 mg/d) is also available and is usually applied for 7 d. When used in combination with a local anesthetic or opioid in an epidural or intrathecal infusion, clonidine may contribute to a synergistic or prolonged analgesic effect, or both, especially for neuropathic pain.

**Opioids**

The most commonly prescribed oral opioid agents are codeine, oxycodone, and
hydrocodone. They are easily absorbed, but hepatic first-pass metabolism limits systemic delivery. Like other opioids, they undergo hepatic biotransformation and conjugation before renal elimination. Codeine is transformed by the liver into morphine. The side effects of orally administered opioids are similar to those of systemic opioids. When prescribed on a fixed schedule, stool softeners or laxatives are often indicated. Tramadol (Rybic, Ryzolt, Ultram) is a synthetic oral opioid that also blocks neuronal reuptake of norepinephrine and serotonin. It appears to have the same efficacy as the combination of codeine and acetaminophen but is associated with significantly less respiratory depression and has little effect on gastric emptying.

Moderate to severe cancer pain is usually treated with an immediate-release oral morphine preparation (eg, liquid morphine, Roxanol, 10–30 mg every 1–4 h). These preparations have an effective half-life of 2 to 4 h. Once the patient’s daily requirements are determined, the same dose can be given in the form of a sustained-release morphine preparation (MS Contin or Oramorph SR), which is dosed every 8 to 12 h. The immediate-release preparation is then used only as needed for breakthrough pain. Oral transmucosal fentanyl lozenges (Actiq, 200–1600 mcg) can also be used for breakthrough pain but are very expensive. Excessive sedation can be treated with dextroamphetamine (Dexedrine, ProCentra) or methylphenidate (Ritalin), 5 mg in the morning and 5 mg the early afternoon. Most patients require a stool softener. Nausea may be treated with transdermal scopolamine, oral meclizine, or metoclopramide. Hydromorphone (Dilaudid) is an excellent alternative to morphine, particularly in elderly patients because of fewer side effects, and in patients with impaired kidney function. Methadone (Dolophine) has a half-life of 15 to 30 h, but clinical duration is shorter and quite variable (usually 6–8 h).

Patients who experience opioid tolerance require escalating doses of opioid to maintain the same analgesic effect. Physical dependence manifests in opioid withdrawal when the opioid medication is either abruptly discontinued or the dose is abruptly and significantly decreased. Psychological dependence, characterized by behavioral changes focusing on drug craving, is rare in cancer patients. The development of opioid tolerance is highly variable but results in some desirable effects such as decreased opioid-related sedation, nausea, and respiratory depression. Unfortunately, many patients continue to suffer from constipation. Physical dependence occurs in all patients receiving large doses of opioids for extended periods. Opioid withdrawal phenomena can be precipitated by the administration of opioid antagonists. Concomitant use of peripheral opioid antagonists that do not cross the blood–brain barrier, such as
methylnaltrexone (Relistor) and alvimopan (Enterog), may help reduce systemic opioid side effects without significantly affecting analgesia.

Tapentadol (Nucynta), a μ-opioid receptor agonist that also has norepinephrine reuptake inhibition properties, has been introduced for the management of acute and chronic pain. This opioid may be associated with less nausea and vomiting and less constipation. It should not be used concomitantly with monoamine oxidase inhibitors due to potentially elevated levels of norepinephrine.

Propoxyphene with and without acetaminophen (Darvocet and Darvon) was withdrawn from the U.S. market in 2010 due to the risk of cardiac toxicity.

A. Parenteral Opioid Administration
Intravenous, intraspinal (epidural or intrathecal), or transdermal routes of opioid administration may be utilized when the patient fails to adequately respond to, or is unable to tolerate, oral regimens. However, when the patient’s pain increases significantly, or changes markedly in quality, it is equally important to reevaluate the patient for adequacy of pain diagnosis and for the potential of disease progression. In patients with cancer, adjunctive treatments such as surgery, radiation, chemotherapy, hormonal therapy, and neurolysis may be helpful. Intramuscular opioid administration is rarely optimal because of variability in systemic absorption and resultant delay and variation in clinical effect.

B. Intravenous Opioid Therapy
Parenteral opioid therapy is usually best accomplished by intermittent or continuous intravenous infusion, or both, but can also be given subcutaneously. Modern portable infusion devices have patient-controlled analgesia (PCA) capability, allowing the patient to self-treat for breakthrough pain.

C. Spinal Opioid Therapy
The use of intraspinal opioids is an excellent alternative for patients obtaining poor relief with other analgesic techniques or who experience unacceptable side effects. Epidural and intrathecal opioids offer pain relief with substantially lower total doses of opioid and fewer side effects. When compared with intermittent boluses, continuous intraspinal infusion techniques reduce drug requirements, minimize side effects, and decrease the likelihood of catheter occlusion. Myoclonic activity may be occasionally observed with intrathecal morphine or hydromorphone.

Epidural or intrathecal catheters can be placed percutaneously or implanted to
provide long-term effective pain relief. Epidural catheters can be attached to lightweight external pumps that can be worn by ambulatory patients. A temporary catheter must be inserted first to assess the potential efficacy of the technique. Correct placement of the permanent catheter should be confirmed using fluoroscopy with contrast dye. Completely implantable intrathecal catheters with externally programmable pumps can also be used for continuous infusion (Figure 47–6). The reservoir of the implanted pump (Figure 47–7) is periodically refilled percutaneously. Implantable systems are most appropriate for patients with a life expectancy of several months or longer, whereas tunneled epidural catheters are appropriate for patients expected to live only weeks. Formation of an inflammatory mass (granuloma) at the tip of the intrathecal catheter may occur and may reduce efficacy.

**FIGURE 47–6** Placement of an implanted intrathecal drug delivery system. With the patient in right lateral decubitus position, access to the intrathecal space and to the anterior abdominal wall is optimized. After the posterior incision is made, a needle is advanced through the incision into the intrathecal space, and a catheter is advanced through the needle into the posterior intrathecal space. After the proximal catheter end is anchored, the distal end of the catheter is tunneled around the flank, beneath the costal margin to the anterolateral aspect of the abdominal wall.
The most frequently encountered problem associated with intrathecal opioids is tolerance, which is usually, but not always, a slowly developing phenomenon. Adjuvant therapy may be used to address this problem, and may include intermittent local anesthetics or a mixture of opioids with local anesthetics (bupivacaine or ropivacaine 2–24 mg/d), clonidine (2–4 mcg/kg/h or 48–800 mcg/d, respectively), or the GABA agonist baclofen. Clonidine is particularly useful for neuropathic pain. In high doses, it is more likely to be associated with hypotension and bradycardia.

Complications of spinal opioid therapy include local skin infection, intrathecal pump pocket infection, meningitis, other infections, and death or permanent injury related to pump programming, pump refill or drug dilution errors. Superficial infections can be reduced by the use of a silver-impregnated cuff close to the exit site. Other complications of spinal opioid therapy include epidural hematoma, which may become clinically apparent either immediately following catheter placement or several days later, and respiratory depression. Respiratory depression secondary to spinal opioid overdose can be treated by
decreasing the pump infusion rate to its lowest setting and initiating a naloxone intravenous infusion.

D. Transdermal Fentanyl
Transdermal fentanyl (Duragesic patch) is an alternative to sustained-release oral morphine and oxycodone preparations, particularly when oral medication is not possible. Currently available patches are constructed as a drug reservoir that is separated from the skin by a microporous rate-limiting membrane and an adhesive polymer. A very large quantity of fentanyl (10 mg) provides a large force for transdermal diffusion. Transdermal fentanyl patches are available in 25, 50, 75, and 100 mcg/h sizes that provide drug for 2 to 3 days. The largest patch is equivalent to 60 mg/d of intravenous morphine. The major obstacle to fentanyl absorption through the skin is the stratum corneum. Because the dermis acts as a secondary reservoir, fentanyl absorption continues for several hours after the patch is removed. The transdermal route avoids hepatic first-pass metabolism.

Major disadvantages of the transdermal route are its slow rate of drug delivery onset and the inability to rapidly change dosage in response to changing opioid requirements. Blood fentanyl levels rise and reach a plateau in 12 to 40 h, providing average concentrations of 1, 1.5, and 2 ng/mL for the 50, 75, and 100 mcg/h patches, respectively. Large interpatient variability results in actual delivery rates ranging from 50 to 200 mcg/h. Transdermal fentanyl patches are often diverted for illicit use, resulting in numerous accidental fatalities.

E. Opioid Risks and the Opioid Abuse Crisis
Opioid medications have been identified as having greater risks to patients than were previously considered, including dependence, addiction, overdose, endocrine changes, immunological compromise, hyperalgesia, and respiratory depression that may be life threatening. The efficacy and appropriateness of opioid treatment of chronic benign pain has increasingly come into question as well. For these reasons, risks may outweigh potential or real benefits. In 2016 the U.S. Centers for Disease Control and Prevention published guidelines for prescribing opioids for chronic pain to help mitigate risks (see Guidelines at end of chapter).

Botulinum Toxin (Botox)
OnabotulinumtoxinA (Botox) injection has been increasingly utilized in the treatment of pain syndromes. Studies support its use in the treatment of
conditions associated with involuntary muscle contraction (eg, focal dystonia and spasticity), and it is approved by the U.S. FDA for prophylactic treatment of chronic migraine headache. This toxin blocks acetylcholine released at the synapse in motor nerve endings but not sensory nerve fibers. Proposed mechanisms of analgesia include improved local blood flow, relief of muscle spasms, and release of muscular compression of nerve fibers.

**PROCEDURAL THERAPY**

1. **Diagnostic & Therapeutic Blocks**

Local anesthetic nerve blocks are useful in delineating pain mechanisms, and they play a major role in the management of patients with acute or chronic pain. Pain relief following diagnostic nerve blockade often carries favorable prognostic implications for a subsequent therapeutic series of blocks. This technique can identify patients exhibiting a placebo response and those with psychogenic mechanisms. In selected patients, “permanent” neurolytic nerve blocks may be appropriate.

The efficacy of nerve blocks is due to interruption of afferent nociceptive activity, which may be in addition to, or in combination with, blockade of afferent and efferent limbs of abnormal reflex activity involving sympathetic nerve fibers and skeletal muscle innervation. The pain relief frequently outlasts the known pharmacological duration of the agent employed by hours or up to several weeks. Selection of the type of block depends on the location of pain, its presumed mechanism, and the skills of the treating physician. Local anesthetic solutions may be infiltrated locally or injected at specific peripheral nerve, somatic plexus, sympathetic ganglia, or nerve root sites. The local anesthetic may also be applied centrally in the neuraxis.

**Ultrasound-Guided Procedures**

The use of ultrasound in interventional pain medicine has increased dramatically over the past decade due to its utility in precisely visualizing vascular, neural, and other anatomic structures, its role as an alternative to the use of fluoroscopy and radiocontrast agents, and progressive improvements in technology leading to better visual images and greater simplicity of use. Procedures that may benefit from ultrasound guidance include trigger point injections, nerve blocks, and joint injections.
Fluoroscopy

Fluoroscopy is highly effective for visualizing bony structures and observing the spread of radiopaque contrast agents. Live fluoroscopy with contrast agent may be used to minimize the risk of intravascular injection of therapeutic agents. Care should be taken to avoid excessive radiation dosage and to employ appropriate radiation shielding, given the risks of ionizing radiation to the patient and to the health care team in the fluoroscopy suite.

2. Somatic Nerve Blocks

Trigeminal Nerve Block

A. Indications
The two principal indications for trigeminal nerve block are trigeminal neuralgia and intractable facial cancer pain. Depending on the site of pain, these blocks may be performed on the gasserian ganglion itself, on one of the major divisions (ophthalmic, maxillary, or mandibular), or on one of their smaller branches.

B. Anatomy
The rootlets of cranial nerve V arise from the brainstem and join one another to form a crescent-shaped sensory (gasserian) ganglion in Meckel’s cave. Most of the ganglion is invested with a dural sleeve. The three subdivisions of the trigeminal nerve arise from the ganglia and exit the cranium separately (Figure 47–8A).
C. Technique

1. **Gasserian ganglion block**—Fluoroscopic guidance is mandatory for the performance of this procedure (Figure 47–8B). An 8- to 10-cm 22-gauge needle is inserted approximately 3 cm lateral to the angle of the mouth at the level of the upper second molar. The needle is then advanced posteromedially and angled superiorly to bring it into alignment with the pupil in the anterior plane and with the mid-zygomatic arch in the lateral plane. Without entering the mouth, the needle should pass between the mandibular ramus and the maxilla, and lateral to the pterygoid process to enter the cranium through the foramen ovale. After a negative aspiration for cerebrospinal fluid and blood, local anesthetic is injected.

2. **Blocks of the ophthalmic nerve and its branches**—In this procedure, to avoid denervation-related keratitis, only the supraorbital branch is blocked in most cases (Figure 47–8C); the ophthalmic division itself is not blocked. The nerve is easily located and blocked with local anesthetic at the supraorbital notch, which is located on the supraorbital ridge above the pupil. The
supratrochlear branch can also be blocked with local anesthetic at the superior medial corner of the orbital ridge.

3. **Blocks of the maxillary nerve and its branches**—With the patient’s mouth slightly opened, an 8- to 10-cm 22-gauge needle is inserted between the zygomatic arch and the notch of the mandible (Figure 47–8D). After contact with the lateral pterygoid plate at about 4-cm depth (position 1 in figure), the needle is partially withdrawn and angled slightly superiorly and anteriorly to pass into the pterygopalatine fossa (position 2). Local anesthetic is injected once paresthesias are elicited. Both the maxillary nerve and the sphenopalatine (pterygopalatine) ganglia are usually anesthetized by this technique. The sphenopalatine ganglion (and anterior ethmoid nerves) can be anesthetized transmucosally with topical anesthetic applied through the nose; several cotton applicators soaked with local anesthetic (cocaine or lidocaine) are inserted along the medial wall of the nasal cavity into the area of the sphenopalatine recess. The sphenopalatine ganglion blockade may be helpful for patients with chronic nasal pain, cluster headache, or Sluder neuralgia.

The infraorbital branch of cranial nerve V passes through the infraorbital foramen, where it can be blocked with local anesthetic. This foramen is approximately 1 cm below the orbit and is usually located with a needle inserted about 2 cm lateral to the nasal ala and directed superiorly, posteriorly, and slightly laterally.

4. **Blocks of the mandibular nerve and its branches**—With the patient’s mouth slightly opened (Figure 47–8E), an 8- to 10-cm 22-gauge needle is inserted between the zygomatic arch and the mandibular notch. After contact with the lateral pterygoid plate (position 1 in figure), the needle is partially withdrawn and angled slightly superiorly and posteriorly toward the ear (position 2). Local anesthetic is injected once paresthesias are elicited. The lingual and inferior mandibular branches of the mandibular nerve may be blocked intraorally utilizing a 10-cm 22-gauge needle (Figure 47–8F). The patient is asked to open the mouth maximally and the coronoid notch is palpated with the index finger of the nonoperative hand. The needle is then introduced at the same level (approximately 1 cm above the surface of the last molar), medial to the finger but lateral to the pterygomandibular plica (position 1 in figure). It is advanced posteriorly 1.5 to 2 cm along the medial side of the mandibular ramus, making contact with the bone (position 2). Both nerves are usually blocked following injection of local anesthetic.

The terminal portion of the inferior alveolar nerve may be blocked as it emerges from the mental foramen at the mid-mandible just beneath the corner of
the mouth. Local anesthetic is injected once paresthesias are elicited or the needle is felt to enter the foramen.

D. Complications
Complications of a gasserian ganglion block include accidental intravascular injection, subarachnoid injection, Horner syndrome, and motor block of the muscles of mastication. The potential for serious hemorrhage is greatest for blockade of the maxillary nerve. The facial nerve may be unintentionally blocked during blocks of the mandibular division.

Facial Nerve Block

A. Indications
Blockade of the facial nerve is occasionally indicated to relieve spastic contraction of the facial muscles, to treat herpes zoster involving the facial nerve, and to facilitate certain surgical procedures involving the eye.

B. Anatomy
The facial nerve can be blocked where it exits the cranium through the stylomastoid foramen. A small sensory component supplies special sensation (taste) to the anterior two thirds of the tongue and general sensation to the tympanic membrane, external auditory meatus, soft palate, and part of the pharynx.

C. Technique
The entry point is just anterior to the mastoid process, beneath the external auditory meatus, and at the midpoint of the mandibular ramus. The nerve is approximately 1 to 2 cm deep and is blocked with local anesthetic just below the stylomastoid process.

D. Complications
If the needle is inserted too deeply past the level of the styloid bone, the glossopharyngeal and vagal nerves may also be blocked. Careful aspiration is necessary because of the proximity of the facial nerve to the carotid artery and the internal jugular vein.

Glossopharyngeal Block
A. Indications
Glossopharyngeal nerve block may be used for patients with pain due to cancer involving the base of the tongue, the epiglottis, or the palatine tonsils. It can also be used to distinguish glossopharyngeal neuralgia from trigeminal and geniculate neuralgia.

B. Anatomy
The nerve exits from the cranium via the jugular foramen medial to the styloid process and courses anteromedially to supply the posterior third of the tongue, pharyngeal muscles, and mucosa. The vagus and spinal accessory nerves also exit the cranium via the jugular foramen and descend alongside the glossopharyngeal nerve in close proximity to the internal jugular vein.

C. Technique
The block is performed using a 5-cm 22-gauge needle inserted just posterior to the angle of the mandible (Figure 47–9). The nerve is approximately 3 to 4 cm deep; therefore, use of a nerve stimulator facilitates correct placement of the needle. An alternative approach is from a point over the styloid process, midway between the mastoid process and the angle of the mandible; the nerve is located just anteriorly.

FIGURE 47–9 Glossopharyngeal nerve block.
D. Complications
Complications include dysphagia and vagal blockade resulting in ipsilateral vocal cord paralysis and tachycardia. Block of the accessory nerve and hypoglossal nerves causes ipsilateral paralysis of the trapezius muscle and the tongue, respectively. Careful aspiration is necessary to prevent intravascular injection.

Occipital Nerve Block

A. Indications
Occipital nerve block is useful diagnostically and therapeutically in patients with occipital headaches and neuralgias.

B. Anatomy
The greater occipital nerve is derived from the dorsal primary rami of the C2 and C3 spinal nerves, whereas the lesser occipital nerve arises from the ventral rami of the same roots.

C. Technique
The greater occipital nerve is blocked approximately 3 cm lateral to the occipital prominence at the level of the superior nuchal line (Figure 47–10); the nerve is just medial to the occipital artery, which is often palpable. The lesser occipital nerve is blocked 2 to 3 cm more laterally along the nuchal ridge. Ultrasound guidance may be employed to help identify the nerves. For patients who have responded well but temporarily to occipital nerve blocks, implantation of an occipital nerve stimulator may provide prolonged relief.
D. Complications
Rarely, intravascular injections may occur.

Suprascapular Nerve Block

A. Indications
This block is useful for painful conditions arising from the shoulder, including arthritis, bursitis, and myofascial pain.

B. Anatomy
The suprascapular nerve is the major sensory nerve of the shoulder joint. It arises from the brachial plexus (C4–C6) and passes over the upper border of the scapula in the suprascapular notch to enter the suprascapular fossa.
C. Technique
The nerve is blocked at the suprascapular notch, which is located at the junction of the lateral and middle thirds of the superior scapular border (Figure 47–11). Correct placement of the needle is determined by paresthesia, ultrasound, or the use of a nerve stimulator.

D. Complications
Pneumothorax is possible if the needle is advanced too far anteriorly. Paralysis of the supraspinatus and infraspinatus muscles will result in impaired shoulder abduction.

Cervical Paravertebral Nerve Blocks
A. Indications
Cervical paravertebral nerve blocks can be useful diagnostically and therapeutically for patients with cervical disc displacement, cervical foraminal stenosis, or cancer-related pain originating from the cervical spine or shoulder.

B. Anatomy
The cervical spinal nerves lie in the sulcus of the transverse process of their respective vertebral levels. As noted earlier in this chapter, unlike thoracic and lumbar nerve roots, those in the cervical spine exit the foramina above the vertebral bodies for which they are named.

C. Technique
The lateral approach is most commonly used to block C2–C7 (Figure 47–12). Patients are asked to turn the head to the opposite side while in a sitting or supine position. A line is then drawn between the mastoid process and the tubercle of the C6 transverse process (Chassaignac’s tubercle). A series of injections are made with a 5-cm 22-gauge needle along a second parallel line 0.5 cm posterior to the first line. In the case of diagnostic blocks, a smaller injectate volume may be helpful in order to minimize local anesthetic spread to adjacent structures and thereby increase block specificity. Because the transverse process of C2 is usually difficult to palpate, the injection for this level is placed 1.5 cm beneath the mastoid process. The other transverse processes are usually interspaced 1.5 cm apart and are 2.5 to 3 cm deep. Fluoroscopy is useful in identifying specific vertebral levels during diagnostic blocks. This block may also be performed with ultrasound guidance.
D. Complications
Unintentional intrathecal or epidural anesthesia at this level rapidly causes respiratory paralysis and hypotension. Injection of even small volumes of local anesthetic into the vertebral artery causes unconsciousness and seizures. Other complications include Horner syndrome and blockade of the recurrent laryngeal and phrenic nerves.

Embolic cerebrovascular and spinal cord complications have resulted from injection of particulate steroid with this block. **Particulate steroid should not be used with cervical paravertebral nerve blocks because of possible anomalous vertebral artery anatomy in this region.**

Thoracic Paravertebral Nerve Block
This technique may be used to block the upper thoracic dermatome segments because the scapula interferes with the intercostal technique at these levels. Unlike an intercostal nerve block, a thoracic paravertebral nerve block anesthetizes both the dorsal and ventral rami of spinal nerves. It is therefore useful in patients with pain originating from the thoracic spine, thoracic cage, or abdominal wall, including compression fractures, proximal rib fractures, and acute herpes zoster. This block is also frequently utilized for intraoperative anesthesia and for postoperative pain management in breast surgery and is described in detail in **Chapter 46.**

Lumbar Paravertebral Nerve Blocks
A. Indications
Lumbar paravertebral nerve blocks may be useful in evaluating pain due to disorders involving the lumbar spine or spinal nerves.

B. Anatomy
The lumbar spinal nerves enter the *psoas compartment* after exiting the intervertebral foramina beneath the pedicles and transverse processes. This compartment is formed by the psoas fascia anteriorly, the quadratus lumborum fascia posteriorly, and the vertebral bodies medially.

C. Technique
The approach to lumbar spinal nerves is essentially the same as for thoracic paravertebral blockade (Figure 47–13). An 8-cm 22-gauge needle is usually used, and radiographic confirmation of the correct level is helpful. For diagnostic blocks, only 2 mL of local anesthetic is injected at any one level, because larger volumes may block more than one level. Larger volumes of local anesthetic are used for therapeutic blocks, or to produce complete somatic and sympathetic block of the lumbar nerves.

![Image: Lumbar paravertebral nerve blocks.](image_url)

**FIGURE 47–13** Lumbar paravertebral nerve blocks.

**D. Complications**
Complications are primarily those of unintentional intrathecal or epidural anesthesia. Patients may experience paresthesias if inadvertent nerve injury occurs during needle placement. Some physicians advocate the use of a blunt-tipped needle to (theoretically) decrease the risk of accidental intraneural injection. Digital subtraction angiography with radiopaque contrast may lessen the risk of intravascular injection of local anesthetic or steroid medication.

**Cervical, Thoracic, & Lumbar Medial Branch Blocks**

**A. Indications**
These blocks may be utilized in patients with back pain to assess the contribution of lumbar facet (zygapophyseal) joint disease. Corticosteroids are commonly injected with the local anesthetic when the intraarticular technique is chosen. The cervical, thoracic, or lumbar facet joints may be injected for
diagnostic and potentially therapeutic purposes.

**B. Anatomy**

Each facet joint is innervated by the medial branches of the posterior primary division of the spinal nerves above and below the joint (Figure 47–14). Thus, every joint is supplied by two or more adjacent spinal nerves. Each medial branch crosses the upper border of the lower transverse process running in a groove between the root of the transverse process and the superior articular process.
FIGURE 47–14 Lumbar medial branch nerve and facet blocks. A: Posterior view; B: 30° oblique posterior view.

C. Technique
These blocks are performed under fluoroscopic guidance with the patient in a prone position, or in some cases, the lateral position for cervical procedures. A posterior–anterior view facilitates visualization of the spine for lumbar medial branch blocks. A 10-cm 22-gauge needle is inserted 3 to 4 cm lateral to the
spinous process at the desired level and directed anteriorly toward the junction of the transverse process and the superior articular process to block the medial branch of the posterior division of the spinal nerve (Figures 47–15 through 47–17).

**FIGURE 47–15** Anatomy of the lumbar facet joint and location for blocking the medial branch of the posterior primary division of the lumbar spinal nerves above and below the joint.
FIGURE 47–16 Fluoroscopic image of a cervical medial branch blockade. A: Anteroposterior view; B: Lateral view. The lateral view reveals the needles at C4, C5, and C6 advanced toward the trapezoid of the articular pillar at each level. Note the “waist” of the vertebrae. Spinal needles may be advanced to come into contact with the medial branch of the nerve.
Alternatively, local anesthetic with or without corticosteroid may be directly injected into the facet joint. Positioning the patient prone and using an oblique fluoroscopic view facilitates identification of the joint space. Correct placement of the needle may be confirmed by injecting radiopaque contrast prior to injection of local anesthetic. Total injection volumes should ideally be limited to less than 1 mL in order to prevent rupture of the joint capsule.

**D. Complications**

Injection into a dural sleeve results in a subarachnoid block, whereas injection near the spinal nerve root results in sensory and motor block at that level. Because the joint normally has a small volume, larger injections can cause rupture of the joint capsule.

If a patient achieves improved pain control after a diagnostic block, he or she may be considered for radiofrequency ablation of the medial branch. There is debate about whether a second, confirmatory diagnostic block should be performed prior to radiofrequency ablation. Injection of steroid may be considered before or after radiofrequency ablation to theoretically decrease the chance for postprocedural neuritis.
Trans-Sacral Nerve Block

A. Indications
This technique is useful in the diagnosis and treatment of pelvic and perineal pain. In addition, blockade of the S1 spinal root can help define its role in back pain.

B. Anatomy
The five paired sacral spinal nerves and one pair of coccygeal nerves descend in the sacral canal, and each nerve then exits through its respective intervertebral foramen. The S5 and coccygeal nerves exit through the sacral hiatus.

C. Technique
While the patient is prone, the sacral foramina are identified with a needle along a line drawn 1.5 cm medial to the posterior superior iliac spine and 1.5 cm lateral to the ipsilateral sacral cornu (Figure 47–18). Correct positioning requires entry of the needle into the posterior sacral foramen and usually produces paresthesias. The S1 nerve root is usually 1.5 cm above the level of the posterior superior iliac spine along this imaginary line. Blockade of the S5 and coccygeal nerves can be accomplished by injection at the sacral hiatus.

![Figure 47–18](image)

**FIGURE 47–18** Trans-sacral nerve block.

D. Complications
Complications are rare but include nerve damage and intravascular injection.
Pudendal Nerve Block

A. Indications
Pudendal nerve block is useful in evaluating patients with perineal somatosensory pain.

B. Anatomy
The pudendal nerve arises from S2–S4 and courses between the sacrospinous and the sacrotuberous ligaments to reach the perineum.

C. Technique
This block is usually performed transperineally with the patient in the lithotomy position (Figure 47–19) although it may be performed via a posterior approach in the prone position. Injection of anesthetic is carried out percutaneously just posterior to the ischial spine at the attachment of the sacrospinous ligament. The ischial spine can be palpated transrectally or transvaginally. Alternatively, this procedure may be performed in the prone position with a 22-gauge needle directed toward the base of the ischial spine. Patients should be advised that they may have numbness of the genitalia for hours after this procedure is performed.
D. Complications
Potential complications include unintentional sciatic blockade and intravascular injection.

3. Sympathetic Nerve Blocks
Sympathetic blockade can be accomplished by a variety of techniques, including intrathecal, epidural, and paravertebral blocks. Unfortunately, these approaches usually block both somatic and sympathetic fibers. Problems with differential spinal and epidural techniques are discussed later in this section. The following techniques specifically block sympathetic fibers and can be used to define the role of the sympathetic system in a patient’s pain and possibly also provide long-term pain relief. The most common indications for sympathetic nerve blocks include reflex sympathetic dystrophy, visceral pain, acute herpetic neuralgia, postherpetic pain, and peripheral vascular disease. Isolated sympathetic blockade to a region is characterized by loss of sympathetic tone, as evidenced by increased cutaneous blood flow and cutaneous temperature, and by unaltered
somatic sensation. Other tests include loss of the skin conductance (sympathogalvanic reflex) and sweat response (ninhydrin, cobalt blue, or starch tests) following a painful stimulus.

Cervicothoracic (Stellate) Block

A. Indications
This block is often used for patients with head, neck, arm, and upper chest pain. It is commonly referred to as a stellate block but usually blocks the upper thoracic as well as all cervical ganglia. Injection of larger volumes of anesthetic often extends the block to the T5 ganglia. Stellate blocks may also be used for vasospastic disorders of the upper extremity.

B. Anatomy
Sympathetic innervation of the head, neck, and most of the arm is derived from four cervical ganglia, the largest being the stellate ganglion. The latter usually represents a fusion of the lower cervical and first thoracic ganglia. Some sympathetic innervation of the arm (T1) as well as innervation of all of the thoracic viscera derives from the five upper thoracic ganglia. The sympathetic supply to the arm in some individuals may also originate from T2–T3 via anatomically distinct nerves (Kuntz’s nerves) that join the brachial plexus high in the axilla. These nerves may be missed by a stellate block but not an axillary block. The point of injection is at the level of the stellate ganglion, which lies posterior to the origin of the vertebral artery from the subclavian artery, anterior to the longus colli muscle and the first rib, anterolateral to the prevertebral fascia, and medial to the scalene muscles. The sympathetic supply to the arm in some individuals may also originate from T2–T3 via anatomically distinct nerves (Kuntz’s nerves) that join the brachial plexus high in the axilla. These nerves may be missed by a stellate block but not an axillary block.

C. Technique
The paratracheal technique is most commonly used (Figure 47–20), although an oblique or posterior approach may also be taken. With the patient’s head extended, a 4- to 5-cm 22-gauge needle is inserted at the medial edge of the sternocleidomastoid muscle just below the level of the cricoid cartilage at the level of the transverse process of C6 (Chassaignac’s tubercle) or C7 (3–5 cm above the clavicle). The nonoperative hand should be used to retract the muscle together with the carotid sheath prior to needle insertion. The needle is advanced
to the transverse process and withdrawn 2 to 3 mm prior to injection. Aspiration must be carried out in two planes before a 1-mL test dose is used to exclude unintentional intravascular injection into the vertebral or subclavian arteries or subarachnoid injection into a dural sleeve. A total of 5 to 10 mL of local anesthetic may be injected. Fluoroscopy or ultrasound may be used to visualize the anatomy and decrease the risk of inadvertent intravascular injection.

**FIGURE 47–20** Stellate block.

Correct placement of the needle is usually followed promptly by an increase in the skin temperature of the ipsilateral arm and the onset of Horner syndrome. The latter consists of ipsilateral ptosis, meiosis, enophthalmos, nasal congestion, and anhydrosis of the neck and face.

**D. Complications**

In addition to intravascular and subarachnoid injection, other complications of stellate block include hematoma, pneumothorax, epidural anesthesia, brachial plexus block, hoarseness due to blockade of the recurrent laryngeal nerve, and, rarely, osteomyelitis or mediastinitis following esophageal puncture, particularly if a left-sided approach is taken. The posterior approach may have the highest incidence of pneumothorax.

**Thoracic Sympathetic Chain Block**

The thoracic sympathetic ganglia lie just lateral to the vertebral bodies and anterior to the spinal nerve roots, but this block is generally not used because of
a significant risk of pneumothorax.

**Splanchnic Nerve Block**

Three groups of splanchnic nerves (greater, lesser, and least) arise from the lower seven thoracic sympathetic ganglia on each side and descend alongside the vertebral bodies to communicate with the celiac ganglia. Although similar to celiac plexus block, the splanchnic nerve block may be preferred because it is less likely to block the lumbar sympathetic chain and because it requires less anesthetic.

The needle is inserted 6 to 7 cm from the midline at the lower end of the T11 spinous process, and advanced under fluoroscopic guidance to the anterolateral surface of T12. Ten milliliters of local anesthetic is injected on each side. The needle should maintain contact with the vertebral body at all times to avoid a pneumothorax. Other complications may include hypotension and possible injury to the azygos vein on the right or to the hemiazygos vein and the thoracic duct on the left.

If a patient’s pain lessens after a splanchnic nerve block, the procedure may be repeated to ensure that this result was not due to placebo effect. In addition, if the patient obtained pain relief from the initial block, he or she may subsequently benefit from radiofrequency ablation of the splanchnic nerves at T11 and T12, with potentially longer duration of analgesia. Performing the procedure on one side initially, and then the other side on a subsequent day, is advised due to the risk of pneumothorax.

**Celiac Plexus Block**

**A. Indications**

A celiac plexus block is indicated for patients with pain arising from the abdominal viscera, particularly intraabdominal cancers.

**B. Anatomy**

The celiac ganglia vary in number (one to five), form, and position. They are generally clustered at the level of the body of L1, posterior to the vena cava on the right, just lateral to the aorta on the left, and posterior to the pancreas.

**C. Technique**

The patient is placed in a prone position and a 15-cm 22-gauge needle is used to
inject 15 to 20 mL of local anesthetic (Figure 47–21). Under fluoroscopic guidance, each needle is inserted 7 to 8 cm from the midline at the inferior edge of the spinous process of L1 and advanced under radiographic guidance toward the midline. The needle passes under the edge of the 12th rib and should be positioned anterior to the body of L1 in the lateral radiographic view and close to the midline overlying the same vertebral body in the anteroposterior view. When CT guidance is used, the tip of the needle should come to lie anterolateral to the aorta at a level between the celiac and superior mesenteric arteries.

**FIGURE 47–21** Celiac plexus block.

The celiac plexus block may be performed from multiple approaches, including a posterior retrocrural approach, a posterior anterocrural approach, a posterior transaortic approach, and an anterior approach. These blocks may be facilitated with fluoroscopic, CT, or ultrasound guidance.

**D. Complications**

The most common complication is postural hypotension from block of visceral sympathetic innervation and resultant vasodilation. For this reason, patients should be adequately hydrated intravenously prior to this block and precautions taken to minimize the risk of orthostatic lightheadedness or syncope. Accidental intravascular injection into the vena cava is more likely to produce a severe systemic reaction than accidental intraaortic injection. Other, less common, complications include pneumothorax, retroperitoneal hemorrhage, injury to the kidneys or pancreas, sexual dysfunction, or, rarely, paraplegia (due to spasm of, or injury to, the lumbar artery of Adamkiewicz). Blocking the sympathetic chain may result in relatively unopposed parasympathetic activity that may lead to
increased gastrointestinal motility and diarrhea. Back pain is another common side effect of a celiac plexus block.

**Lumbar Sympathetic Block**

**A. Indications**
Lumbar sympathetic block may be indicated for painful conditions involving the pelvis or the lower extremities, and possibly for some patients with peripheral vascular disease.

**B. Anatomy**
The lumbar sympathetic chain contains three to five ganglia and is a continuation of the thoracic chain. It also supplies sympathetic fibers to the pelvic plexus and ganglia. The lumbar sympathetic chain ganglia are in a more anteromedial position to the vertebral bodies than the thoracic ganglia, and are anterior to the psoas muscle and fascia. The lumbar chain is usually posterior to the vena cava on the right but is just lateral to the aorta on the left.

**C. Technique**
A single-needle technique at the L3 level on either side is most commonly employed with the patient either prone or in a lateral position (Figure 47–22). The needle is inserted at the upper edge of the spinous process and is directed above or just lateral to the transverse process of the vertebrae (depending on the distance from the midline). Fluoroscopic or ultrasound guidance is often used.
D. Complications
Complications include intravascular injection into the vena cava, aorta, or lumbar vessels and somatic nerve block of the lumbar plexus. In particular, the genitofemoral nerve may be blocked.

Superior Hypogastric Plexus Block

A. Indications
This procedure is indicated for pelvic pain that is unresponsive to lumbar or caudal epidural blocks. The hypogastric plexus contains visceral sensory fibers that bypass the lower spinal cord. This block is usually appropriate for patients with cancer of the cervix, uterus, bladder, prostate, or rectum, and may also be effective for some women with chronic noncancer pelvic pain.

B. Anatomy
The hypogastric plexus contains not only postganglionic fibers derived from the lumbar sympathetic chain, but also visceral sensory fibers from the cervix, uterus, bladder, prostate, and rectum. The superior hypogastric plexus usually lies just to the left of the midline at the L5 vertebral body and beneath the bifurcation of the aorta. The fibers of this plexus divide into left and right
branches and descend to the pelvic organs via the left and right inferior hypogastric and pelvic plexuses. The inferior hypogastric plexus additionally receives preganglionic parasympathetic fibers from the S2–S4 spinal nerve roots.

**C. Technique**
The patient is positioned prone, and a 15-cm needle is inserted approximately 7 cm lateral to the L4–L5 spinal interspace. The needle is directed medially and caudally under fluoroscopic or ultrasound guidance so that it passes by the transverse process of L5. In its final position, the needle should lie anterior to the intervertebral disc between L5 and S1 and within 1 cm of the vertebral bodies in the anteroposterior view. When fluoroscopy is used, injection of radiopaque contrast confirms correct position of the needle in the retroperitoneal space; 8 to 10 mL of local anesthetic is then injected. The superior hypogastric plexus block may also be performed using a transdiscal approach, though there is a risk of discitis associated with this procedure.

**D. Complications**
Complications include intravascular injection and transient bowel and bladder dysfunction.

**Ganglion Impar Block**

**A. Indications**

*Ganglion impar block* is effective for patients with visceral or sympathetically maintained pain in the perineal area.

**B. Anatomy**
The ganglion impar (ganglion of Walther) is the most caudal part of the sympathetic trunks. The two lowest pelvic sympathetic ganglia often fuse forming one ganglion in the midline just anterior to the coccyx.

**C. Technique**
The patient may be positioned in the prone, lateral decubitus, or lithotomy position. A 22-gauge needle is advanced through the sacrococcygeal ligament and the rudimentary disc into a position just anterior to the coccyx. This procedure can be facilitated with fluoroscopy or ultrasound. Radiofrequency ablation, or in some cases a neurolytic injection, may provide longer duration of
analgesia for this sympathetically mediated pain.

D. Complications
Intravascular injection and transient bowel or bladder dysfunction are possible. Alternative approaches involve placement of the needle through the anococcygeal ligament, although these may have higher potential to perforate the rectum.

Intravenous Regional Block
A Bier block (see Chapter 46) utilizing local anesthetic solution with or without adjuvants can be used to interrupt sympathetic innervation to an extremity. A total volume of 50 mL of 0.5% lidocaine is typically injected, either alone or in combination with clonidine (150 mcg) and in some cases ketorolac (15–30 mg). The technique is described in Chapter 46.

4. Epidural Injections
Epidural steroid injections (Figure 47–23) are used for symptomatic relief of radicular pain associated with nerve root compression. Pathological studies often demonstrate local inflammatory changes following disc herniation, and clinical improvement appears to be correlated with resolution of resultant nerve root edema. Epidural steroid injections are clearly superior to local anesthetics alone. They are most effective when given within 2 weeks of pain onset but appear to be of little benefit in the absence of neural compression or irritation. Long-term studies have failed to show any persistent benefit after 3 months, and these injections may change the time course of pain relief without changing long-term outcomes.
FIGURE 47–23 Epidural injection.

The two most commonly used agents are methylprednisolone acetate (40–80 mg) and triamcinolone diacetate (40–80 mg). Dexamethasone is being used with increased frequency due to its smaller particulate size (smaller than an erythrocyte). Intravascular injection of steroid suspension with larger particulate size may lead to embolic complications. The steroid may be injected with diluent (saline) or local anesthetic in volumes of 6 to 10 mL or 10 to 20 mL for lumbar and caudal injections, respectively. Simultaneous injection of opioids offers no added benefit and may significantly increase risks. The epidural needle should be cleared of the steroid prior to its withdrawal to prevent formation of a fistula
tract or skin discoloration. Injection of local anesthetic along with the steroid can be helpful if the patient has significant muscle spasm, but it is associated with risks of intrathecal or subdural injection resulting in lower extremity weakness and risk of patient fall, and of intravascular injection. The presenting pain is often transiently intensified following injection, and the local anesthetic provides immediate pain relief until the steroidal antiinflammatory effects take place, usually within 12 to 48 h.

Epidural steroid injections may be most effective when the injection is at the site of injury. Only a single injection is given if complete pain relief is achieved. If there is a good but temporary response, a second injection may be given 2 to 4 weeks later. Larger or more frequent doses increase the risk of adrenal suppression and systemic side effects. Most pain practitioners utilize fluoroscopy for epidural injection and confirm correct placement with injection of radiopaque contrast (Figures 47–24 through 47–26). A transforaminal epidural steroid injection may be more effective than the standard interlaminar epidural technique, especially for radicular pain. The needle is directed under fluoroscopic guidance into the foramen of the affected nerve root; contrast is then injected to confirm spread into the epidural space and absence of intravascular injection prior to steroid injection. This technique differs from a selective nerve root block (SNRB) in two important ways; with an SNRB, the needle does not enter the foramen and the injected solution tracks along the nerve but not into the epidural space. The SNRB may be helpful as a diagnostic procedure for the surgeon who is considering a foraminotomy at a particular affected level based upon imaging, clinical presentation, and the results of the SNRB.
FIGURE 47–24 Fluoroscopic image of a C7–T1 epidural steroid injection; anteroposterior view. Note the Tuohy needle advanced just to the right of midline for treatment of degenerative disc disease and right radicular pain.
FIGURE 47–25 Fluoroscopic image of a C7–T1 epidural steroid injection with contrast; lateral view. Note radiopaque contrast confirmation of the needle in the epidural space. Live fluoroscopy is used to minimize the risk of inadvertent intravascular injection.
FIGURE 47–26  Lumbar epidural steroid injection, anteroposterior view. The epidural injection of contrast followed by local anesthetic and steroid solution results in spread at multiple levels of the epidural space and through the neuroforamen.

Caudal injection may be used in patients with previous back surgery when scarring and anatomic distortion make lumbar epidural injections more difficult. Unfortunately, migration of the steroid to the site of injury may not be optimal due to anatomic distortion of the epidural space. The use of a catheter to more precisely direct the injection within the sacral and epidural canal may improve outcome. However, above the level of S2, there is a risk of thecal perforation with a stylet-guided catheter. Intrathecal steroid injections are not recommended because the ethylene glycol preservative in the suspension has been implicated in arachnoiditis following unintentional subarachnoid injections.

5. **Radiofrequency Ablation & Cryoneurolysis**

Percutaneous *radiofrequency ablation* (RFA) relies on the heat produced by current flow from an active electrode that is incorporated at the tip of a special
needle. The needle is positioned using fluoroscopic guidance. Electrical stimulation (2 Hz for motor responses, 50 Hz for sensory responses) and impedance measurement via the electrode prior to ablation also help confirm correct electrode positioning. Depending on the location of the block, the heating temperature generated at the electrode is precisely controlled (60–90°C for 1–3 min) to ablate the nerve without causing excessive collateral tissue damage. RFA is commonly used for trigeminal rhizotomy and medial branch (facet) rhizotomy. It has also been used for dorsal root rhizotomy and lumbar sympathectomy, and may be effective for medial branches of the spinal nerves that innervate facet joints. Pain relief is usually limited to 3 to 12 months due to nerve regeneration after RFA. The lesion from thermal RFA is typically ovoid in shape and dependent upon factors such as the gauge of the needle, temperature of the needle tip, and duration of the heating procedure. Cooling the RFA needle with a sterile water system may decrease the charring associated with thermal lesioning and extend the spread of the lesion while heating at lower temperatures. Pulsed radiofrequency at 42°C is also being evaluated for various pain conditions.

Cryoneurolysis may produce temporary analgesia (cryoanalgesia) for weeks to months by freezing and thawing tissue. The temperature at the tip of a cryoprobe rapidly drops as carbon dioxide or nitrous oxide gas at high pressure is allowed to expand. The probe tip, which can achieve temperatures of –50°C to –70°C, is introduced via a 12- to 16-gauge catheter. Electrical stimulation (2–5 Hz for motor responses and 50–100 Hz for sensory responses) helps confirm correct positioning of the probe. Two or more 2-min cycles of freezing and thawing are usually administered. Cryoneurolysis is most commonly used to achieve long-term blockade of peripheral nerves and may be particularly useful for post-thoracotomy pain. Patients often have neuropathic pain following thoracotomy or similar surgery. Diagnostic intercostal nerve blocks may be helpful to identify the nerve(s) that may be contributing to chronic thoracic or abdominal pain, and intercostal nerve blocks may also be utilized for longer term analgesia. The principal risks of intercostal nerve blocks are pneumothorax and local anesthetic toxicity. RFA of the intercostal nerves may be helpful as a palliative therapy for intercostal neuralgia, although there is a risk of deafferentation pain after this procedure.

6. Chemical Neurolysis

Neurolytic blocks are indicated for patients with severe, intractable cancer pain in whom more conventional therapy proves inadequate or conventional analgesic modalities are accompanied by unacceptable side effects. The most
common chemical neurolytic techniques utilized for cancer patients are celiac plexus, lumbar sympathetic chain, hypogastric plexus, and ganglion impar blocks. Chemical neurolysis may also occasionally be used in patients with refractory benign neuralgia and, rarely, in patients with peripheral vascular disease. These blocks can be associated with considerable morbidity (loss of motor and sensory function), so patients must be selected carefully, and only after thorough consideration of alternative analgesic modalities. Moreover, although the initial result may be excellent, the original pain may recur or new (deafferentation or central) pain develop in a majority of patients within weeks to months.

Temporary destruction of nerve fibers or ganglia can be accomplished by injection of alcohol or phenol. These neurolytic agents are not selective, affecting visceral, sensory, and motor fibers equally. Ethyl alcohol 50% to 100% causes extraction of membrane phospholipids and precipitation of lipoproteins in axons and Schwann cells, whereas phenol 6% to 12% coagulates proteins. Alcohol causes severe pain on injection; thus local anesthetic is usually administered first. For peripheral nerve blocks, alcohol may be given undiluted, but for sympathetic blocks in which large volumes are injected, it is given in a 1:1 mixture with bupivacaine. Phenol is usually painless when injected either as a 6% or an 8% aqueous solution or in glycerol; a 12% phenol solution can be prepared in radiopaque contrast solution.

**Neurolytic Techniques**

Neurolytic celiac plexus or splanchnic nerve blocks may be effective for painful intraabdominal neoplasms, especially pancreatic cancer. Lumbar sympathetic, hypogastric plexus, or ganglion impar neurolytic blocks can be used for pain secondary to pelvic neoplasms. Neurolytic saddle block can provide pain relief for patients with refractory pain from pelvic malignancy; however, bowel and bladder dysfunction should be expected. Neurolytic intercostal blocks can be helpful for patients with painful rib metastases. Additional neurodestructive procedures, such as pituitary adenolysis and cordotomy, may be useful in end-of-life palliative care.

When considering any neurolytic technique, at least one diagnostic block with a local anesthetic solution alone should be used initially to confirm the pain pathway(s) involved and to assess the potential efficacy and morbidity of the planned neurolysis. Local anesthetic solution should again be injected immediately prior to the neurolytic agent under fluoroscopic guidance. Following injection of any neurolytic agent, the needle must be cleared with air
or saline prior to withdrawal to prevent damage to superficial structures.

Many clinicians prefer alcohol for celiac plexus block and phenol for lumbar sympathetic block. For subarachnoid neurolytic techniques, very small amounts of neurolytic agent (0.1 mL) are injected. Alcohol is hypobaric, whereas phenol in glycerin is hyperbaric; the patient undergoing subarachnoid neurolysis is carefully positioned so that the solution travels to the appropriate level and is confined to the dorsal horn region following subarachnoid administration.

Cancer patients frequently receive anticoagulation therapy if they are at elevated risk for venous thromboembolic phenomena. When such a patient has discontinued anticoagulant medication in preparation for a diagnostic local anesthetic block, it may be more practical to obtain consent for a neurolytic procedure in advance and to follow the diagnostic block immediately with chemical neurolysis if the diagnostic procedure has resulted in pain relief.

7. Differential Neural Blockade

Pharmacological or anatomic differential neural blockade has been advocated as a method of distinguishing somatic, sympathetic, and psychogenic pain mechanisms. The procedure is controversial owing to the challenges of interpreting the data and the inability to define exactly which nerve fibers or pathways are blocked. Theoretically, the pharmacological approach relies on the differential sensitivity of nerve fibers to local anesthetics. Preganglionic sympathetic (B) fibers are reported to be most sensitive, closely followed by pain (Aδ) fibers, somatosensory (Aβ) fibers, motor fibers (Aα), and finally C fibers. By using different concentrations of local anesthetic, it may be possible to selectively block certain types of fibers while preserving the function of others. The challenge is that the critical concentration needed to block sympathetic fibers can vary considerably between patients, and conduction block by local anesthetics is dependent not only on fiber size but also on the duration of contact and frequency of impulses conducted. Many clinicians have therefore abandoned the use of pharmacological differential neural blocks in favor of anatomic differential blockade.

Stellate ganglion blocks can be used to selectively block sympathetic fibers to the head, neck, and arm. Celiac plexus, hypogastric plexus, and lumbar paravertebral sympathetic blocks can be used for sympathetic blocks of the abdomen, pelvis, and leg, respectively. Selective nerve root, intercostal, cervical plexus, brachial plexus, or lumbosacral plexus blocks may be used for somatic nerve blockade.
Differential epidural blocks may be used for thoracic pain when the techniques for sympathetic blockade carry a significant risk of pneumothorax (Table 47–16). After each epidural injection, the patient is evaluated for pain relief, signs of sympathetic blockade (a decrease in blood pressure), sensation to pinprick and light touch, and motor function. If the pain disappears after the saline injection, the patient either has psychogenic pain (usually a profound long-lasting effect) or is displaying a placebo effect (usually short lasting). If pain relief coincides with isolated signs of sympathetic blockade, it is likely mediated by sympathetic fibers. If pain relief only follows somatosensory blockade, it is likely mediated by somatic fibers. Lastly, if the pain persists even after signs of motor blockade, the pain is either central (supraspinal) or psychogenic.

1Chloroprocaine may be used instead.

The differential epidural block carries the risk of any neuraxial block, and the possibility of hypotension and blocking cardiac accelerator fibers at T1–T4. The level should not extend above the T5 dermatome due to these risks. Following catheter insertion, injections should be administered with the patient in a monitored setting for the rest of this procedure.

Although differential epidural blockade has limitations, it may be helpful to identify primarily centralized pain when a patient continues to have a significant level of pain despite multilevel dermatomal blockade over the painful region. It is unlikely that a subsequent nerve block would help to treat the painful condition.

When it is thought that a patient may have abdominal pain from the anterior abdominal wall, a TAP block may be performed using ultrasound guidance. This may offer potential short- or long-term relief and can be considered as an alternative to differential epidural blockade. If no relief is obtained, the pain may
have a visceral origin or a central cause. Visceral pain may best respond to a celiac or splanchnic nerve block and possibly to subsequent splanchnic RFA. Patients with pain that is primarily of a central origin may respond to multidisciplinary therapy, including counseling and biofeedback training.

8. Neuromodulation

Electrical stimulation of the nervous system can produce analgesia in patients with acute and chronic pain. Current may be applied transcutaneously, epidurally, or by electrodes implanted into the central nervous system.

Transcutaneous Electrical Nerve Stimulation

TENS is thought to produce analgesia by stimulating large afferent fibers. It may have a role for patients with mild to moderate acute pain and those with chronic low back pain, arthritis, and neuropathic pain. The gate theory of pain processing suggests that the afferent input from large epicritic fibers competes with that from the smaller pain fibers. An alternative theory proposes that at high rates of stimulation, TENS causes conduction block in small afferent pain fibers. With conventional TENS, electrodes are applied to the same dermatome as the pain and are stimulated periodically by direct current from a generator (usually for 30 min several times a day). A current of 10 to 30 mA with a pulse width of 50 to 80 μs is applied at a frequency of 80 to 100 Hz. Some patients whose pain is refractory to conventional TENS respond to low-frequency TENS (acupuncture-like TENS), which employs stimuli with a pulse width greater than 200 μs at frequencies less than 10 Hz (for 5–15 min). Unlike conventional TENS, low-frequency stimulation is at least partly reversed by naloxone, suggesting a role for endogenous opioids. This technique is also called dorsal column stimulation because it was thought to produce analgesia by directly stimulating large Aβ fibers in the dorsal columns of the spinal cord.

Spinal Cord Stimulation

Spinal cord stimulation (SCS) may be effective for neuropathic pain; accepted indications include sympathetically mediated pain, spinal cord lesions with localized segmental pain, phantom limb pain, ischemic lower extremity pain due to peripheral vascular disease, adhesive arachnoiditis, peripheral neuropathies, post-thoracotomy pain, intercostal neuralgia, postherpetic neuralgia, angina, visceral abdominal pain, and visceral pelvic pain. Patients with persisting pain
after back surgery, which is typically a mixed nociceptive–neuropathic disorder, also appear to benefit from SCS.

Temporary electrodes are initially placed in the posterior epidural space and connected to an external generator to evaluate efficacy in a 5- to 7-day trial (Figures 47–27 and 47–28). The trial may be extended, particularly if it allows a patient, such as one with CRPS, to tolerate more aggressive physical therapy. If a favorable response is obtained, a fully implantable system is inserted. Unfortunately, the effectiveness of the technique decreases with time in some patients. Complications include infection, lead migration, and lead breakage.

**FIGURE 47–27** Patient positioning for insertion of a spinal cord stimulator (SCS) with fluoroscopic guidance.
FIGURE 47–28 Two-lead SCS placement. A: Anteroposterior view. The right contact lead has been advanced to its final position at the top of T10. The left lead is advanced through the Tuohy needle. B: Lateral view. The first lead is in position, with the left lead entering the epidural space.

*Dorsal root ganglion (DRG) stimulation* has been shown to be an effective therapy and alternative to SCS to help treat CRPS in the lower extremities and allow for improved tolerance of physical therapy (Figure 47–29). Complications of SCS and DRG stimulation include infection, lead migration, and lead breakage.
**Peripheral Nerve Stimulation**

*Peripheral nerve stimulation* (PNS) differs from SCS in that leads are placed in close anatomic proximity to an injured peripheral nerve. The leads may be placed percutaneously, with or without ultrasound guidance, or surgically under direct vision of the nerve. Occipital nerve stimulators are one form of peripheral nerve stimulator that may be helpful in treating occipital neuralgia and migraine headache (Figure 47–30).
Deep Brain Stimulation

*Deep brain stimulation* (DBS) is used for intractable cancer pain and for intractable nonmalignant neuropathic pain. Electrodes are implanted stereotactically into the periaqueductal and periventricular gray areas for nociceptive pain, usually in patients with cancer or chronic low back pain. For neuropathic pain, the electrodes are frequently implanted into the ventral posterolateral and ventral posteromedial thalamic nuclei. DBS may also be helpful for patients with movement disorders, headache, and neuropsychiatric disorders. The most serious complications are intracranial hemorrhage and infection.

9. *Vertebral Augmentation*
Patients with pathological or osteoporotic vertebral compression fractures may benefit from *vertebral augmentation* with polymethylmethacrylate (PMMA) cement. *Vertebroplasty* involves injection of the cement through the trocar needle. *Kyphoplasty* involves inflation of a balloon inserted through a percutaneously placed trocar needle, with subsequent injection of cement (*Figure 47–31*). Anteroposterior and lateral fluoroscopic views facilitate optimal placement of the cement. For patients with a sacral insufficiency fracture, cement sacroplasty may help stabilize the fracture. Risks of vertebral augmentation include direct nerve injury (due to placement of the trocar needle), hemorrhage, cement extravasation, and embolic events.

**FIGURE 47–31** Kyphoplasty. **A:** Anteroposterior view reveals inflation of balloons at L2 prior to deflation and subsequent injection of polymethylmethacrylate (PMMA) at that level. Previously injected PMMA can be seen at L3 into the cavity created by bilateral balloon inflation and deflation. **B:** Lateral view. The balloons are inflated above the introducers at L2. The previously injected PMMA can be seen in the L3 vertebral body.

Kiva VCF vertebral augmentation has become available as an alternative approach to increase vertebral height after a recent compression fracture. The Kiva procedure involves placing a coil into the vertebral body over which a polyetheretherketone (PEEK) implant may be inserted. PMMA cement may be injected subsequently into the PEEK implant (*Figure 47–32*).
FIGURE 47–32 Kiva VCF vertebral augmentation. **A:** Anteroposterior view reveals appropriate width of coil to allow for subsequent polyetheretherketone (PEEK) implant deployment. **B:** Lateral view reveals advancing coil to create a cavity and allow for advancing and deployment of a PEEK implant and subsequent injection of PMMA.

**MULTIDISCIPLINARY TREATMENT**

**Psychological Interventions**

Psychological techniques, including cognitive therapy, behavioral therapy, biofeedback, relaxation techniques, and hypnosis, are widely used as part of a multidisciplinary approach to pain control. Cognitive interventions are based on the assumption that a patient’s attitude toward pain can influence the perception of pain. Maladaptive attitudes contribute to suffering and disability. The patient is taught skills for coping with pain either individually or in group therapy. The most common techniques include attention diversion and imagery. Behavioral (operant) therapy is based on the premise that behavior in patients
with chronic pain is determined by consequences of the behavior. Positive reinforcers (such as attention from a spouse) tend to enable or intensify the pain, whereas negative reinforcers reduce pain. The therapist’s role is to guide behavior modification with the aid of family members and medical providers in order to nurture negative reinforcers and minimize positive reinforcers.

Relaxation techniques teach the patient to alter the arousal response and the increase in sympathetic tone associated with pain. The most commonly employed technique is a progressive muscle relaxation exercise. Biofeedback and hypnosis are closely related interventions. All forms of biofeedback are based on the principle that patients can be taught to control involuntary physiological parameters. Once proficient in the technique, the patient may be able to induce a relaxation response and more effectively apply coping skills to control physiological factors (eg, muscle tension) that worsen pain. The most commonly utilized physiological parameters in biofeedback are muscle tension (electromyographic biofeedback) and temperature (thermal biofeedback). The effectiveness of hypnosis varies considerably among individuals. Hypnotic techniques teach patients to alter pain perception by having them focus on other sensations, localize the pain to another site, and dissociate themselves from a painful experience through imagery. Patients with chronic headaches and musculoskeletal disorders benefit most from these relaxation techniques.

**Physical Therapy**

Heat and cold can provide pain relief by alleviating muscle spasm. In addition, heat decreases joint stiffness and increases blood flow, and cold vasoconstricts and can reduce tissue edema. The analgesic action of heat and cold may at least partially be explained by the gate theory of pain processing.

Superficial heating modalities include conductive (hot packs, paraffin baths, fluidotherapy), convective (hydrotherapy), and radiant (infrared) techniques. Techniques for application of deep heat include ultrasound as well as shortwave and microwave diathermy. These modalities are more effective for pain involving deep joints and muscles. Cold is most effective for pain associated with acute injuries and edema. When applied selectively, cold can also relieve muscle spasm. Application may take the form of cold packs, ice massage, or vapocoolant sprays (ethyl chloride or fluoromethane).

Exercise should be part of any rehabilitation program for chronic pain. A graded exercise program prevents joint stiffness, muscle atrophy, and contractures, all of which can contribute to the patient’s pain and functional
disabilities. McKenzie exercises are particularly helpful for patients with lumbar disc displacement. Patients may state that physical therapy has not helped in the past. The efficacy of previous physical therapy techniques should be assessed, and the appropriateness of current physical therapy sessions and of the home exercise program should also be evaluated. By facilitating increased range of motion and providing constant resistance, aquatherapy may be particularly helpful for patients who may not be able to tolerate other forms of therapy.

**Acupuncture**

Acupuncture can be a useful adjunct for patients with chronic pain, particularly that associated with chronic musculoskeletal disorders and headaches. The technique involves insertion of needles into discrete anatomically defined points, called *meridians*. Stimulation of the needle after insertion takes the form of twirling or of application of a mild electrical current. Insertion points appear to be unrelated to the conventional anatomy of the nervous system. Although the scientific literature concerning the mechanism of action and role of acupuncture in pain management is controversial, some studies suggest that acupuncture stimulates the release of endogenous opioids, as its effects can be antagonized by naloxone.

**GUIDELINES**

**SUGGESTED READINGS**

A well-functioning enhanced recovery program (ERP) uses evidence-based practices that ensure continuity of care, decrease variation in clinical management, minimize organ dysfunction, decrease postoperative complications, and accelerate convalescence.

The perioperative surgical home (PSH) is defined by interdisciplinary, team-based global management of the surgical patient throughout the surgical care continuum. PSH management begins following the initial surgical diagnosis and patient preparation, and ends when the patient is returned to the care of his or her primary health care provider after full recovery. It includes several perioperative enhanced recovery program (ERP) elements that are adapted to the local clinical care environment.

Persistent postsurgical pain (chronic pain that continues beyond the typical healing period of 1 to 2 months following surgery, or well past the normal period for postoperative follow-up) is increasingly acknowledged as a common and significant problem following surgery.

The magnitude of the surgical stress response is related to the intensity of the surgical stimulus, hypothermia, and psychological stress. It can be moderated by perioperative interventions, including neural blockade and reduction in procedural invasiveness.

Neuraxial blockade of nociceptive stimuli by epidural and spinal local anesthetics has been shown to blunt the metabolic, inflammatory, and
neuroendocrine stress response to surgery. In major open abdominal and thoracic procedures, thoracic epidural blockade with local anesthetic provides excellent analgesia, facilitates mobilization, and decreases the incidence and severity of ileus.

Epidural blockade using a solution of local anesthetic and low-dose opioid provides better postoperative analgesia at rest and with movement than systemic opioids. By sparing opioid use and minimizing the incidence of systemic opioid-related side effects, epidural analgesia facilitates both earlier mobilization and earlier resumption of oral nutrition, expediting exercise activity and attenuating loss of body mass.

Peripheral nerve blocks (PNBs) with local anesthetics (single-shot or continuous infusion) block afferent nociceptive pathways and are an excellent way to minimize the need for systemic opioids and thereby reduce the incidence of opioid-related side effects.

Lidocaine (intravenous bolus of 100 mg or 1.5–2 mg/kg, followed by continuous intravenous infusion of 1.5–3 mg/kg/h or 2–3 mg/min) has analgesic, antihyperalgesic, and antiinflammatory properties.

Multimodal analgesia combines different classes of medications that have different (multimodal) pharmacological mechanisms of action, resulting in additive or synergistic effects to reduce postoperative pain and its sequelae.

The addition of nonsteroidal antiinflammatory drugs (NSAIDs) to systemic opioid analgesia diminishes postoperative pain intensity, reduces opioid requirements, and decreases opioid-related side effects such as postoperative nausea and vomiting (PONV), sedation, and urinary retention. However, NSAIDs may increase the risk of gastrointestinal and wound bleeding, decrease kidney function, and impair wound healing.

Opioid administration by patient-controlled analgesia provides better pain control, greater patient satisfaction, and fewer opioid side effects when compared to nurse-administered on-request (PRN) parenteral opioid administration.

Single-shot and continuous peripheral nerve blockade is frequently utilized for fast-track ambulatory and inpatient orthopedic surgery, and can accelerate recovery from surgery and improve analgesia and patient satisfaction.

Postoperative ileus delays postoperative resumption of enteral feeding,
is often a source of considerable patient discomfort, and is one of the most common causes of prolonged postoperative hospital length of stay and preventable hospitalization costs. Nasogastric tubes should be discouraged whenever possible or used for only a very short period of time, even with gastrointestinal surgery. The opioid-sparing effects of multimodal analgesia shorten the duration of postoperative ileus or may preempt it entirely.

Because either excessive, or excessively restricted, perioperative fluid therapy increases the incidence and severity of postoperative ileus, a goal-directed fluid administration strategy may be beneficial, especially in patients undergoing major surgery associated with large fluid shifts or patients at high risk of developing postoperative gastrointestinal complications.

### Evolution of Enhanced Recovery Programs

Major advances in surgical and anesthetic management have progressively decreased risk-adjusted perioperative mortality and morbidity. Continued improvement in perioperative outcomes, including accelerated postoperative convalescence and decreased perioperative complications, depends upon the continued evolution of integrated, multidisciplinary team approaches to perioperative care. The goal of team-based care is to combine individual evidence-based elements of perioperative care (eg, analgesic regimens, nutritional interventions, and physical therapy), each of which may have modest benefits when used in isolation into a tightly coordinated effort that has significant synergistic, beneficial effects upon surgical outcomes (the theory of aggregation of marginal gains).

Such coordinated, multidisciplinary perioperative care programs are termed enhanced recovery programs (ERPs), fast-track surgery, or enhanced recovery after surgery (ERAS) (Figure 48–1). A well-functioning ERP uses evidence-based practices that ensure continuity of care, decrease variation in clinical management, minimize organ dysfunction, decrease postoperative complications, and accelerate convalescence (Figure 48–2). The success of ERPs relies upon the additive or synergistic effects of the interventions included in these programs. Adherence to ERP pathways is associated with better postoperative outcomes, accelerated convalescence, and lower costs.
Assessing outcomes following ERP adoption is critical. Hospital length of stay is a commonly used measure of success, although in many health care systems the timing of hospital discharge is more directly related to administrative and organizational issues than to discrete surgical and medical milestones in the patient’s postoperative recovery. Little research has been undertaken to define the process of postoperative recovery, and few outcome measures are currently available to confirm that postoperative recovery has been accomplished for a given surgical disease. Other measures of successful implementation of ERPs include reduced rates of hospital readmission and reduced rates and severity of perioperative complications. Promising data suggest that ERPs may improve oncologic outcomes after surgery.

Anesthetic interventions that reduce pain, facilitate earlier postoperative mobilization, and allow earlier resumption of oral feeding accelerate the pace of perioperative recovery. In this context, the anesthesia provider must not only provide ideal anesthetic management throughout the procedure, but must also help improve overall perioperative care. These goals are achieved through optimizing the patient’s preoperative medical condition, avoiding prolonged
fasting, moderating the adverse effects of the intraoperative neuroendocrine stress response, and providing multimodal pain and symptom management to accelerate postoperative recovery.

Initially developed for patients undergoing colorectal and cardiac surgery, ERPs have also been developed for patients undergoing esophageal, bariatric, pancreatic, liver, head and neck, breast, orthopedic, bariatric, and pediatric abdominal surgery. Many ERP guidelines and consensus statements are available from the various specialty societies.

The perioperative surgical home (PSH) has been defined as a “patient centered, innovative model of delivering health care during the entire patient surgical/procedural experience; from the time of the decision for surgery until the patient has recovered and returned to the care of his or her patient centered medical home or primary health care provider.” The PSH “provides coordination of care throughout all of the clinical microsystems of care.” PSH programs can be considered an evolution of ERPs, because they include several perioperative ERP elements but are adapted to the local clinical environment. Based on their unique clinical skills, anesthesiologists are called to play a pivotal, coordinating care role in the PSH. To accomplish this, anesthesia providers must integrate with the surgical and medical teams with whom they jointly provide perioperative care. Accordingly, anesthesiology training programs must expand their curricula to include the entire continuum of perioperative care.

Persistent postsurgical pain (chronic pain that continues beyond the typical healing period of 1–2 months following surgery) is increasingly acknowledged as a common and significant issue following surgery. The incidence of persistent postsurgical pain may exceed 30% after some operations, especially amputations, thoracotomy, mastectomy, and inguinal herniorrhaphy. Although the cause is unclear, several risk factors have been identified (Figure 48–3). Multimodal perioperative pain control is often suggested as a fundamental preemptive strategy to reduce the incidence of persistent postsurgical pain (see Chapter 47).
Anesthetic Management–Related Factors Contributing to Enhanced Recovery

PREOPERATIVE PERIOD

Patient Education

Cooperation from the patient and family is essential if an ERP is to be effectively implemented. Preoperative teaching must use plain language and avoid medical jargon. Well-designed print, video, and online materials presented in the patient’s native language are useful to introduce ERPs. Smartphone text messaging and patient navigation apps are increasingly utilized to help organize and coordinate the patient’s perioperative care continuum.

Preoperative Risk Assessment & Optimization of
**Functional Status**

Reducing the likelihood of perioperative complications improves surgical recovery. Preoperative assessment is discussed in detail in Chapter 18. Although international guidelines evaluating the risk for developing cardiovascular, respiratory, or metabolic complications have been extensively reviewed and published, less attention has been given to assessment and optimization of preoperative functional and physiological status. Nonetheless, some recommendations can be made. For example, perioperative β-blockers should be continued in patients already receiving this therapy. Perioperative statins appear to decrease postoperative cardiovascular complications and should not be abruptly discontinued perioperatively. Several procedure-specific scoring systems based on patient comorbidity, type of surgery, and biochemical data are being used to predict postoperative mortality and morbidity. In addition, risk-adjusted scoring systems, such as the American College of Surgeons’ National Surgical Quality Improvement Program (NSQIP) and the Society of Thoracic Surgeons’ National Database, can be used to compare outcomes among institutions.

**Smoking & Alcohol Cessation**

Preoperative evaluation of surgical risk and optimization of medical comorbidities also provides opportunity to modify habits that may significantly impact the patient’s short-term and long-term health and quality of life. Smoking, drug abuse, and excessive alcohol use are risk factors for the development of postoperative complications. Perioperative interventions aimed at risk modification can reduce risks of complications, accelerate surgical recovery, and reduce perioperative costs. A recent meta-analysis found that preoperative smoking cessation, for any type of surgery, reduced postoperative complications by 41%, especially those related to wound healing and the lungs. Intense preoperative smoking cessation programs of 3 to 4 weeks’ duration that include pharmacological interventions (eg, nicotine replacement therapy) and patient counseling produce better results than brief and isolated preoperative smoking cessation interventions. Many psychological and pharmacological strategies are also available to help patients stop excessive alcohol consumption and reduce the risk of alcohol withdrawal.

**Guidelines for Food & Fluid Intake**
Preoperative fasting and surgical stress induce insulin resistance. Furthermore, patients who are not allowed to drink fluids after an overnight fast and those who receive a mechanical bowel preparation experience dehydration, which may increase discomfort and cause drowsiness and orthostatic lightheadedness. Although fasting has been advocated as a preoperative strategy to minimize the risk of pulmonary aspiration during induction of anesthesia, this benefit must be weighed against the detrimental aspects of this practice.

Research suggests that avoiding preoperative fasting and ensuring adequate hydration and energy supply may moderate postoperative insulin resistance. Preliminary evidence has shown that preoperative administration of carbohydrate (CHO) drinks (eg, 50 g of maltodextrin 2–3 h before induction of anesthesia) is safe and reduces insulin resistance, hunger, fatigue, and postoperative nausea and vomiting (PONV). Moreover, CHO drinks positively influence recovery of bowel and immune function. However, these results have been achieved mainly with maltodextrin CHO drinks, and the metabolic and clinical impacts of simple sugar CHO drinks are unknown. It is important to educate patients to drink preoperative CHO over a short time, as sipping these beverages over hours does not induce a sufficient insulin response to reduce insulin resistance.

Contemporary international fasting guidelines allow clear fluids up to 2 h prior to induction of anesthesia in patients at low risk for pulmonary aspiration (see Chapter 18). The safety of allowing clear fluids, CHO drinks, or both, 2 h before induction of anesthesia has been demonstrated by magnetic resonance imaging studies in healthy volunteers. Residual gastric volume 2 h after 400 mL of oral carbohydrate (12.5% maltodextrins) was found to be similar to the residual gastric volume following an overnight fast (mean volume 21 mL). The safety of this practice has been tested in patients with uncomplicated type 2 diabetes mellitus, none of whom showed evidence of worsened risk of aspiration. Despite several clinical trials demonstrating that prolonged fasting impairs postoperative recovery, compliance with evidence-based fasting guidelines remains low, as physicians continue to order nil per os (NPO) after midnight.

**INTRAOPERATIVE PERIOD**

**Antithrombotic Prophylaxis**

Antithrombotic prophylaxis reduces perioperative venous thromboembolism risk
and related morbidity and mortality. Both pneumatic compression devices and anticoagulant medications are now commonly used. Because neuraxial anesthesia techniques are commonly employed for many patients undergoing major abdominal, vascular, thoracic, and orthopedic procedures, appropriate timing and administration of antithrombotic agents in these cases is of critical importance in order to avoid the risk of epidural hematoma. International recommendations on the management of anticoagulated patients receiving regional anesthesia are discussed in Chapter 45.

**Antibiotic Prophylaxis**

Appropriate selection and timing of preoperative antibiotic prophylaxis reduces the risk of surgical site infections. Antibiotics should be administered intravenously within 1 h before skin incision and, based on their plasma half-life and estimated blood loss, should be repeated during lengthy surgeries to ensure adequate tissue concentrations. Recent data from large national databases have demonstrated that administration of oral antibiotics 24 h prior to colorectal surgery in patients receiving mechanical bowel preparation (MBP) reduces the risk of surgical site infections, when compared with patients receiving MBP alone or those not receiving MBP. Antibiotic prophylaxis for surgical site infections should be discontinued within 24 h following surgery, although current guidelines permit cardiothoracic patients to receive antibiotics for 48 h following surgery.

**Strategies to Minimize the Surgical Stress Response**

The surgical stress response is characterized by neuroendocrine, metabolic, inflammatory, and immunological changes initiated by the physiological trespass of the surgical incision and subsequent invasive procedures. The stress response can adversely affect organ function and perioperative outcomes, and may include induction of a catabolic state as well as a transient, but reversible, state of insulin resistance, characterized by decreased peripheral glucose uptake and increased endogenous glucose production. The magnitude of the surgical stress response is related to the intensity of the surgical stimulus, hypothermia, and psychological stress. It can be moderated by perioperative interventions, including neural blockade and reduction in procedural invasiveness. Much recent effort has focused on developing surgical and anesthetic techniques that reduce the surgical stress response, with the goal of lowering the risk of stress-related organ dysfunction and perioperative complications. An overview of several
techniques that have proved effective in ERP protocols follows.

A. Minimally Invasive Surgery
It is well established that minimally invasive surgical procedures are associated with significantly less surgical stress when compared with corresponding “open” procedures. Published data highlight the safety of minimally invasive procedures in the hands of adequately trained and experienced surgeons. Moreover, a longer term salutary impact is achieved when laparoscopic techniques are included in ERPs. For example, laparoscopic procedures are associated with a reduced incidence of surgical complications, especially surgical site infections, when compared with the same procedures performed in “open” fashion. A laparoscopic approach is also associated with less postoperative surgical pain, better postoperative respiratory function, and less morbidity in elderly surgical patients. Over the past 15 years, further advancements in surgical care, such as robotic surgery, natural orifice specimen extraction during laparoscopic surgery, endoscopic surgical approaches, and minimally invasive orthopedic surgery, have further moderated the impact of surgery on surgical stress, and such progress is expected to continue.

B. Regional Anesthesia/Analgesia Techniques
A variety of fast-track surgical procedures have taken advantage of the beneficial clinical and metabolic effects of regional anesthesia/analgesia techniques (Table 48–1). Neuraxial blockade of nociceptive stimuli by epidural and spinal local anesthetics has been shown to blunt the metabolic, inflammatory, and neuroendocrine stress responses to surgery. In major open abdominal and thoracic procedures, thoracic epidural blockade with local anesthetic is a recommended anesthetic component of a postoperative ERP, providing excellent analgesia, facilitating mobilization and physical therapy, and decreasing the incidence and severity of ileus. However, the advantages of epidural blockade in such cases are not as evident when minimally invasive surgical techniques are used, and in certain cases, epidural blockade has even been shown to delay recovery and prolong hospital stay. Lumbar epidural anesthesia/analgesia should be discouraged for abdominal surgery because it often does not provide adequate segmental analgesia for an abdominal incision. In addition, it frequently causes urinary retention and lower limb sensory and motor blockade, increasing the need for urinary drainage catheters (with accompanying increased risk of urinary tract infection), delaying mobilization and recovery, and increasing the risk of falls.
Enhanced recovery programs that incorporate regional anesthesia/analgesia techniques.\(^1\)

**Epidural blockade using a solution of local anesthetic and low-dose opioid provides better postoperative analgesia at rest and with movement than systemic opioids (Figure 48–4 and Table 48–2).** By sparing opioid use and minimizing the incidence of systemic opioid-related side effects, epidural analgesia facilitates both earlier mobilization and earlier resumption of oral nutrition, expediting exercise activity and attenuating loss of body mass. It minimizes postoperative insulin resistance by attenuating the postoperative hyperglycemic response and by facilitating utilization of exogenous glucose, thereby preventing postoperative loss of amino acids and conserving lean body mass.

TABLE 48–2 Options for composition of thoracic epidural infusion analgesia solutions.¹
If spinal anesthesia is used for fast-track (and especially ambulatory) surgery, attention must be paid to delayed recovery due to prolonged motor blockade. The use of smaller doses of intrathecal local anesthetics (lidocaine, 30–40 mg; bupivacaine, 3–10 mg; or ropivacaine, 5–10 mg) with lipophilic intrathecal opioids (fentanyl, 10–25 mcg, or sufentanil, 5–10 mcg) can prolong postoperative analgesia and minimize motor block without delaying recovery from anesthesia. The introduction of ultra-short-acting intrathecal agents such as 2-chloroprocaine (still controversial at present) may further speed the fast-track process. Spinal opioids are associated with side effects such as nausea, pruritus, and postoperative urinary retention. Adjuvants such as clonidine are effective alternatives to intrathecal opioids, with the goal of avoiding opioid side effects that may delay hospital discharge. For example, intrathecal clonidine added to spinal local anesthetic provides effective analgesia with less urinary retention than intrathecal morphine. In a recent study, lower cortisol and glucose levels were observed in colorectal patients receiving spinal anesthesia with intrathecal local anesthetic and morphine compared with patients receiving systemic opioids; however, the inflammatory response did not differ between the two analgesic techniques. Further studies are needed to define the safety and efficacy of regional anesthesia techniques in fast-track cardiac surgery. Although some cardiac surgery studies have shown that spinal analgesia with intrathecal morphine decreases extubation time, decreases length of stay in the intensive care unit (ICU), reduces pulmonary complications and arrhythmias, and provides analgesia with less respiratory depression, other studies have shown no benefit to this approach.

Peripheral nerve blocks (PNBs) with local anesthetics (single-shot or continuous infusion) block afferent nociceptive pathways and are an excellent way to minimize the need for systemic opioids and thereby reduce the incidence of opioid-related side effects and facilitate recovery (see Chapter 46). The choice of local anesthetic, dosage, and concentration should be made with the goal of avoiding prolonged motor blockade and delayed mobilization and discharge.

C. Intravenous Lidocaine Infusion

Lidocaine (intravenous bolus of 100 mg or 1.5–2 mg/kg, followed by continuous intravenous infusion of 1.5–3 mg/kg/h or 2–3 mg/min) has analgesic, antihyperalgesic, and anti-inflammatory properties. In patients undergoing colorectal and radical retropubic prostate surgeries, intravenous lidocaine has been shown to reduce requirements for opioids and general anesthetic agents, provide satisfactory analgesia, facilitate early return of bowel function, and accelerate hospital discharge. Although lidocaine infusion potentially may replace neuraxial blockade and regional anesthesia in some circumstances, more studies are needed to confirm the advantage of this technique in the context of ERPs. The most effective dose and duration of infusion for various surgical procedures remains to be determined; even short duration of lidocaine infusion may have benefit.

D. β-Blockade Therapy

β-Blockers have been used to blunt the sympathetic response during laryngoscopy and intubation and to attenuate the surgical stress-induced increase in circulating catecholamines. They also have been shown to prevent perioperative cardiovascular events in at-risk patients undergoing noncardiac surgery and to help maintain hemodynamic stability during the intraoperative period and during emergence from anesthesia. They possess anticatabolic properties, which may be explained by reduced energy requirements associated with decreased adrenergic stimulation. Intravenous esmolol reduces the requirement of volatile anesthetic agents and decreases minimum alveolar concentration values; it has also been shown to reduce postoperative pain intensity, opioid consumption, and PONV. A positive protein balance has been reported in critically ill patients when β-blockade is combined with parenteral nutrition. However, the precise role of β-blockers as adjuvant analgesics in the context of ERPs remains undetermined.

E. Intravenous α₂-Agonist Therapy
Both clonidine and dexmedetomidine have anesthetic and analgesic properties. Clonidine decreases postoperative pain, reduces opioid consumption and opioid-related side effects, and prolongs neuraxial and peripheral nerve local anesthetic blockade. In patients undergoing cardiovascular fast-track surgery, spinal morphine with clonidine decreases extubation time, provides effective analgesia, and improves quality of recovery. The role of dexmedetomidine in ERP pathways has not been extensively studied.

Use of Short-Acting Intravenous & Inhalation Agents

A. Intravenous Anesthetics
Intravenous propofol is the deep sedation and general anesthesia induction agent of choice for most surgical procedures. Propofol total intravenous anesthesia (TIVA) is often used as part of a multimodal regimen for patients at high risk for PONV.

B. Inhalational Anesthetics
When compared with other volatile anesthetic agents, desflurane and sevoflurane may shorten anesthesia emergence, reduce postanesthesia care unit (PACU) length of stay, and decrease recovery-associated costs. There is evidence that avoidance of deep general anesthesia by use of bispectral index (BIS) monitoring may improve outcomes, including a reduction of the incidence of postoperative delirium and cognitive dysfunction. Nitrous oxide, because of its anesthetic- and analgesic-sparing effects, rapid pharmacokinetic profile, and low cost, is sometimes administered with other inhalation agents. However, routine administration of nitrous oxide has declined recently, as it may cause bowel distention and impair the laparoscopic surgeon’s view of anatomic structures, and may increase the risk of PONV (see Chapter 8).

C. Opioids
Short-acting opioids such as fentanyl, alfentanil, and remifentanil are commonly used during fast-track surgery in combination with inhalation agents or propofol, and with regional or local anesthesia/analgesia techniques. However, intraoperative administration of remifentanil to patients who will experience extensive postoperative pain has been associated with opioid-induced hyperalgesia, acute opioid tolerance, and increased analgesic requirements during the postoperative period. There is increasing evidence that the use of opioids should be minimized in all phases of the perioperative course as part of a
multimodal analgesia technique to reduce opioid side effects and optimize recovery. Opioid-free anesthesia has been shown to reduce PONV and postoperative opioid use when compared with opioid-based anesthesia and may be an alternative technique, especially in patients at high risk for PONV, sleep apnea, or respiratory depression.

**Maintenance of Normothermia**

The inhibitory effects of anesthetic agents on thermoregulation, exposure to the relatively cool surgical environment, and intraoperative heat loss can lead to hypothermia in all patients undergoing surgical procedures. The duration and extent of the surgical procedure directly correlates with hypothermia risk. Perioperative hypothermia increases cardiovascular morbidity and wound infection risk by increasing sympathetic discharge and inhibiting the immune cellular response. A decrease in core body temperature of 1.9°C triples the incidence of surgical wound infection. The risk of bleeding and blood transfusion requirement are also increased with hypothermia. Furthermore, by impairing the metabolism of many anesthetic agents, hypothermia may significantly prolong anesthesia recovery (see Chapter 52).

**Maintenance of Adequate Tissue Oxygenation**

Surgical stress leads to impaired pulmonary function and to peripheral vasoconstriction, resulting in arterial and local tissue hypoxemia, respectively. Perioperative hypoxia can increase cardiovascular and cerebral complications, and many strategies should be adopted during the perioperative period to prevent its development.

Maintenance of adequate perioperative oxygenation by oxygen supplementation has been associated with the improvement of some clinically relevant outcomes. Intraoperative and postoperative (for 2 h) inspired oxygen concentration of 80% increases arterial and subcutaneous oxygen tension and may decrease the rate of wound infection and lower the incidence of PONV, without increasing potential complications associated with high inspired oxygen fraction, such as atelectasis and hypercapnia. Regional anesthesia techniques decrease vascular resistance and may improve peripheral tissue perfusion and oxygenation. Finally, early mobilization and avoidance of bedrest improve postoperative central and peripheral tissue oxygenation.
Postoperative Nausea & Vomiting Prophylaxis

PONV is a frequent complication that delays early feeding and postoperative recovery. Preemptive strategies minimizing the risk of PONV are strongly advocated for any type of surgery, and consensus guidelines for prevention and management of PONV are available in the current literature (see Chapters 17 and 56).

Goal-Directed Fluid & Hemodynamic Therapy

There is increasing evidence that perioperative fluid administration affects patient outcome following major surgery, with the quantity of fluid administered—either too restrictive or too liberal—being associated with increased incidence of postoperative complications. Observational studies reveal large variation in practitioners’ fluid management strategies. Most attention is focused on avoiding hypovolemia, whereas excessively liberal fluid administration and its attendant adverse effects, though more difficult to observe in the operating room, are probably more common. Fluid overload, especially of crystalloid, has been associated with reduced tissue oxygenation, anastomotic leakage, pulmonary edema, pneumonia, wound infection, postoperative ileus, and prolonged hospitalization. Furthermore, excess fluids commonly increase body weight by 3 to 6 kg and may impair postoperative mobilization.

The concept of goal-directed fluid therapy (GDFT) is based on optimization of hemodynamic measures such as heart rate, blood pressure, stroke volume, pulse pressure variation, and stroke volume variation obtained by noninvasive cardiac output devices such as pulse-contour arterial waveform analysis, transesophageal echocardiography, or esophageal Doppler (see Chapter 5). GDFT aims to avoid both hypovolemia and fluid excess, and has been shown to be the optimal approach for fluid administration in high-risk surgical patients.

The type of fluid infused is also important: isotonic balanced crystalloid should be used to replace extracellular losses, whereas iso-oncotic colloids are commonly used to replace intravascular volume (Table 48–3).

**POSTOPERATIVE PERIOD**

**Immediate Postoperative Care**

**A. Strategies to Minimize Postoperative Shivering**

The primary cause of postoperative shivering is perioperative hypothermia, although other, non-thermoregulatory, mechanisms may be involved. Postoperative shivering can greatly increase oxygen consumption, catecholamine release, cardiac output, heart rate, blood pressure, and intracranial and intraocular pressure. It increases cardiovascular morbidity, especially in elderly patients, and increases PACU length of stay and cost. Shivering is uncommon in
elderly and hypoxic patients: the efficacy of thermoregulation decreases with aging, and hypoxia can directly inhibit shivering. Many drugs, notably meperidine, clonidine, and tramadol, can be used to reduce postoperative shivering; however, prevention via strategies intended to minimize thermal loss is optimal (see Chapter 52).

B. PONV Treatment
Pharmacological treatment of PONV should be promptly initiated once medical or surgical causes of PONV have been ruled out (see Chapters 17 and 56).

C. Multimodal Analgesia
Multimodal analgesia combines different classes of medications that have different (multimodal) pharmacological mechanisms of action, resulting in additive or synergistic effects to reduce postoperative pain and its sequelae. Such an approach may achieve desired analgesic effects while reducing analgesic dosage and associated side effects. Multimodal pain management often includes utilization of regional analgesic techniques, including local anesthetic wound infusion, epidural/intrathecal analgesia, or single-shot/continuous peripheral nerve blockade. Multimodal analgesia is routinely utilized in ERPs to improve postoperative outcomes. Discussion here focuses on principal analgesic interventions used in perioperative multimodal analgesia regimens.

1. NSAIDs—The addition of nonsteroidal antiinflammatory drugs (NSAIDs) to systemic opioid analgesia diminishes postoperative pain intensity, reduces opioid requirements, and decreases opioid-related side effects such as PONV, sedation, and urinary retention. However, NSAIDs may increase the risk of gastrointestinal and wound bleeding, decrease kidney function, and impair wound healing. There is also a concern that NSAIDs may have a detrimental effect on anastomotic healing of the gastrointestinal tract and increase the risk of anastomotic leak, although this is controversial and further research is needed.

Perioperative administration of selective cyclooxygenase-2 (COX-2) inhibitor NSAIDs likewise reduces postoperative pain and decreases both opioid consumption and opioid-related side effects, and although their use reduces the incidence of NSAID-related platelet dysfunction and gastrointestinal bleeding, the potential adverse effects of COX-2 inhibitors on kidney function remain controversial. Concerns have also been raised, primarily with rofecoxib and valdecoxib, regarding COX-2 safety for patients undergoing cardiovascular surgery. Increased cardiovascular risk associated with the perioperative use of celecoxib or valdecoxib in patients with minimal cardiovascular risk factors and
undergoing nonvascular surgery is unproven. Further studies are needed to establish the analgesic efficacy and safety of COX-2 inhibitors, their clinical impact on postoperative outcomes, and their precise role in ERPs.

2. **Acetaminophen (paracetamol)**—Oral, rectal, and parenteral acetaminophen is a common component of multimodal analgesia. Acetaminophen’s analgesic effect is 20% to 30% less than that of NSAIDs, but its pharmacological profile is safer. Analgesic efficacy improves when the drug is administered together with NSAIDs, and it significantly reduces pain intensity and spares opioid consumption after orthopedic and abdominal surgery. However, acetaminophen may not reduce opioid-related side effects. Routine administration of acetaminophen in combination with regional anesthesia and analgesia techniques may allow NSAIDs to be reserved for control of breakthrough pain, thus limiting the incidence of NSAID-related side effects.

3. **Gabapentinoids**—Oral gabapentin and pregabalin given as a single dose preoperatively have been shown to decrease postoperative pain and opioid consumption in the first 24 h following surgery. There is debate about the dose and duration of perioperative use of these drugs, and whether they may potentially alter the incidence of chronic pain after surgery. Common side effects include sedation and dizziness, especially in elderly patients.

4. **N-methyl-d-aspartate (NMDA) receptor antagonists**—Ketamine: Perioperative low-dose ketamine (bolus, infusion) has been associated with significant reduction in pain, opioid consumption, and PONV. Ketamine has also been shown to be of particular benefit in patients on chronic opioids.

   Magnesium: Magnesium may also reduce postoperative pain and opioid consumption, although the optimal dosing is uncertain. Side effects include hypotension and potentiation of neuromuscular blockade.

5. **Intravenous lidocaine**—Intravenous lidocaine infusion analgesia has recently increased in popularity because there is good evidence to support its use as a component of multimodal analgesia. In major abdominal surgery, it is associated with faster return of bowel function and decreased hospital length of stay. Continuous cardiovascular monitoring is frequently advocated for patients receiving intravenous lidocaine, and therefore its use is currently limited to settings such as the PACU, ICU, or a monitored hospital ward. However, several centers have developed and implemented perioperative protocols to safely use intravenous lidocaine on surgical wards without continuous cardiovascular monitoring.
6. Opioids—Despite the increasing use of new, nonopioid analgesic medications and adjuvants and of regional anesthesia and analgesia techniques intended to minimize opioid requirements and opioid-related side effects (Table 48–4), the use of systemic opioids remains a cornerstone in the management of surgical pain. Parenteral opioids are frequently prescribed in the postoperative period during the transitional phase to oral analgesia. Opioid administration by patient-controlled analgesia (PCA) provides better pain control, greater patient satisfaction, and fewer opioid side effects when compared to nurse-administered, on-request (PRN) parenteral opioid administration. Oral administration of opioids, such as oxycodone or hydrocodone, in combination with NSAIDs or acetaminophen, or both, is common in the perioperative period.

7. **Epidural analgesia**—In addition to providing excellent analgesia, epidural blockade blunts the stress response associated with surgery, decreases postoperative morbidity, attenuates catabolism, and accelerates postoperative functional recovery. Compared with systemic opioid analgesia, thoracic epidural analgesia provides better static and dynamic pain relief. However, these benefits have mainly been observed in patients undergoing open abdominal and thoracic surgery; its usefulness in patients undergoing minimally invasive abdominal and thoracic surgery is questionable, as recent trials have suggested it may actually prolong in-hospital recovery in such cases. Long-acting local anesthetics such as ropivacaine (0.2%), bupivacaine (0.0625–0.125%), and levobupivacaine (0.1–0.125%) are commonly administered together with lipophilic opioids by continuous epidural infusion or by patient-controlled epidural analgesia (PCEA). As previously noted, administering low doses of local anesthetic via thoracic epidural infusion instead of lumbar levels avoids lower extremity motor blockade that may delay postoperative mobilization and recovery and will increase the risk of patient falls. Adding opioids to epidural local anesthetics improves the quality of postoperative analgesia without delaying recovery of bowel function.

8. **Paravertebral nerve blocks**—Paravertebral nerve blocks provide similar parietal analgesia to epidural blockade but without the risk of epidural-related side effects. However, they have been poorly studied in the context of ERPs.

9. **Peripheral nerve blockade**—Single-shot and continuous peripheral nerve blockade is frequently utilized for fast-track ambulatory and inpatient orthopedic
surgery, and can accelerate recovery from surgery and improve both analgesia and patient satisfaction (see Chapters 38 and 46). For some procedures, blocking multiple nerves can provide analgesic benefits superior to blockade of a single nerve. The opioid-sparing effect of nerve blocks minimizes the risk of systemic opioid-related side effects. Appropriate patient selection and strict adherence to institutional clinical pathways helps ensure the success of peripheral nerve blockade as a fast-track orthopedic analgesia technique and also helps minimize its risks.

Advances in ultrasound imaging technology and techniques have accelerated interest in abdominal wall blockade, facilitating the selective localization of specific nerves and the direct deposition of local anesthetic solutions in proximity to the compartments where specific nerves are located (see Chapters 38 and 46).

Single-shot perineural administration of liposomal bupivacaine has been used recently to extend the analgesic duration of peripheral nerve blocks to up to 72 h after surgery. However, preliminary studies have not consistently shown expected benefits, and the role of liposomal local anesthetic preparations in postoperative analgesia and ERPs has, therefore, yet to be precisely defined.

10. High-volume local anesthetic infiltration analgesia and wound infusion
—High-volume local anesthetic infiltration analgesia with a mixture of local anesthetic and epinephrine, with or without systemic NSAIDs, has recently gained popularity in patients undergoing total hip and knee replacements, and is currently replacing peripheral nerve blocks in many institutions, especially in the context of an ERP (see Chapter 38). However, supporting evidence demonstrating that this technique is superior to peripheral nerve blockade is currently lacking. Moreover, its impact on metabolic and inflammatory responses and on non–analgesic-related outcomes remains unknown. The impact of peripheral nerve blocks and rehabilitation therapy on functional outcomes also remains incompletely studied.

Local anesthetic wound infusions can be used to improve postoperative pain control and reduce the necessity for opioids, especially in patients undergoing open abdominal surgery and in whom epidural analgesia is contraindicated. The analgesic efficacy of local anesthetic wound infusion has been also established for multiple other surgical procedures. Inconsistent results from wound infusion may be secondary to type, concentration, and dose of local anesthetic employed; catheter placement; and mode of local anesthetic delivery.

11. Intraperitoneal instillation and nebulization of local anesthetic—
Instillation and nebulization of intraperitoneal local anesthetic decreases pain
intensity and decreases opioid consumption following open abdominal and laparoscopic surgery. However, the precise roles of these techniques in multimodal management remain to be determined.

**Strategies to Facilitate Recovery on the Surgical Unit**

**A. Organization of Multidisciplinary Surgical Care**

The multidisciplinary aspect of postoperative care should bring together the surgeon, anesthesia care team, nurses, nutritionist, physiotherapist, pharmacist, and case manager/social worker in an interdisciplinatory team effort to optimize each patient’s care based upon standardized, procedure-specific protocols. Comfortable chairs and walkers should be made readily available near each patient bed to encourage patients to sit, stand, and walk. Routine bedrest after surgery should be avoided. Patients should be encouraged to sit in a chair the afternoon or evening following surgery, with ambulation starting the same or next day. If patients are unable to get out of bed, they should be instructed and encouraged to perform physical and deep breathing exercises in their beds.

**B. Optimization of Analgesia to Facilitate Functional Recovery**

A well-organized, well-trained, acute pain service (APS) utilizing procedure-specific clinical protocols to optimally manage analgesia and related side effects helps drive ERPs. The quality of pain relief and symptom control heavily influences postoperative recovery; optimal mobilization and dietary intake depend upon adequate analgesia with minimal analgesic-related side effects. The surgeon and the APS must identify and employ optimal analgesic techniques tailored to the specific surgical procedure, and the quality of analgesia and risk of analgesic-related side effects must be closely and continuously assessed. The goal is not to achieve “zero pain,” but to make patients comfortable while walking and performing physiotherapy, with minimal side effects such as lightheadedness, sedation, nausea and vomiting, urinary retention, ileus, and leg weakness. **It should be noted that opioid-related PONV is the most common cause of unplanned hospital admission following ambulatory surgery, and opioid-related ileus is one of the most common causes of extended hospital length of stay. Both of these problems significantly increase perioperative costs.**

**C. Strategies to Minimize Postoperative Ileus**

Postoperative ileus delays postoperative resumption of enteral feeding, is
often a source of considerable patient discomfort, and is one of the most common causes of prolonged postoperative hospital length of stay and preventable hospitalization costs. Because early enteral nutrition is associated with decreased postoperative morbidity, interventions and strategies aimed at minimizing the risk and severity of postoperative ileus are essential for patients in an ERP. Four main mechanisms contribute to ileus: sympathetic inhibitory reflexes, local inflammation initiated by the operative procedure, intraoperatively- and postoperatively-administered systemic opioids, and bowel edema caused by administration of excess intravenous fluid. Nasogastric tubes, frequently inserted after abdominal surgery, do not speed the recovery of bowel function and may increase pulmonary morbidity by increasing the risk of aspiration. Therefore, nasogastric tubes should be discouraged whenever possible or used for only a very short period of time, even with gastrointestinal surgery.

The opioid-sparing effects of multimodal analgesia with minimal or non–opioid analgesia techniques shorten the duration of postoperative ileus or may preempt it entirely. Minimally invasive surgical techniques are associated with less surgical stress and inflammation than open procedures, resulting in more rapid return of bowel function. For open abdominal procedures, thoracic epidural local anesthetic infusions not only provide superior analgesia, but also speed recovery of bowel function by suppressing inhibitory sympathetic spinal cord reflexes that promote the development and severity of postoperative ileus. Epidural analgesia does not appear to have the same impact following laparoscopic procedures. Laxatives, such as milk of magnesia and bisacodyl, reduce postoperative ileus duration. Prokinetic medications such as metoclopramide are ineffective. Neostigmine increases peristalsis but may also increase the incidence of PONV.

Postoperative chewing gum, by stimulating gastrointestinal reflexes, may decrease ileus duration. Although its effect has not been evaluated in ERP patients, postoperative chewing gum may be included in multimodal interventions to decrease postoperative ileus because of its safety and low cost. Peripheral opioid μ-receptor antagonists methylnaltrexone (Relistor) and alvimopan (Entereg) minimize the adverse effects of opioids on bowel function without antagonizing systemic opioid analgesia because of their limited ability to cross the blood–brain barrier. In laparotomy patients receiving high-dose intravenous morphine analgesia, alvimopan decreases the duration of postoperative ileus by 16 to 18 h, decreases the incidence of nasogastric tube reinsertion, shortens hospital length of stay, and lowers hospital readmission
rates, especially in patients undergoing bowel resection. Nevertheless, recovery of postoperative bowel function in such alvimopan-treated, high-dose systemic morphine analgesia patients remains slower than that of patients utilizing opioid-sparing, multimodal ERPs.

Excessive perioperative fluid administration commonly causes bowel mucosal edema and delays postoperative return of bowel function. Because either excessive, or excessively restricted, perioperative fluid therapy increases the incidence and severity of postoperative ileus, a goal-directed fluid administration strategy may be beneficial, especially in patients undergoing major surgery associated with large fluid shifts and patients at high risk of developing postoperative gastrointestinal complications (see Chapter 51). However, results from a recent randomized double-blind study of liberal versus restricted fluid administration showed no differences with regard to recovery of bowel function in patients undergoing fast-track abdominal surgery.

---

**Issues in the Implementation of Enhanced Recovery Programs**

The success of ERPs depends upon the ability and willingness of perioperative team stakeholders to reach evidence-based interdisciplinary consensus. Many traditional aspects of perioperative care, such as use of drains, dietary and activity restrictions, excessive or excessively restrictive fluid management, and bedrest, must be extensively revised in ERPs. Patient involvement and patient and family expectations are fundamentally important, but frequently overlooked, aspects of these programs. New surgical techniques, such as transverse incisions or minimally invasive surgery, may require surgeons to acquire and perfect new skills. Similarly, the emphasis on thoracic epidural blockade or peripheral nerve blocks, pharmacological modulation of the neuroendocrine stress response to surgery, goal-directed fluid and hemodynamic therapy, and integral involvement of a well-organized and managed APS requires a substantial expansion of the traditional roles of anesthesiologists and of the anesthesia care team. Aggressive analgesia and symptom management, early ambulation and physiotherapy, early nutrition protocols, and early removal or total avoidance of urinary drainage catheters significantly change the way patients are cared for in the postanesthesia recovery unit and on the surgical unit and require a well-organized, highly trained, highly motivated nursing staff.

Although there are published studies of successful ERPs, there are no “off-
“the-shelf” protocols with universal application: Local differences in goals, expertise, experience, resources, and politics markedly influence the development, implementation, and management of ERPs for each institution or health care system. Each family of similar surgical procedures requires a standardized interdisciplinary clinical protocol or pathway, with specialized input from a team with experience in caring for those patients. Such an interdisciplinary team should include representation from surgery, anesthesiology, nursing, pharmacy, physiotherapy, nutrition, and administration, and it should be responsible not only for each clinical protocol’s creation, but also for continuously monitoring its efficacy and cost, and for instituting continuous improvement-related protocol modifications and provider feedback as indicated by outcomes data (Figure 48–5).

Optimal perioperative care requires the anesthesia provider to be an integral part of the perioperative surgical care team leadership and management. The skill sets of the anesthesiologist and anesthesia care team are essential for the success of ERPs and have potential benefits for surgical care delivery on a global basis, from initial surgical diagnosis, preoperative evaluation, and presurgical
preparation through postoperative recovery and return of the patient to his or her primary healthcare provider. The perioperative surgical home concept represents an accumulation of developments derived from ambulatory, minimally invasive, fast-track, enhanced recovery, and interdisciplinary, team-based surgical care and allows both quality- and cost-related variables to be analyzed and optimized from the patient’s perspective (eg, incidence and severity of perioperative complications, hospital length of stay, hospital readmission rate, return to work, and return to chemotherapy). By optimizing these many variables, the PSH contributes to delivering a higher value surgical experience to the patient. This will require new standards for clinical education and training.

CHAPTER 49

Management of Patients with Fluid & Electrolyte Disturbances

KEY CONCEPTS

1. Osmotic pressure is generally dependent only on the number of nondiffusible solute particles. This is because the average kinetic energy of particles in solution is similar regardless of their mass.

2. Potassium is the most important determinant of intracellular osmotic pressure, whereas sodium is the most important determinant of extracellular osmotic pressure.

3. Fluid exchange between the intracellular and interstitial spaces is governed by the osmotic forces created by differences in nondiffusible solute concentrations.

4. Serious manifestations of hyponatremia are generally associated with plasma sodium concentrations less than 120 mEq/L.

5. Excessively rapid correction of hyponatremia has been associated with demyelinating lesions in the pons (central pontine myelinolysis), and more generally in both pontine and extrapontine central nervous system structures (osmotic demyelination syndrome), resulting in both temporary and permanent neurological sequelae.

6. A major hazard of increased extracellular volume is impaired gas exchange due to pulmonary interstitial edema, alveolar edema, and/or large collections of pleural or ascitic fluid.

7. Intravenous replacement of potassium chloride is usually reserved for patients with, or at risk for, significant cardiac manifestations or severe muscle weakness.

8. Because of its lethal potential, hyperkalemia exceeding 6 mEq/L should always be corrected.
Fluid and electrolyte disturbances associated with surgical and coexisting medical disease are extremely common in the perioperative period. Moreover, large volumes of intravenous fluids and blood components are frequently required to correct fluid deficits and compensate for blood loss during surgery. Major disturbances in fluid and electrolyte balance can rapidly alter cardiovascular, neurological, and neuromuscular functions, and anesthesia providers must have a clear understanding of normal water and electrolyte physiology. This chapter examines the body’s fluid compartments and common water and electrolyte derangements, their treatment, and anesthetic implications. Acid–base disorders and intravenous fluid and blood therapy are discussed in Chapters 50 and 51.

**Nomenclature of Solutions**

The system of international units (SI) has still not gained universal acceptance in clinical practice, and many older expressions of concentration remain in common use. Thus, for example, the quantity of a solute in a solution may be expressed in grams, moles, or equivalents. To complicate matters further, the concentration of a solution may be expressed either as quantity of solute per volume of solution or quantity of solute per weight of solvent.

**MOLARITY, MOLALITY, & EQUIVALENCY**

One mole (mol) of a substance represents $6.02 \times 10^{23}$ molecules. Molarity is the
standard SI unit of concentration that expresses the number of moles of solute per \textit{liter of solution} (mol/L, or M). \textit{Molarity} is an alternative term that expresses moles of solute per \textit{kilogram of solvent}. Equivalency is also commonly used for substances that ionize: The number of equivalents of an ion in solution is the number of moles multiplied by its charge (valence). Thus, a 1 M solution of MgCl\textsubscript{2} yields 2 equivalents of magnesium per liter and 2 equivalents of chloride per liter.

**OSMOLARITY, OSMOLALITY, & TONICITY**

\textit{Osmosis} is the net movement of water across a semipermeable membrane as a result of a difference in nondiffusible solute concentrations between the two sides. \textit{Osmotic pressure} is the pressure that must be applied to the side with more solute to prevent a net movement of water across the membrane to dilute the solute.

Osmotic pressure is generally dependent only on the number of nondiffusible solute particles. This is because the average kinetic energy of particles in solution is similar regardless of their mass. One \textit{osmole} (Osm) equals 1 mol of nondissociable substances. For substances that ionize, however, each mole results in \(n\) Osm, where \(n\) is the number of ionic species produced. Thus, 1 mol of a highly ionized substance such as NaCl dissolved in solution should produce 2 Osm; in reality, ionic interaction between the cation and anion reduces the effective activity of each such that NaCl behaves as if it is only 75% ionized. A difference of 1 mOsm/L between two solutions results in an osmotic pressure of 19.3 mm Hg. The osmolality of a solution is equal to the number of osmoles per \textit{liter} of solution, whereas its osmolality equals the number of osmoles per \textit{kilogram} of solvent. \textit{Tonicity}, a term that is often used interchangeably with osmolarity and osmolality, refers to the effect a solution has on cell volume. An \textit{isotonic} solution has no effect on cell volume, whereas \textit{hypotonic} and \textit{hypertonic} solutions increase and decrease cell volume, respectively.

**Fluid Compartments**

Body water is distributed between two major fluid compartments separated by cell membranes: intracellular fluid (ICF) and extracellular fluid (ECF). The latter can be further subdivided into intravascular and interstitial compartments. The interstitium includes all fluid that is both outside cells and outside the vascular endothelium. The relative contributions of each compartment to total body water
(TBW) and body weight are delineated in Table 49–1.

**TABLE 49–1**  Body fluid compartments (based on average 70-kg male).

The volume of fluid (water) within each compartment is determined by its solute composition and concentrations (Table 49–2). Differences in solute concentrations are largely due to the characteristics of the physical barriers that separate compartments. The osmotic forces created by “trapped” solutes govern the distribution of water between compartments and ultimately each compartment’s volume.

**INTRACELLULAR FLUID**
The outer membrane of cells plays an important role in regulating intracellular volume and composition. A membrane-bound adenosine triphosphate (ATP)–dependent pump exchanges Na\(^+\) for K\(^+\) in a 3:2 ratio. Because cell membranes are relatively impermeable to sodium and, to a lesser extent, potassium ions, potassium is concentrated intracellularly, whereas sodium is concentrated extracellularly. As a result, potassium is the most important determinant of intracellular osmotic pressure, whereas sodium is the most important determinant of extracellular osmotic pressure.

The impermeability of cell membranes to most proteins results in a high intracellular protein concentration. Because proteins act as nondiffusible solutes (anions), the unequal exchange ratio of 3 Na\(^+\) for 2 K\(^+\) by the cell membrane pump is critical in preventing relative intracellular hyperosmolality. Interference with Na\(^+\)–K\(^+\)-ATPase activity, as occurs during ischemia or hypoxia, results in progressive swelling of cells.

**EXTRACELLULAR FLUID**

The principal function of ECF is to provide a medium for delivery of cell nutrients and electrolytes and for removal of cellular waste products. Maintenance of a normal extracellular volume—particularly the circulating component (intravascular volume)—is critical. For the reasons described earlier, sodium is quantitatively the most important extracellular cation and the major determinant of extracellular osmotic pressure and volume. Changes in ECF volume are therefore related to changes in total body sodium content. The latter is a function of sodium intake, renal sodium excretion, and extrarenal sodium losses (see later discussion).

**Interstitial Fluid**

Very little interstitial fluid is normally in the form of free fluid. Most interstitial water is in chemical association with extracellular proteoglycans, forming a gel. Interstitial fluid pressure is generally thought to be negative (approximately −5 mm Hg). Increases in extracellular volume are normally proportionately reflected in intravascular and interstitial volume. However, as interstitial fluid volume progressively increases, interstitial pressure also rises and eventually becomes positive. When the latter occurs, free fluid in the interstitial gel matrix increases rapidly and the result is expansion only of the interstitial fluid compartment (Figure 49–1). In this way, the interstitial compartment acts as an
overflow reservoir for the intravascular compartment, as seen clinically in tissue edema.

Because only small quantities of plasma proteins can normally cross capillary clefts, the protein content of interstitial fluid is relatively low (2 g/dL). Protein entering the interstitial space is returned to the vascular system via the lymphatic system.

**Intravascular Fluid**

Intravascular fluid, commonly referred to as *plasma*, is restricted to the intravascular space by the vascular endothelium. Most electrolytes (small ions) freely pass between plasma and the interstitium, resulting in nearly identical electrolyte composition. However, the tight intercellular junctions between adjacent endothelial cells impede the passage of plasma proteins to outside the intravascular compartment. As a result, plasma proteins (mainly albumin) are the only osmotically active solutes in fluid not normally exchanged between plasma and interstitial fluid.

**EXCHANGE BETWEEN FLUID COMPARTMENTS**

*Diffusion* is the random movement of molecules due to their kinetic energy and is responsible for the majority of fluid and solute exchange between
compartments. The rate of diffusion of a substance across a membrane depends upon (1) the permeability of that substance through that membrane; (2) the concentration difference for that substance between the two sides; (3) the pressure difference between either side, because pressure imparts greater kinetic energy; and (4) the electrical potential across the membrane for charged substances.

**Diffusion Through Cell Membranes**

Diffusion between interstitial fluid and ICF may take place by one of several mechanisms: (1) directly through the lipid bilayer of the cell membrane, (2) through protein channels within the membrane, or (3) by reversible binding to a carrier protein that can traverse the membrane (*facilitated diffusion*). Oxygen, CO₂, water, and lipid-soluble molecules penetrate the cell membrane directly. Cations such as Na⁺, K⁺, and Ca²⁺ penetrate the lipid membrane poorly and can diffuse only through specific protein channels. Passage through these channels is dependent on membrane voltage and the binding of ligands (such as acetylcholine) to the membrane receptors. Glucose and amino acids diffuse with the help of membrane-bound carrier proteins.

Fluid exchange between the intracellular and interstitial spaces is governed by the osmotic forces created by differences in nondiffusible solute concentrations. Relative changes in osmolality between the intracellular and interstitial compartments result in a net water movement from the hypoosmolar to the hyperosmolar compartment.

**Diffusion Through Capillary Endothelium**

Capillary walls are typically 0.5 μm thick, consisting of a single layer of endothelial cells with their basement membrane. Intercellular clefts, 6 to 7 nm wide, separate each cell from its neighbors. Oxygen, CO₂, water, and lipid-soluble substances can penetrate directly through both sides of the endothelial cell membrane. Only low-molecular-weight, water-soluble substances such as sodium, chloride, potassium, and glucose readily cross intercellular clefts. High-molecular-weight substances such as plasma proteins penetrate the endothelial clefts poorly, with the exception of the liver and the lungs, where the clefts are larger.

Fluid exchange across capillaries differs from that across cell membranes in that it is governed by significant differences in hydrostatic pressures in addition
to osmotic forces (Figure 49–2). These forces are operative on both arterial and venous ends of capillaries, with a tendency for fluid to move out of capillaries at the arterial end and back into capillaries at the venous end. Moreover, the magnitude of these forces differs between the various tissue beds. Arterial capillary pressure is determined by precapillary sphincter tone. Thus, capillaries that require a high pressure, such as glomeruli, have low precapillary sphincter tone, whereas the normally low-pressure capillaries of muscle have high precapillary sphincter tone. Normally, all but 10% of the fluid filtered is reabsorbed back into capillaries. What is not reabsorbed (about 2 mL/min) enters the interstitial fluid and is then returned by lymphatic flow to the intravascular compartment.
FIGURE 49–2 Capillary fluid exchange. The numbers in this figure are in mm Hg and indicate the pressure gradient for the respective pressures. “Net” refers to the net pressure at either end of the capillary, i.e., 13 mm Hg at the arterial and 7 mm Hg at the venous end of the capillary.

Disorders of Water Balance

The human body at birth is approximately 75% water by weight. By 1 month this value decreases to 65%, and by adulthood to 60% for males and 50% for females. The higher fat content in females decreases water content. For the same
reason, obesity and advanced age further decrease water content.

**NORMAL WATER BALANCE**

The normal adult daily water intake averages 2500 mL, which includes approximately 300 mL as a byproduct of the metabolism of energy substrates. Daily water loss averages 2500 mL and is typically accounted for by 1500 mL in urine, 400 mL in respiratory tract evaporation, 400 mL in skin evaporation, 100 mL in sweat, and 100 mL in feces. Evaporative loss is very important in thermoregulation because this mechanism normally accounts for 20% to 25% of heat loss.

Both ICF and ECF osmolalities are tightly regulated to maintain normal water content in tissues. Changes in water content and cell volume may induce significant impairment of function, particularly in the brain (see later discussion).

**RELATIONSHIP OF PLASMA SODIUM CONCENTRATION, EXTRACELLULAR OSMOLALITY, & INTRACELLULAR OSMOLALITY**

The osmolality of ECF is equal to the sum of the concentrations of all dissolved solutes. Because Na\(^+\) and its anions account for nearly 90% of these solutes, the following approximation is valid:

\[
\text{Plasma osmolality} = 2 \times \text{Plasma sodium concentration}
\]

Moreover, because ICF and ECF are in osmotic equilibrium, plasma sodium concentration \([\text{Na}^+]_{\text{plasma}}\) generally reflects total body osmolality:

\[
\text{Total body osmolality} = \frac{\text{Extracellular solutes} + \text{Intracellular solutes}}{\text{TBW}}
\]

Because sodium and potassium are the major intra- and extracellular solutes, respectively:
Total body osmolality = \( \frac{(\text{Na}^+_{\text{extracellular}} \times 2) + (\text{K}^+_{\text{intracellular}} \times 2)}{\text{TBW}} \)

Combining the two approximations:

\[ [\text{Na}^+]_{\text{plasma}} \approx \frac{(\text{Na}^+_{\text{extracellular}} \times 2) + (\text{K}^+_{\text{intracellular}} \times 2)}{\text{TBW}} \]

Using these principles, the effect of isotonic, hypotonic, and hypertonic fluid loads on compartmental water content and plasma osmolality can be calculated (Table 49–3). The potential importance of intracellular potassium concentration is readily apparent from this equation. Thus, significant potassium losses may contribute to hyponatremia.

**TABLE 49–3** Effect of different fluid loads on extracellular and intracellular water contents.¹
### A. Normal
Total body solute = $280 \text{ mOsm/kg} \times 42 \text{ kg} = 11,760 \text{ mOsm}$
Intracellular solute = $280 \text{ mOsm/kg} \times 25 \text{ kg} = 7000 \text{ mOsm}$
Extracellular solute = $280 \text{ mOsm/kg} \times 17 \text{ kg} = 4760 \text{ mOsm}$
Extracellular sodium concentration = $280 \div 2 = 140 \text{ mEq/L}$

Net effect: Fluid remains in extracellular compartment.

### C. Free water (hypotonic) load: 2 L water
New body water = $42 + 2 = 44 \text{ kg}$
New body osmolality = $11,760 \text{ mOsm} \div 44 \text{ kg} = 267 \text{ mOsm/kg}$
New intracellular volume = $7000 \text{ mOsm} \div 267 \text{ mOsm/kg} = 26.2 \text{ kg}$
New extracellular sodium concentration = $267 \div 2 = 133 \text{ mEq/L}$
In pathological states, glucose and—to a much lesser extent—urea can contribute significantly to extracellular osmolality. A more accurate approximation of plasma osmolality is therefore given by the following equation:

\[
\text{Plasma osmolality (mOsm/kg)} = [\text{Na}^+] \times 2 + \frac{\text{BUN}}{2.8} + \frac{\text{Glucose}}{18}
\]

where \([\text{Na}^+]\) is expressed as mEq/L and blood urea nitrogen (BUN) and glucose as mg/dL. Urea is an ineffective osmole because it readily permeates cell membranes and is therefore frequently omitted from this calculation:

\[
\text{Effective plasma osmolality} = [\text{Na}^+] \times 2 + \frac{\text{Glucose}}{18}
\]

</table>

Net effect: Fluid distributes between both compartments.

---

**D. Hypertonic load: 600 mEq NaCl (no water)**

Total body solute = 11,760 + 600 = 12,360 mOsm/kg
New body osmolality = 12,360 mOsm/kg ÷ 42 kg = 294 mOsm
New extracellular solute = 600 + 4760 = 5360 mOsm
New extracellular volume = 5360 mOsm ÷ 294 mOsm/kg = 18.2 kg
New intracellular volume = 42 – 18.2 = 23.8 kg
New extracellular sodium concentration = 294 ÷ 2 = 147 mEq/L

Net effect: An intracellular to extracellular movement of water.

---

¹Based on a 70-kg adult male.
Plasma osmolality normally varies between 280 and 290 mOsm/L. Plasma sodium concentration decreases approximately 1 mEq/L for every 62 mg/dL increase in glucose concentration. A discrepancy between the measured and calculated osmolality is referred to as an osmolal gap. Significant osmolal gaps indicate a high concentration of an abnormal osmotically active molecule in plasma such as ethanol, mannitol, methanol, ethylene glycol, or isopropyl alcohol. Osmolal gaps may also be seen in patients with chronic kidney failure (attributed to retention of small solutes), patients with ketoacidosis (as a result of a high concentration of ketone bodies), and those receiving large amounts of glycine (as during transurethral resection of the prostate). Lastly, osmolal gaps may also be present in patients with marked hyperlipidemia or hyperproteinenemia. In such instances, the protein or lipid part of plasma contributes significantly to plasma volume; although plasma [Na⁺] is decreased, [Na⁺] in the water phase of plasma (true plasma osmolality) remains normal. The water phase of plasma is normally only 93% of its volume; the remaining 7% consists of plasma lipids and proteins.

CONTROL OF PLASMA OSMOLALITY

Plasma osmolality is closely regulated by the hypothalamus, which controls both the secretion of antidiuretic hormone (ADH) and the thirst mechanism. Plasma osmolality is therefore maintained within relatively narrow limits by control of both water intake and water excretion.

Secretion of Antidiuretic Hormone

Specialized neurons in the supraoptic and paraventricular nuclei of the hypothalamus are sensitive to changes in extracellular osmolality. When ECF osmolality increases, these cells shrink and release ADH from the posterior pituitary. ADH markedly increases water reabsorption in renal collecting tubules (see Chapter 30), which tends to reduce plasma osmolality back to normal. Conversely, a decrease in extracellular osmolality causes osmoreceptors to swell and suppresses the release of ADH. Decreased ADH secretion allows a water diuresis, which tends to increase osmolality to normal. Peak diuresis occurs once circulating ADH is metabolized (90–120 min). With complete suppression of ADH secretion, the kidneys can excrete up to 10 to 20 L of water per day.

Nonosmotic Release of Antidiuretic Hormone
Carotid baroreceptors (volume receptors), as well as low-pressure volume receptors in the atria, vena cavae, and pulmonary arteries, also influence ADH release. A fall in wall tension results in a reflex increase of ADH secretion from the posterior pituitary. Increased stretch of these receptors not only suppresses ADH secretion, but the increased atrial volume receptor stretch also increases secretion of atrial natriuretic peptide (ANP; see later discussion), which promotes renal excretion of sodium and water. Increased sympathetic activity associated with conditions such as pain, emotional stress, and hypoxia also promotes ADH release.

**Thirst**

Activation of osmoreceptors in the lateral preoptic area of the hypothalamus neurons by increases in ECF osmolality induces thirst, stimulating the individual to drink water. Conversely, hypoosmolality suppresses thirst. *Thirst is the major defense mechanism against hyperosmolality and hypernatremia*, because it is the only mechanism that increases water intake.

**HYPEROSMOLALITY & HYPERNATREMIA**

Hyperosmolality occurs whenever total body solute content increases relative to TBW and is usually, but not always, associated with hypernatremia ([Na⁺] > 145 mEq/L). Hyperosmolality without hypernatremia may be seen during marked hyperglycemia or following the accumulation of abnormal osmotically active substances in plasma (see earlier discussion). In the latter two instances, plasma sodium concentration may actually decrease as water is drawn from the intracellular to the extracellular compartment. For every 100 mg/dL increase in plasma glucose concentration, plasma sodium decreases approximately 1.6 mEq/L.

Hypernatremic patients may be hypovolemic, euvoletic, or hypervolemic (Table 49–4). However, hypernatremia is nearly always the result of either a relative loss of water in excess of sodium (hypotonic fluid loss) or the retention of large quantities of sodium. Even when kidney concentrating ability is impaired, thirst is normally highly effective in preventing hypernatremia. Hypernatremia is therefore most commonly seen in debilitated patients who are unable to drink, the very aged, the very young, and patients with altered consciousness. Much of the total body sodium is stored in the skin, bone, and cartilage, which serves as a reservoir for the rest of the body, and patients with dysnatremias may have a low, normal, or high total body sodium content.

Hypernatremia & Low Total Body Sodium Content

These patients have lost both sodium and water, but the water loss is in relative excess to that of the sodium loss. Hypotonic losses can be renal (osmotic diuresis) or extrarenal (diarrhea or sweat). In either case, patients usually manifest signs of hypovolemia (see Chapter 51). Urinary sodium concentration is generally greater than 20 mEq/L with renal losses and less than 10 mEq/L with extrarenal losses.

Hypernatremia & Normal Total Body Sodium Content

This group of patients generally manifests signs of water loss without overt hypovolemia unless the water loss is massive. Total body sodium content is generally normal. Nearly pure water losses can occur via the skin, respiratory tract, or kidneys. Occasionally transient hypernatremia is observed with movement of water into cells following exercise, seizures, or rhabdomyolysis. The most common cause of hypernatremia in conscious patients with normal total body sodium content is diabetes insipidus. Diabetes insipidus (DI) is
characterized by marked impairment in renal concentrating ability that is due either to decreased ADH secretion (central DI) or failure of the renal tubules to respond normally to circulating ADH (nephrogenic DI). Rarely, essential hypernatremia may be encountered in patients with central nervous system disorders. These patients appear to have “reset” osmoreceptors that function at a higher baseline osmolality.

A. Central Diabetes Insipidus
Lesions in or around the hypothalamus and the pituitary stalk frequently produce DI. DI often develops with brain death. Transient DI is also commonly seen following neurosurgical procedures and head trauma. The diagnosis is suggested by a history of polydipsia, polyuria (often >6 L/d), and the absence of hyperglycemia. In the perioperative setting, the diagnosis of DI is suggested by marked polyuria without glycosuria and a urinary osmolality lower than plasma osmolality. The absence of thirst in unconscious individuals leads to marked water losses and can rapidly produce hypovolemia. The diagnosis of central DI is confirmed by an increase in urinary osmolality following the administration of exogenous ADH. Aqueous vasopressin (5–10 units subcutaneously or intramuscularly every 4–6 h) is the treatment of choice for acute central DI. Vasopressin in oil (0.3 mL intramuscularly every day) is longer lasting but is more likely to cause water intoxication. Desmopressin (DDAVP), a synthetic analogue of ADH with a 12- to 24-h duration of action, is available as an intranasal preparation (10–40 mcg/d either as a single daily dose or divided into two doses) that can be used in both ambulatory and perioperative settings.

B. Nephrogenic Diabetes Insipidus
Nephrogenic DI can be congenital but is more commonly secondary to other disorders, including chronic kidney disease, hypokalemia, hypercalcemia, sickle cell disease, and hyperproteinemias. Nephrogenic DI can also be secondary to the side effects of some drugs (amphotericin B, lithium, demeclocycline, ifosfamide, mannitol). ADH secretion in nephrogenic DI is normal, but the kidneys fail to respond to ADH and urinary concentrating ability is therefore impaired. The diagnosis is confirmed by failure of the kidneys to produce hypertonic urine following the administration of exogenous ADH. Treatment is generally directed at the underlying illness and ensuring an adequate fluid intake. Volume depletion by a thiazide diuretic can paradoxically decrease urinary output by reducing water delivery to collecting tubules. Sodium and protein restriction can similarly reduce urinary output.
Hypernatremia & Increased Total Body Sodium Content

This condition most commonly results from the administration of large quantities of hypertonic saline solutions (3% NaCl or 7.5% NaHCO₃). Patients with primary hyperaldosteronism and Cushing syndrome may also have elevations in serum sodium concentration along with signs of increased sodium retention.

Clinical Manifestations of Hypernatremia

Neurological manifestations predominate in patients with symptomatic hypernatremia, and restlessness, lethargy, and hyperreflexia can progress to seizures, coma, and ultimately death. Symptoms correlate more closely with the rate of movement of water out of brain cells than with the absolute level of hypernatremia. Rapid decreases in brain volume can rupture cerebral veins and result in focal intracerebral or subarachnoid hemorrhage. Seizures and serious neurological damage are common, particularly in children with acute hypernatremia when plasma [Na⁺] exceeds 158 mEq/L. Chronic hypernatremia is usually better tolerated than the acute form. After 24 to 48 h, intracellular osmolality begins to rise as a result of increases in intracellular inositol and amino acid concentrations, and brain intracellular water content slowly returns to normal.

Treatment of Hypernatremia

The treatment of hypernatremia is aimed at restoring plasma osmolality to normal and correcting the underlying cause. Water deficits should generally be corrected over 48 h, as rapid correction (or overcorrection) can cause cerebral edema. Enteral free water administration is preferable when feasible, but a hypotonic intravenous solution such as 5% dextrose in water can also be used (see later discussion). Abnormalities in extracellular volume must also be corrected (Figure 49–4). Hypernatremic patients with decreased total body sodium should be given isotonic fluids to restore plasma volume to normal prior to treatment with a hypotonic solution. Hypernatremic patients with increased total body sodium should be treated with a loop diuretic along with intravenous 5% dextrose in water. The treatment of DI is discussed in the preceding section.
Rapid correction of hypernatremia can result in seizures, brain edema, permanent neurological damage, and even death. Serial Na\(^+\) osmolalities should be obtained during treatment. In general, decreases in plasma sodium concentration should not proceed at a rate faster than 0.5 mEq/L/h.

**Example:** A 70-kg man is found to have a plasma \([\text{Na}^+]\) of 160 mEq/L. What is his water deficit?

If one assumes that hypernatremia in this case represents water loss only, then total body osmoles are unchanged. Thus, assuming a normal \([\text{Na}^+]\) of 140 mEq/L and TBW content that is 60% of body weight:

\[
\text{Normal TBW} \times 140 = \text{Present TBW} \times [\text{Na}^+]_{\text{plasma}} \quad \text{or} \quad (70 \times 0.6) \times 140 = \text{Present TBW} \times 160
\]

Solving the equation:

\[
\text{Present TBW} = 36.7 \text{ L}
\]

Water deficit = Normal TBW – Present TBW or \((70 \times 0.6) – 36.7 = 5.3 \text{ L}\)

To replace this deficit over 48 h, it is necessary to administer 5.3 L enteral
free water in small amounts over 48 h, or, 5% dextrose in water intravenously, 5300 mL over 48 h, or 110 mL/h.

Note that this method ignores any coexisting isotonic fluid deficits, which if present should be replaced with an isotonic solution.

**Anesthetic Considerations**

Hypernatremia has been demonstrated to increase the minimum alveolar concentration for inhalation anesthetics in animal studies, but its clinical significance is more closely related to the associated fluid deficits. Hypovolemia accentuates any vasodilation or cardiac depression from anesthetic agents and predisposes to hypotension and hypoperfusion of tissues. Decreases in the volume of distribution for drugs necessitate dose reductions for most intravenous agents, whereas decreases in cardiac output enhance the uptake of inhalation anesthetics.

Even mild serum sodium elevation is associated with increased perioperative morbidity, mortality, and hospital length of stay, and thus hypernatremia must not be ignored. Elective anesthetics should be postponed in patients with significant hypernatremia (>150 mEq/L) until the cause is established and total body sodium or TBW, or both, corrected.

**HYPOOSMOLALITY & HYponATREMIA**

Hypoosmolality is nearly always associated with hyponatremia ([Na⁺] <135 mEq/L). Table 49–5 lists rare instances in which hyponatremia does not necessarily reflect hypoosmolality (*pseudohyponatremia*). Routine measurement of plasma osmolality in hyponatremic patients rapidly excludes pseudohyponatremia.

**TABLE 49–5  Causes of pseudohyponatremia.**

Hyperglycemia
Administration of mannitol

Hyponatremia invariably reflects water retention from either an absolute increase in TBW or a loss of sodium in relative excess to loss of water. The kidneys’ normal capacity to produce dilute urine with an osmolality as low as 40 mOsm/kg (specific gravity 1.001) allows them to excrete over 10 L of free water per day if necessary. Because of this tremendous reserve, hyponatremia is nearly always the result of a defect in urinary diluting capacity (urinary osmolality >100 mOsm/kg or specific gravity >1.003—ie, limited ability of the kidneys to excrete free water). Rare instances of hyponatremia without an abnormality in renal diluting capacity (urinary osmolality <100 mOsm/kg) are generally attributed to primary polydipsia or reset osmoreceptors; the latter two conditions can be differentiated by water restriction.

Clinically, hyponatremia is best classified according to total body sodium content (Table 49–6). Hyponatremia associated with transurethral resection of the prostate is discussed in Chapter 32.

Hyponatremia & Low Total Body Sodium

Progressive losses of both sodium and water eventually lead to extracellular volume depletion. As the intravascular volume deficit approaches 5% to 10%, nonosmotic ADH secretion is activated (see earlier discussion). With further volume depletion, the stimuli for nonosmotic ADH release overcome any hyponatremia-induced suppression of ADH, and preservation of circulatory volume takes place at the expense of plasma osmolality.

Fluid losses resulting in hyponatremia may be renal or extrarenal in origin. Renal losses are most commonly related to thiazide diuretics and result in a urinary $[\text{Na}^+]$ greater than 20 mEq/L. Extrarenal losses are typically gastrointestinal and usually are associated with a urinary $[\text{Na}^+]$ of less than 10 mEq/L. A major exception to the latter is hyponatremia due to vomiting, which can result in a urinary $[\text{Na}^+]$ greater than 20 mEq/L. In this situation, renal compensation for the associated metabolic alkalosis results in bicarbonaturia, with concomitant excretion of $\text{Na}^+$ with $\text{HCO}_3^-$ to maintain electrical neutrality in the urine; urinary chloride concentration, however, is usually less than 10 mEq/L.

Hyponatremia & Increased Total Body Sodium

Edematous disorders are characterized by an increase in both total body sodium and TBW. When the increase in TBW is relatively greater than the increase in total body sodium, hyponatremia occurs. Edematous disorders include congestive heart failure, cirrhosis, kidney failure, and nephrotic syndrome. Hyponatremia in these settings results from progressive impairment of renal free water excretion and generally parallels underlying disease severity. Pathophysiologic mechanisms include nonosmotic ADH release and decreased delivery of fluid to nephron distal diluting segments (see Chapter 30).

Hyponatremia with Normal Total Body Sodium

Hyponatremia in the absence of edema or hypovolemia may be seen with
glucocorticoid insufficiency, hypothyroidism, drug therapy, and the syndrome of inappropriate antidiuretic hormone secretion (SIADH, also referred to as the syndrome of inappropriate diureses [SIAD]; Table 49–7). The hyponatremia associated with adrenal hypofunction may be due to co-secretion of ADH with corticotropin-releasing factor (CRF). Diagnosis of SIADH requires exclusion of other causes of hyponatremia and the absence of hypovolemia, edema, and adrenal, renal, or thyroid disease. Various malignant tumors, pulmonary diseases, and central nervous system disorders are commonly associated with SIADH. In most such instances, plasma ADH concentration is not elevated but is inadequately suppressed relative to the degree of hypoosmolality in plasma; urine osmolality is usually greater than 100 mOsm/kg and urine sodium concentration is greater than 40 mEq/L.

**Cerebral salt wasting (CSW)** is a syndrome of inappropriate renal sodium wasting and hyponatremia with polyuria and hypovolemia that may be seen with intracranial disease, including brain tumors, subarachnoid hemorrhage, subdural hematoma, meningitis, and head trauma. Proposed mechanisms for this disorder include excess secretion of natriuretic peptides and altered sympathetic stimulation to the kidney. Both SIADH and CSW are characterized by elevated urine sodium concentration, low serum osmolality, and high urine osmolality. However, patients with SIADH are usually euvoletic or mildly hypervolemic, whereas patients with CSW are hypovolemic, and thus treatments for these two disorders are very different. The treatment of SIADH is free water restriction, and the treatment of CSW is volume and sodium replacement with normal or hypertonic saline.

### Clinical Manifestations of Hyponatremia

Symptoms of hyponatremia are primarily neurological and result from an increase in intracellular water. Their severity is generally related to the rapidity with which extracellular hypoosmolality develops. Patients with mild to moderate hyponatremia ([Na⁺] > 125 mEq/L) are frequently asymptomatic. Early symptoms are typically nonspecific and may include anorexia, nausea, and weakness. Progressive cerebral edema, however, results in lethargy, confusion, seizures, coma, and finally death. Serious manifestations of hyponatremia are generally associated with plasma sodium concentrations less than 120 mEq/L. Patients with slowly developing or chronic hyponatremia are generally less

symptomatic, probably because the gradual compensatory loss of intracellular solutes (primarily Na\(^+\), K\(^+\), and organic osmolytes) restores cell volume to near normal. Neurological symptoms in patients with chronic hyponatremia may be related more closely to changes in cell membrane potential (due to a low extracellular [Na\(^+\)]) than to changes in cell volume.

**Treatment of Hyponatremia**

As with hypernatremia, the treatment of hyponatremia (Figure 49–5) is directed at correcting both the underlying disorder as well as the plasma [Na\(^+\)]. **Isotonic saline is generally the treatment of choice for hyponatremic patients with decreased total body sodium content.** Once the ECF deficit is corrected, spontaneous water diuresis returns plasma [Na\(^+\)] to normal. **Conversely, water restriction is the primary treatment for hyponatremic patients with normal or increased total body sodium.** More specific treatments such as hormone replacement in patients with adrenal or thyroid hypofunction and measures aimed at improving cardiac output in patients with heart failure may also be indicated. Demeclocycline (Declomycin, Declostatin), a tetracycline antibiotic that antagonizes ADH activity at the renal tubules, is often used as an adjunct in the treatment of SIADH when water restriction alone is insufficient.
Acute, symptomatic hyponatremia requires prompt treatment. In such instances, correction of plasma $[Na^+]$ to greater than 125 mEq/L is usually sufficient to alleviate symptoms and signs. The amount of NaCl necessary to raise plasma $[Na^+]$ to the desired value, the $Na^+$ deficit, can be estimated by the following formula:

$$Na^+ \text{ deficit} = TBW \times (\text{Desired } [Na^+] - \text{Present } [Na^+])$$

Excessively rapid correction of hyponatremia has been associated with demyelinating lesions in the pons (central pontine myelinolysis) and more generally in both pontine and extrapontine central nervous system structures (osmotic demyelination syndrome), resulting in both temporary and permanent neurological sequelae. The rapidity with which hyponatremia is corrected should be tailored to the severity of symptoms. The following correction rates have been suggested: for mild symptoms, 0.5 mEq/L/h or less; for moderate symptoms, 1 mEq/L/h or less; and for severe symptoms, 1.5 mEq/L/h or less.
Example: An 80-kg woman is lethargic and is found to have plasma [Na⁺] of 118 mEq/L. How much NaCl must be given to raise her plasma [Na⁺] to 130 mEq/L?

\[
\text{Na}^+ \text{ deficit } = \text{TBW} \times (130 - 118)
\]

TBW is approximately 50% of body weight in females:

\[
\text{Na}^+ \text{ deficit } = 80 \times 0.5 \times (130 - 118) = 480 \text{ mEq}
\]

Because normal (isotonic) saline contains 154 mEq/L, the patient should receive 480 mEq ÷ 154 mEq/L, or 3.12 L of normal saline. For a correction rate of 0.5 mEq/L/h, this amount of saline should be given over 24 h (130 mL/h).

Note that this calculation does not take into account any coexisting isotonic fluid deficits, which, if present, should also be replaced. More rapid correction of hyponatremia can be achieved by giving a loop diuretic to induce water diuresis while replacing urinary Na⁺ losses with isotonic saline. Even more rapid corrections can be achieved with intravenous hypertonic saline (3% NaCl). Hypertonic saline may be indicated in markedly symptomatic patients with plasma [Na⁺] less than 110 mEq/L. Three percent NaCl should be administered with caution, as it can precipitate pulmonary edema, hypokalemia, hyperchloremic metabolic acidosis, and transient hypotension; bleeding associated with prolongation of the prothrombin time and activated partial thromboplastin time has been reported.

**Anesthetic Considerations**

Hyponatremia is the most common electrolyte disorder, and SIADH is its most common cause. Hyponatremia, in association with its underlying disorder(s), increases both perioperative morbidity and mortality. A plasma sodium concentration greater than 130 mEq/L is usually considered safe for patients undergoing general anesthesia. In most circumstances, plasma [Na⁺] should be corrected to greater than 130 mEq/L for elective procedures, even in the absence of neurological symptoms. Lower concentrations may result in significant cerebral edema that can be manifested intraoperatively as a decrease in minimum alveolar concentration or postoperatively as agitation, confusion, or somnolence. Patients undergoing transurethral resection of the prostate can absorb significant amounts of water from irrigation fluids (as much as 20 mL/min) and are at high risk for rapid development of profound acute water intoxication (see Chapter
Disorders of Sodium Balance

ECF volume is directly proportionate to total body sodium content. Variations in ECF volume result from changes in total body sodium content. A positive sodium balance increases ECF volume, whereas a negative sodium balance decreases ECF volume. *Extracellular (plasma) Na⁺ concentration is more indicative of water balance than total body sodium content.*

NORMAL SODIUM BALANCE

Net sodium balance is equal to total sodium intake (adults average 170 mEq/d) minus both renal sodium excretion and extrarenal sodium losses. (One gram of sodium yields 43 mEq of Na⁺ ions, whereas 1 g of sodium chloride yields 17 mEq of Na⁺ ions.) The kidneys’ ability to vary urinary Na⁺ excretion from less than 1 mEq/L to more than 100 mEq/L allows them to play a critical role in sodium balance (see Chapter 30).

REGULATION OF SODIUM BALANCE & EXTRACELLULAR FLUID VOLUME

Because of the relationship between ECF volume and total body sodium content, regulation of one is intimately tied to the other. This regulation is achieved via sensors that detect changes in the most important component of ECF, namely, the “effective” intravascular volume. The latter correlates more closely with the rate of perfusion in renal capillaries than with measurable intravascular fluid (plasma) volume. Indeed, with edematous disorders (heart failure, cirrhosis, and kidney failure), “effective” intravascular volume can be independent of the measurable plasma volume, ECF volume, and even cardiac output.

ECF volume and total body sodium content are ultimately controlled by appropriate adjustments in renal Na⁺ excretion. In the absence of kidney disease, diuretic therapy, and renal ischemia, urinary Na⁺ concentration reflects “effective” intravascular volume. A low urine Na⁺ concentration (<10 mEq/L) is therefore generally indicative of a low “effective” intravascular fluid volume and reflects secondary retention of Na⁺ by the kidneys.
**Control Mechanisms**

The multiple mechanisms involved in regulating ECF volume and sodium balance normally complement one another but can function independently.

**A. Sensors of Volume**

Baroreceptors are the principal volume receptors in the body. Significant changes in intravascular volume (preload) not only affect cardiac output but also affect arterial blood pressure. The baroreceptors at the carotid sinus and afferent renal arterioles (juxtaglomerular apparatus) indirectly function as sensors of intravascular volume. Changes in blood pressure at the carotid sinus modulate sympathetic nervous system activity and nonosmotic ADH secretion, whereas changes at the afferent renal arterioles modulate the renin–angiotensin–aldosterone system (RAAS). As previously noted, stretch receptors in both atria are affected by changes in intravascular volume, and the degree of atrial distention modulates the release of atrial natriuretic hormone and ADH.

**B. Effectors of Volume Change**

Regardless of the mechanism, effectors of volume change ultimately alter urinary Na\(^+\) excretion. *Decreases in “effective” intravascular volume decrease urinary Na\(^+\) excretion, whereas increases in the “effective” intravascular volume increase urinary Na\(^+\) excretion.* These mechanisms include the following:

1. **Renin–angiotensin–aldosterone**—Renin secretion increases the formation of angiotensin II. The latter increases the secretion of aldosterone and has a direct effect in enhancing Na\(^+\) reabsorption in the proximal renal tubules. Angiotensin II is also a potent direct vasoconstrictor and potentiates the actions of norepinephrine. Secretion of aldosterone enhances Na\(^+\) reabsorption in the distal nephron (see Chapter 30) and is a major determinant of urinary Na\(^+\) excretion.

2. **Atrial natriuretic peptide (ANP)**—This peptide is normally released from both right and left atrial cells in response to atrial distention. ANP appears to have two major actions: arterial vasodilation and increased urinary sodium and water excretion in the renal collecting tubules. Na\(^+\)-mediated afferent arteriolar dilation and efferent arteriolar constriction can also increase glomerular filtration rate (GFR). Other effects include the inhibition of both renin and aldosterone secretion and antagonism of ADH.

3. **Brain natriuretic peptide (BNP)**—ANP, BNP, and C-type natriuretic peptide
are structurally related peptides. BNP is released by the cardiac ventricles in response to increased ventricular volume and pressure, including ventricular overdistention, and also by the brain in response to increased blood pressure. BNP levels are usually approximately 20% of ANP levels, but in congestive heart failure BNP levels may exceed those of ANP.

4. **Sympathetic nervous system activity**—Enhanced sympathetic activity increases Na\(^+\) reabsorption in the proximal renal tubules, resulting in Na\(^+\) retention, and increases renal vasoconstriction, which reduces renal blood flow (see Chapter 30). Conversely, stimulation of left atrial stretch receptors results in decreases in renal sympathetic tone and increases in renal blood flow (cardiorenal reflex) and glomerular filtration.

5. **Glomerular filtration rate and plasma sodium concentration**—The amount of Na\(^+\) filtered in the kidneys is directly proportionate to the product of the GFR and plasma Na\(^+\) concentration. Because GFR is usually proportionate to intravascular volume, intravascular volume expansion can increase Na\(^+\) excretion. Conversely, intravascular volume depletion decreases Na\(^+\) excretion. Similarly, even small elevations of blood pressure can result in a relatively large increase in urinary Na\(^+\) excretion because of the resultant increase in renal blood flow and glomerular filtration rate. Blood pressure–induced diuresis (*pressure natriuresis*) appears to be independent of any known humorally or neurally mediated mechanism.

6. **Tubuloglomerular balance**—Despite wide variations in the amount of Na\(^+\) filtered in nephrons, Na\(^+\) reabsorption in the proximal renal tubules is normally controlled within narrow limits. Factors considered to be responsible for tubuloglomerular balance include the rate of renal tubular flow and changes in peritubular capillary hydrostatic and oncotic pressures.

7. **Antidiuretic hormone**—Although ADH secretion normally has little effect on Na\(^+\) excretion, nonosmotic secretion of this hormone (see above) can play an important part in maintaining extracellular volume with moderate to severe decreases in the “effective” intravascular volume.

**Extracellular Osmoregulation versus Volume Regulation**

Osmoregulation protects the normal ratio of solutes to water, whereas extracellular volume regulation preserves absolute solute and water content
As noted previously, **volume regulation generally takes precedence over osmoregulation.**

### Anesthetic Implications
Problems related to altered sodium balance (dysnatremia) result from its direct manifestations as well as those of its the underlying disorder(s). Although patients with disorders of sodium balance may be euvolemic, they usually present with either hypovolemia (sodium deficit) or hypervolemia (sodium excess); see Tables 49-4 and 49-6. Both disturbances should be corrected prior to elective surgical procedures. Cardiac, liver, and kidney function should also be carefully evaluated in the presence of sodium excess (typically manifested as tissue edema).

Hypovolemic patients are sensitive to the vasodilating and negative inotropic effects of vapor anesthetics, propofol, and drug-induced histamine release. Dosage requirements for other drugs may be reduced to compensate for decreases in their volume of distribution. Hypovolemic patients are particularly sensitive to sympathetic blockade from spinal or epidural anesthesia. If a general anesthesia must be administered prior to adequate correction of hypovolemia, etomidate or ketamine may be the induction agents of choice.

Hypervolemic patients are sensitive to the vasodilating effects of hypervolemia, etomidate or ketamine may be the induction agents of choice. Hypervolemia may be corrected preoperatively with diuretics. A major hazard of increased extracellular volume is impaired gas exchange due to pulmonary interstitial edema, alveolar edema, and/or large collections of pleural or ascitic fluid.

Disorders of Potassium Balance

Potassium plays a major role in regulating membrane potential as well as in carbohydrate and protein synthesis (see later discussion). Intracellular potassium concentration is estimated to be 140 mEq/L, whereas normal extracellular potassium concentration is approximately 4 mEq/L.

NORMAL POTASSIUM BALANCE

Dietary potassium intake averages 80 mEq/d in adults (range, 40–140 mEq/d). About 70 mEq of that amount is normally excreted in urine, whereas the remaining 10 mEq is lost through the gastrointestinal tract.

Renal excretion of potassium can vary from as little as 5 mEq/L to over 100 mEq/L. Nearly all the potassium filtered in glomeruli is normally reabsorbed in the proximal tubule and the loop of Henle. As a component of the RAAS, the mineralocorticoid aldosterone is secreted by the adrenal cortex in response to stimulation by angiotensin II. Acting on mineralocorticoid receptors in the distal tubules and collecting ducts of the kidney, aldosterone promotes sodium
resorption directly coupled to potassium secretion. Thus, through this influence on kidney reabsorption/loss of sodium, and the resultant regulatory influence on kidney water reabsorption/loss and blood volume and blood pressure, aldosterone also directly influences potassium balance (see earlier discussion and Chapter 30). Mineralocorticoid receptor antagonists (MRAs) block the sodium retention/potassium loss effects of aldosterone. The potassium-sparing diuretics spironolactone and eplerenone are MRAs that exemplify these effects by promoting sodium and water loss along with potassium retention. Amiloride and triamterene also antagonize the sodium retention/potassium loss effects of aldosterone, but do so by blocking sodium channels in renal collecting tubule epithelial cells.

REGULATION OF EXTRACELLULAR POTASSIUM CONCENTRATION

Extracellular potassium concentration is determined by cell membrane Na\(^{+}\)–K\(^{+}\)-ATPase activity and plasma [K\(^{+}\)], and is influenced by the balance of total body potassium intake and excretion. Cell membrane Na\(^{+}\)–K\(^{+}\)-ATPase activity regulates the distribution of potassium between cells and ECF, whereas plasma [K\(^{+}\)], nephron Na\(^{+}\) load, and aldosterone are the major determinants of urinary potassium excretion.

INTERCOMPARTMENTAL SHIFTS OF POTASSIUM

Intercompartmental shifts of potassium are known to occur following changes in extracellular pH (see Chapter 50), circulating insulin levels, circulating catecholamine activity, and plasma osmolality. Insulin and catecholamines directly affect Na\(^{+}\)–K\(^{+}\)-ATPase activity and decrease plasma [K\(^{+}\)]. Exercise may transiently increase plasma [K\(^{+}\)] as a result of the release of K\(^{+}\) by muscle cells; the increase in plasma [K\(^{+}\)] (0.3–2 mEq/L) is proportionate to the intensity and duration of muscle activity. Intercompartmental potassium shifts are also likely to be responsible for changes in plasma [K\(^{+}\)] in syndromes of periodic paralysis (see Chapter 29).

Because the ICF may buffer up to 60% of an acid load (see Chapter 50), changes in extracellular hydrogen ion concentration (pH) directly affect extracellular [K\(^{+}\)]. In the setting of acidosis, extracellular hydrogen ions enter
cells, displacing intracellular potassium ions; the resultant movement of potassium ions out of cells maintains electrical balance but increases extracellular and plasma \([K^+]\). Conversely, during alkalosis, extracellular potassium ions move into cells to balance the movement of hydrogen ions out of cells; as a result, plasma \([K^+]\) decreases. Although the relationship is variable, a useful rule of thumb is that plasma potassium concentration changes approximately 0.6 mEq/L per 0.1-unit change in arterial pH (range 0.2–1.2 mEq/L per 0.1 unit).

Changes in circulating insulin levels can directly alter plasma \([K^+]\) independent of that hormone’s effect on glucose transport. Insulin enhances the activity of membrane-bound Na\(^+\)–K\(^+\)-ATPase, increasing cellular uptake of potassium in the liver and in skeletal muscle.

Sympathetic stimulation increases intracellular uptake of potassium by enhancing Na\(^+\)–K\(^+\)-ATPase activity through activation of \(\beta_2\)-adrenergic receptors. In contrast, \(\alpha\)-adrenergic activity may impair the intracellular movement of \(K^+\). Plasma \([K^+]\) often decreases following the administration of \(\beta_2\)-adrenergic agonists as a result of uptake of potassium by muscle and the liver.

Acute increases in plasma osmolality (hypernatremia, hyperglycemia, or mannitol administration) may increase plasma \([K^+]\) (about 0.6 mEq/L per 10 mOsm/L). In such instances, the movement of water out of cells (down its osmotic gradient) is accompanied by movement of \(K^+\) out of cells.

Hypothermia has been reported to lower plasma \([K^+]\) as a result of cellular uptake. Rewarming reverses this shift and may result in transient hyperkalemia if potassium was given during the hypothermia.

**Urinary Excretion of Potassium**

Urinary potassium excretion generally parallels its extracellular concentration (see preceding discussion). Extracellular \([K^+]\) is a major determinant of aldosterone secretion from the adrenal gland. Hyperkalemia stimulates aldosterone secretion, whereas hypokalemia suppresses aldosterone secretion. Renal tubular flow in the distal nephron may also be an important determinant of urinary potassium excretion because high tubular flow rates (as during osmotic diuresis) increase potassium secretion by keeping the capillary to renal tubular gradient for potassium secretion high. Conversely, slow tubular flow rates increase \([K^+]\) in tubular fluid and decrease the gradient for \(K^+\) secretion, thereby decreasing renal potassium excretion.
HYPOKALEMIA

Hypokalemia, defined as plasma $[K^+]$ less than 3.5 mEq/L, can occur as a result of (1) an intercompartmental shift of $K^+$, (2) increased potassium loss, or (3) an inadequate potassium intake (Table 49–9). Plasma potassium concentration typically correlates poorly with the total potassium deficit. A decrease in plasma $[K^+]$ from 4 mEq/L to 3 mEq/L usually represents a 100- to 200-mEq total body deficit, whereas plasma $[K^+]$ below 3 mEq/L can represent a deficit of 200 mEq to 400 mEq.

Hypokalemia due to the Intracellular Movement of Potassium

Hypokalemia due to the intracellular movement of potassium occurs with alkalosis, insulin therapy, β₂-adrenergic agonists, and hypothermia and during attacks of hypokalemic periodic paralysis. Cellular K⁺ uptake by red blood cells (and platelets) also accounts for the hypokalemia seen in patients recently treated with folate or vitamin B₁₂ for megaloblastic anemia.

Hypokalemia due to Increased Potassium Losses

Excessive potassium loss is usually either renal or gastrointestinal. Renal wasting of potassium is most commonly the result of diuresis or enhanced mineralocorticoid activity. Other renal causes include hypomagnesemia, renal tubular acidosis (see Chapter 30), ketoacidosis, salt-wasting nephropathies, and some drug therapies (amphotericin B). Increased gastrointestinal loss of potassium is most commonly due to nasogastric suctioning or to persistent vomiting or diarrhea. Other gastrointestinal causes include losses from fistulae, laxative abuse, villous adenomas, and pancreatic tumors secreting vasoactive intestinal peptide.

Chronic increased sweat formation occasionally causes hypokalemia when potassium intake is limited. Dialysis with a low-potassium-containing dialysate solution can also cause hypokalemia. Uremic patients may actually have a total body potassium deficit (primarily intracellular) despite a normal or even high plasma concentration; the absence of hypokalemia in these instances is probably due to acidosis-induced intercompartmental shifts. Dialysis in these patients unmasks the total body potassium deficit and often results in hypokalemia.

Urinary [K⁺] less than 20 mEq/L is generally indicative of increased extrarenal K⁺ losses, whereas concentrations greater than 20 mEq/L suggest renal wasting of K⁺.
Hypokalemia due to Decreased Potassium Intake

Because of the kidney’s ability to decrease urinary potassium excretion to as low as 5 to 20 mEq/L, marked reductions in potassium intake are required to produce hypokalemia. Low potassium intake, however, often accentuates the effects of increased potassium loss.

Clinical Manifestations of Hypokalemia

Hypokalemia can produce widespread organ dysfunction (Table 49–10). Most patients are asymptomatic until plasma [K+] falls below 3 mEq/L. Cardiovascular effects are most prominent and include an abnormal electrocardiogram (ECG; Figure 49–6), arrhythmias, decreased cardiac contractility, and a labile arterial blood pressure due to autonomic dysfunction. ECG manifestations are primarily due to delayed ventricular repolarization and include T-wave flattening and inversion, an increasingly prominent U wave, ST-segment depression, increased P-wave amplitude, and prolongation of the P–R interval. Increased myocardial cell automaticity and delayed repolarization promote both atrial and ventricular arrhythmias.

Negative nitrogen balance
Encephalopathy in patients with liver disease

FIGURE 49–6 Electrocardiographic effects of acute hypokalemia. Note progressive flattening of the T wave, an increasingly prominent U wave, increased amplitude of the P wave, prolongation of the P–R interval, and ST-segment depression.

Neuromuscular effects of hypokalemia include skeletal muscle weakness, hyporeflexia, muscle cramping, ileus, and, rarely, flaccid paralysis or rhabdomyolysis. Hypokalemia induced by diuretics is often associated with metabolic alkalosis; as the kidneys absorb sodium to compensate for intravascular volume depletion and in the presence of diuretic-induced hypochloremia, bicarbonate is absorbed and potassium is excreted. The end result is hypokalemia and hypochloremic metabolic alkalosis. Renal dysfunction is seen due to impaired concentrating ability (resistance to ADH, resulting in polyuria) and increased production of ammonia resulting in impairment of urinary acidification. Increased ammonia production represents intracellular acidosis; hydrogen ions move intracellularly to compensate for intracellular potassium losses. The resulting metabolic alkalosis, together with increased ammonia production, can precipitate encephalopathy in patients with advanced liver disease.

Treatment of Hypokalemia

The treatment of hypokalemia depends on the presence and severity of any associated organ dysfunction. Significant ECG changes such as ST-segment
changes or arrhythmias mandate continuous ECG monitoring, particularly during intravenous $K^+$ replacement. Digoxin therapy—as well as the hypokalemia itself—sensitizes the heart to changes in potassium ion concentration.

In most circumstances, the safest method by which to correct a potassium deficit is oral replacement over several days (60–80 mEq/d). Intravenous replacement of potassium chloride is usually reserved for patients with, or at risk for, significant cardiac manifestations or severe muscle weakness. The goal of intravenous therapy is to remove the patient from immediate danger, not to correct the entire potassium deficit. Because of potassium’s irritative effect on peripheral veins, peripheral intravenous replacement should not exceed 8 mEq/h. More rapid intravenous potassium replacement (10–20 mEq/h) requires central venous administration and close ECG monitoring. Intravenous replacement should generally not exceed 240 mEq/d. Dextrose-containing solutions should be avoided because the resulting hyperglycemia and secondary insulin secretion may worsen the low plasma $[K^+]$.

Potassium chloride is the preferred potassium salt when a metabolic alkalosis is also present because it also corrects the chloride deficit discussed earlier. Potassium bicarbonate or equivalent ($K^+$ acetate or $K^+$ citrate) is preferable for patients with metabolic acidosis. Potassium phosphate is a suitable alternative with concomitant hypophosphatemia (eg, diabetic ketoacidosis).

**Anesthetic Considerations**

Hypokalemia is a common preoperative finding. The decision to proceed with elective surgery is often based on lower plasma $[K^+]$ limits somewhere around 3 mEq/L. The decision, however, should also be based on the rate at which the hypokalemia developed as well as the presence or absence of secondary organ dysfunction. In general, chronic mild hypokalemia (3–3.5 mEq/L) without ECG changes does not increase anesthetic risk. The exception is patients receiving digoxin, who risk developing digoxin toxicity from the hypokalemia; plasma $[K^+]$ values above 4 mEq/L are desirable in such patients.

The intraoperative management of hypokalemia requires vigilant ECG monitoring. Intravenous potassium should be given if atrial or ventricular arrhythmias develop. Glucose-free intravenous solutions should be used and hyperventilation avoided to prevent further decreases in plasma $[K^+]$. Increased sensitivity to neuromuscular blockers (NMBs) may occur.
HYPERKALEMIA

Hyperkalemia exists when plasma [K\(^+\)] exceeds 5.5 mEq/L, and rarely occurs in normal individuals because of the kidney’s capability to excrete large potassium loads. When potassium intake is increased slowly, the kidneys can excrete as much as 500 mEq of K\(^+\) per day. The sympathetic nervous system and insulin secretion also play important roles in preventing acute increases in plasma [K\(^+\)] following acquired potassium loads.

Hyperkalemia can result from (1) an intercompartmental shift of potassium ions, (2) decreased urinary excretion of potassium, or, rarely, (3) an increased potassium intake or increased release from a formerly ischemic organ (Table 49–11). Measurements of plasma potassium concentration can be spuriously elevated if red cells hemolyze in a blood specimen. In vitro release of potassium from blood specimen leukocytes can also falsely indicate increased levels in the measured plasma [K\(^+\)] when the leukocyte count exceeds 70,000 × 10\(^9\)/L. A similar release of potassium from platelets may occur when the platelet count exceeds 1,000,000 × 10\(^9\)/L.

**Hyperkalemia due to Extracellular Movement of Potassium**

Movement of K\(^+\) out of cells can be seen with acidosis, cell lysis following chemotherapy, hemolysis, rhabdomyolysis, massive tissue trauma, hyperosmolality, digitalis overdoses, during episodes of hyperkalemic periodic paralysis, and with administration of succinylcholine, β\(_2\)-adrenergic blockers, and arginine hydrochloride. The average increase in plasma [K\(^+\)] of 0.5 mEq/L following succinylcholine administration can be exaggerated in patients with large burns or severe muscle trauma and in those with muscle denervation, and its use in these settings should be avoided.

**Hyperkalemia due to Decreased Renal Excretion of Potassium**

Decreased renal excretion of potassium can result from (1) marked reductions in glomerular filtration, (2) decreased aldosterone activity, or (3) a defect in potassium secretion in the distal nephron.

Glomerular filtration rates less than 5 mL/min are nearly always associated with hyperkalemia. Patients with lesser degrees of kidney impairment can also readily develop hyperkalemia when faced with increased potassium loads (dietary, catabolic, or iatrogenic). Uremia may also impair Na\(^+\)–K\(^+\)-ATPase
Hyperkalemia due to decreased aldosterone activity can result from a primary defect in adrenal hormone synthesis or a defect in the RAAS. Patients with primary adrenal insufficiency (Addison disease) and those with isolated 21-hydroxylase adrenal enzyme deficiency have marked impairment of aldosterone synthesis. Patients with the syndrome of isolated hypoaldosteronism (also called hyporeninemic hypoaldosteronism, or type IV renal tubular acidosis) are usually diabetics with renal impairment; they have an impaired ability to increase aldosterone secretion in response to hyperkalemia. These patients develop hyperkalemia when they increase their potassium intake or when given potassium-sparing diuretics. They also often have varying degrees of Na⁺ wasting and a hyperchloremic metabolic acidosis.

Drugs interfering with the RAAS have the potential to cause hyperkalemia, particularly in the presence of kidney disease. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit prostaglandin-mediated renin release. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) interfere with angiotensin II–mediated release of aldosterone. Heparin used in thromboprophylaxis regimens may cause hyperkalemia (heparin–induced hyperkalemia [HIH]) by interfering with aldosterone secretion and antagonizing the activity of angiotensin II receptors. Potassium-sparing diuretics antagonize aldosterone activity in the kidney, impairing potassium excretion (see earlier discussion).

Decreased renal excretion of potassium may also occur as a result of an intrinsic or acquired defect in the distal nephron’s ability to secrete potassium. Such defects may occur even in the presence of normal renal function and are characteristically unresponsive to mineralocorticoid therapy. The kidneys of patients with pseudohypoaldosteronism display an intrinsic resistance to aldosterone. Acquired defects have been associated with systemic lupus erythematosus, sickle cell anemia, obstructive uropathies, and cyclosporine nephropathy in transplanted kidneys.

**Hyperkalemia due to Increased Potassium Intake**

Increased potassium loads rarely cause hyperkalemia in normal individuals unless large amounts are given rapidly and intravenously. Hyperkalemia, however, may be seen when potassium intake is increased in patients receiving β-blockers or in patients with impaired kidney function. Unrecognized sources of potassium include potassium penicillin, sodium substitutes (primarily
potassium salts), and transfusion of stored whole blood. The plasma \([K^+]\) in a unit of whole blood can increase to 30 mEq/L after 21 days of storage. The risk of hyperkalemia from multiple transfusions (transfusion-associated hyperkalemia) is reduced, although not eliminated, by minimizing the volume of plasma given through the use of packed red blood cell transfusions or by using washed red blood cells (see Chapter 51).

**Clinical Manifestations of Hyperkalemias**

The most important effects of hyperkalemia are on skeletal and cardiac muscle. Skeletal muscle weakness is generally not seen until plasma \([K^+]\) is greater than 8 mEq/L. Cardiac manifestations (Figure 49–7) are primarily due to delayed depolarization and are consistently present when plasma \([K^+]\) is greater than 7 mEq/L. ECG changes characteristically progress sequentially from symmetrically peaked T waves (often with a shortened QT interval) → widening of the QRS complex → prolongation of the P–R interval → loss of the P wave → loss of R-wave amplitude → ST-segment depression (occasionally elevation) → an ECG that resembles a sine wave, before progressing to ventricular fibrillation and asystole. Contractility may be relatively well preserved until late in the course of progressive hyperkalemia. Hypocalcemia, hyponatremia, and acidosis accentuate the cardiac effects of hyperkalemia.

**FIGURE 49–7** Electrocardiographic effects of hyperkalemia. Electrocardiographic changes characteristically progress from symmetrically peaked T waves, often with a shortened QT interval, to widening of the QRS complex, prolongation of the P–R interval, loss of the P wave, loss of R-wave amplitude, and ST-segment depression (occasionally elevation)—to an ECG that resembles a sine wave—before final progression into ventricular fibrillation or asystole.
Treatment of Hyperkalemia

Because of its lethal potential, hyperkalemia exceeding 6 mEq/L should always be corrected. Treatment is directed to reversal of cardiac manifestations and skeletal muscle weakness, and to restoration of normal plasma [K⁺]. Therapeutic modalities employed depend on the cause of hyperkalemia and the severity of manifestations. Hyperkalemia associated with hypoaldosteronism can be treated with mineralocorticoid replacement. Drugs contributing to hyperkalemia should be discontinued and sources of increased potassium intake reduced or stopped.

Calcium (5–10 mL of 10% calcium gluconate or 3–5 mL of 10% calcium chloride) partially antagonizes the cardiac effects of hyperkalemia and is useful in symptomatic patients with marked hyperkalemia. Its effects are rapid but short lived. Care must be exercised in administering calcium to patients taking digoxin, as calcium potentiates digoxin toxicity.

An intravenous infusion of glucose and insulin (30–50 g of glucose with 10 units of insulin) is also effective in promoting cellular uptake of potassium and lowering plasma [K⁺], but may take up to 1 h for peak effect. When metabolic acidosis is present, intravenous sodium bicarbonate will promote cellular uptake of potassium and can decrease plasma [K⁺] within 15 min. β-Agonists promote cellular uptake of potassium and may be useful in acute hyperkalemia associated with massive transfusions; low-dose epinephrine infusion often rapidly decreases plasma [K⁺] and provides inotropic support in this setting.

The ultimate goal of urgent or emergent treatment of hyperkalemia is reduction of total body potassium. Forced diuresis with a loop diuretic is an effective treatment of acute hyperkalemia in patients with adequate kidney function, and dialysis is the definitive urgent or emergent therapeutic modality for patients with impaired kidney function. Elimination of excess potassium can also be accomplished with oral or rectal administration of the nonabsorbable cation-exchange resin, sodium polystyrene sulfonate (SPS, Kayexalate). However, the safety and efficacy of SPS have been repeatedly questioned, and a U.S. Food and Drug Administration (FDA) black box warning cautions its use in patients with abnormal bowel function because of the risk of intestinal necrosis in such circumstances. SPS should not be utilized to treat urgent or emergent hyperkalemia, as the onset of its effect takes several hours.

Patiromer, a nonabsorbed cation exchange polymer that binds potassium in exchange for calcium in the gastrointestinal tract, was recently approved by the FDA as an effective treatment for chronic hyperkalemia. Like SPS, it should not
be used to treat urgent or emergent hyperkalemia because of its delayed onset of action.

**Anesthetic Considerations**

Elective surgery should not be undertaken in patients with significant hyperkalemia. Anesthetic management of hyperkalemic perioperative patients is directed at both lowering the plasma potassium concentration and preventing any further increases, with treatment approach dependent upon situational acuity. The ECG should be carefully monitored. Succinylcholine is contraindicated, as is the use of potassium-containing intravenous solutions. The avoidance of metabolic or respiratory acidosis is critical to prevent further increases in plasma [K⁺]. Ventilation should be controlled under general anesthesia, and mild hyperventilation may be desirable. Lastly, neuromuscular function should be monitored closely, as hyperkalemia can accentuate the effects of NMBs.

**Disorders of Calcium Balance**

Although 98% of total body calcium is in bone, maintenance of a normal extracellular calcium concentration is critical to homeostasis. Calcium ions are involved in nearly all essential biological functions, including muscle contraction, the release of neurotransmitters and hormones, blood coagulation, and bone metabolism, and abnormalities in calcium balance can result in profound physiological derangements.

**NORMAL CALCIUM BALANCE**

Calcium intake in adults averages 600 to 800 mg/d, and calcium absorption occurs primarily in the proximal small bowel. Calcium is also secreted into the intestinal tract, a phenomenon that appears to be constant and independent of absorption. Up to 80% of the daily calcium intake is normally lost in feces.

The kidneys are responsible for most calcium excretion. Renal calcium excretion averages 100 mg/d but may vary from as low as 50 mg/d to more than 300 mg/d. Normally, 98% of the filterable calcium is reabsorbed. Calcium reabsorption parallels that of sodium in the proximal renal tubules and the ascending loop of Henle. In the distal tubules, however, calcium reabsorption is dependent on parathyroid hormone (PTH) secretion, whereas sodium reabsorption is dependent on aldosterone secretion. Increased PTH levels
enhance distal calcium reabsorption and thereby decrease urinary calcium excretion.

**Plasma Calcium Concentration**

The normal plasma calcium concentration is 8.5 to 10.5 mg/dL (2.1–2.6 mmol/L). Approximately 50% is in the free, ionized form, 40% is protein bound (mainly to albumin), and 10% is complexed with anions such as citrate and amino acids. The free, ionized calcium concentration ([Ca$^{2+}$]) is physiologically most important. Plasma [Ca$^{2+}$] is normally 4.75 to 5.3 mg/dL (1.19–1.33 mmol/L). Changes in plasma albumin concentration affect the total, but not ionized, calcium concentration: For each increase or decrease of 1 g/dL in albumin, the total plasma calcium concentration increases or decreases approximately 0.8 to 1.0 mg/dL, respectively.

Changes in plasma pH directly affect the degree of protein binding and thus ionized calcium concentration. Ionized calcium increases approximately 0.16 mg/dL for each decrease of 0.1 unit in plasma pH and decreases by the same amount for each 0.1 unit increase in pH.

**Regulation of Extracellular Ionized Calcium Concentration**

Calcium normally enters ECF by either absorption from the intestinal tract or resorption of bone; only 0.5% to 1% of calcium in bone is exchangeable with ECF. In contrast, calcium normally leaves the extracellular compartment by (1) deposition into bone, (2) urinary excretion, (3) secretion into the intestinal tract, and (4) sweat formation. Extracellular [Ca$^{2+}$] is closely regulated by three hormones—PTH, vitamin D, and calcitonin—that act primarily on bone, the distal renal tubules, and the small bowel. Hormonal control of calcium is described in Chapter 35.

**HYPERCALCEMIA**

Hypercalcemia can occur as a result of a variety of disorders (Table 49–12). In primary hyperparathyroidism, secretion of PTH is inappropriately increased in relation to [Ca$^{2+}$]. In contrast, in secondary hyperparathyroidism (eg, chronic kidney failure or malabsorption syndromes), PTH levels are elevated in response to chronic hypocalcemia. Prolonged secondary hyperparathyroidism, however,
can occasionally result in autonomous secretion of PTH, resulting in a normal or elevated [Ca^{2+}] (tertiary hyperparathyroidism).

Patients with cancer can present with hypercalcemia whether or not bone metastases are present. Most often this is due to direct bony destruction, or secretion of humoral mediators of hypercalcemia (PTH-like substances, cytokines, or prostaglandins), or both. Hypercalcemia due to increased turnover of calcium from bone can also be encountered in patients with benign conditions such as Paget disease and chronic immobilization. Increased gastrointestinal absorption of calcium can lead to hypercalcemia in patients with the milk-alkali syndrome (marked increase in calcium intake), excessive vitamin D intake, or granulomatous diseases (enhanced sensitivity to vitamin D).

**Clinical Manifestations of Hypercalcemia**

Hypercalcemia often produces anorexia, nausea, vomiting, weakness, and polyuria. Ataxia, irritability, lethargy, or confusion can rapidly progress to coma. Hypertension is often present initially before hypovolemia supervenes. ECG signs include a shortened ST segment and shortened QT interval. Hypercalcemia increases cardiac sensitivity to digitalis. Hypercalcemia may promote pancreatitis, peptic ulcer disease, and kidney failure.
**Treatment of Hypercalcemia**

Symptomatic hypercalcemia requires rapid treatment. The most effective initial treatment is rehydration followed by a brisk diuresis (urinary output 200–300 mL/h) utilizing intravenous saline infusion and a loop diuretic to accelerate calcium excretion. Premature diuretic therapy prior to rehydration may aggravate the hypercalcemia by exacerbating volume depletion. Renal loss of potassium and magnesium usually occurs during diuresis, mandating laboratory monitoring and intravenous replacement as necessary. Although hydration and diuresis may remove the potential risk of cardiovascular and neurological complications of hypercalcemia, the serum calcium level usually remains elevated above normal. Additional therapy with a bisphosphonate or calcitonin may be required to further lower the serum calcium level. Severe hypercalcemia (>15 mg/dL) usually requires additional therapy after saline hydration and furosemide calciuresis. Bisphosphonates or calcitonin are preferred agents. Intravenous administration of pamidronate (Aredia) or etidronate (Didronel) is often utilized in this setting. Hemodialysis is very effective in correcting severe hypercalcemia and may be necessary in the presence of kidney or heart failure. Additional treatment depends on the underlying cause of the hypercalcemia and may include glucocorticoids in the setting of vitamin D–induced hypercalcemia such as granulomatous disease states.

It is necessary to look for the underlying etiology and direct appropriate treatment toward the cause of the hypercalcemia once any critical hypercalcemia threat has been addressed. **Approximately 90% of all hypercalcemia is due to either malignancy or hyperparathyroidism. The best laboratory test for discriminating between these two main categories of hypercalcemia is the PTH assay.** The serum PTH concentration is usually suppressed in malignancy states and elevated in hyperparathyroidism.

**Anesthetic Considerations**

Significant hypercalcemia is a medical emergency and should be corrected before any elective anesthetic. Ionized calcium levels should be monitored closely. If surgery must be performed, saline diuresis should be continued intraoperatively with care to avoid hypovolemia; appropriate goal-directed hemodynamic and fluid management therapy (see Chapter 51) should be utilized, especially for patients with cardiac or kidney impairment. Serial measurements of \([K^+]\) and \([Mg^{2+}]\) are obtained in anticipation of diuresis-related hypokalemia and hypomagnesemia. Responses to anesthetic agents and NMBs
are not predictable. Ventilation should be controlled under general anesthesia. Acidosis should be avoided so as to not worsen the elevated plasma [Ca\(^{2+}\)].

**HYPOCALCEMIA**

_Hypocalcemia should be diagnosed only on the basis of the plasma ionized calcium concentration._ When direct measurements of plasma [Ca\(^{2+}\)] are not available, the total calcium concentration must be corrected for decreases in plasma albumin concentration (see earlier discussion). Causes of hypocalcemia are listed in Table 49–13.

Hypocalcemia due to hypoparathyroidism is a relatively common cause of symptomatic hypocalcemia. Hypoparathyroidism may be surgical (see Chapter 37), idiopathic, part of multiple endocrine defects (most often with adrenal insufficiency), or associated with hypomagnesemia. Magnesium deficiency may impair the secretion of PTH and antagonize the effects of PTH on bone. Sepsis is often accompanied by suppressed PTH release, resulting in hypocalcemia.
Hyperphosphatemia (see later discussion) is also a relatively common cause of hypocalcemia, particularly in patients with chronic kidney failure. Hypocalcemia due to vitamin D deficiency may be the result of a markedly reduced intake (nutritional), vitamin D malabsorption, or abnormal vitamin D metabolism.

Chelation of calcium ions with the citrate ions in blood preservatives is an important cause of perioperative hypocalcemia in transfused patients; similar transient decreases in $[Ca^{2+}]$ are also possible following rapid infusions of large volumes of albumin. Hypocalcemia following acute pancreatitis is thought to be due to precipitation of calcium with fats (soaps) following the release of lipolytic enzymes and fat necrosis; hypocalcemia following fat embolism may have a similar basis. Hypocalcemia following rhabdomyolysis results from precipitation of calcium in injured muscle tissue or from the forced diuresis used to preempt acute kidney injury in this condition, or both.

*Tumor lysis syndrome*, another cause of hypocalcemia, is the result of rapid destruction of malignant cells from chemotherapy or radiation therapy, and may have an incidence as high as 25% in treatment of some cancers. It is the most common oncologic emergency and is the result of rapid shift of potassium, phosphorus, and nucleic acid material into the extracellular space, overwhelming normal homeostatic mechanisms that would otherwise compensate. Acute kidney injury or failure secondary to acute uric acid nephropathy due to metabolism of released nucleic acids degrades or abolishes the kidney’s ability to excrete potassium and phosphate. Hyperphosphatemia promotes phosphate chelation with calcium, resulting in acute hypocalcemia, and also results in renal calcium–phosphate salt deposition, further promoting acute kidney injury or failure. The acute hypocalcemia and hyperkalemia of tumor lysis syndrome may result in muscle weakness, tetany, cardiac arrhythmia, seizures, and death.

Less common causes of hypocalcemia include calcitonin-secreting medullary carcinomas of the thyroid, osteoblastic metastatic disease (breast and prostate cancer), and pseudohypoparathyroidism (familial unresponsiveness to PTH). Transient hypocalcemia may be seen following heparin, protamine, or glucagon administration.

**Clinical Manifestations of Hypocalcemia**

Manifestations of hypocalcemia include paresthesias, confusion, laryngeal stridor (laryngospasm), carpopedal spasm (Trousseau sign), masseter spasm (Chvostek sign), and seizures. Biliary colic and bronchospasm have also been described. ECG may reveal cardiac irritability or QT interval prolongation,
which may not correlate in severity with the degree of hypocalcemia. Decreased cardiac contractility may result in heart failure, hypotension, or both. Decreased responsiveness to digoxin and β-adrenergic agonists may also occur.

**Treatment of Hypocalcemia**

Symptomatic hypocalcemia is a medical emergency and should be treated immediately with intravenous calcium chloride (3–5 mL of a 10% solution) or calcium gluconate (10–20 mL of a 10% solution). Ten mL of 10% CaCl₂ contains 272 mg of Ca²⁺, whereas 10 mL of 10% calcium gluconate contains 93 mg of Ca²⁺. To avoid precipitation, intravenous calcium should not be given with bicarbonate- or phosphate-containing solutions. Serial ionized calcium monitoring is mandatory. Repeat intravenous boluses or a continuous infusion (Ca²⁺ 1–2 mg/kg/h) may be necessary. Plasma magnesium concentration should be checked to exclude hypomagnesemia. In chronic hypocalcemia, oral calcium (CaCO₃) and vitamin D replacement are usually adequate.

**Anesthetic Considerations**

Significant hypocalcemia should be corrected preoperatively. Serial ionized calcium levels should be monitored intraoperatively in patients with a history of hypocalcemia. Alkalosis should be avoided to prevent further decreases in [Ca²⁺]. Intravenous calcium may be necessary following rapid transfusions of citrated blood products or large volumes of albumin solutions (see Chapter 51). Potentiation of the negative inotropic effects of anesthetics should be expected. Responses to NMBs are inconsistent and require nerve stimulator monitoring.

**Disorders of Phosphorus Balance**

Phosphorus is an important intracellular constituent. Its presence is required for the synthesis of (1) the phospholipids and phosphoproteins in cell membranes and intracellular organelles, (2) the phosphonucleotides involved in protein synthesis and reproduction, and (3) ATP used for the storage of energy. Only 0.1% of total body phosphorus is in ECF, with 85% in bone and 15% intracellular.

NORMAL PHOSPHORUS BALANCE
Phosphorus intake averages 800 to 1500 mg/d in adults, and 80% of that amount is normally absorbed in the proximal small bowel. Vitamin D increases intestinal absorption of phosphorus. The kidneys are the major route for phosphorus excretion and are responsible for regulating total body phosphorus content. Urinary excretion of phosphorus depends on both intake and plasma concentration. Secretion of PTH promotes urinary phosphorus excretion by inhibiting proximal tubular reabsorption. The latter effect may be offset by PTH-induced release of phosphate from bone.

**Plasma Phosphorus Concentration**

Plasma phosphorus exists in both organic and inorganic forms. Organic phosphorus is mainly in the form of phospholipids. Of the inorganic phosphorus fraction, 80% is filterable in the kidneys and 20% is protein bound. The majority of inorganic phosphorus is in the form of $\text{H}_2\text{PO}_4^-$ and $\text{HPO}_4^{2-}$ in a 1:4 ratio. By convention, plasma phosphorus is measured as milligrams of elemental phosphorus. Normal plasma phosphorus concentration is 2.5 to 4.5 mg/dL (0.8–1.45 mmol/L) in adults and up to 6 mg/dL in children. Plasma phosphorus concentration is usually measured during fasting, because recent carbohydrate intake transiently decreases plasma phosphorus concentration. Hypophosphatemia increases vitamin D production, whereas hyperphosphatemia depresses it. The latter plays an important role in the genesis of secondary hyperparathyroidism in patients with chronic kidney failure (see Chapter 31).

**HYPERPHOSPHATEMIA**

Hyperphosphatemia may be seen with increased phosphorus intake (abuse of phosphate laxatives or excessive potassium phosphate administration), decreased phosphorus excretion (chronic kidney disease), or tumor lysis syndrome (see earlier discussion).

**Clinical Manifestations of Hyperphosphatemia**

Although hyperphosphatemia per se does not appear to be directly responsible for any functional disturbances, significant hyperphosphatemia may produce hypocalcemia via phosphate chelation with plasma $[\text{Ca}^{2+}]$ and may also produce acute kidney injury via parenchymal and tubular deposits of calcium-phosphate salts. Hyperphosphatemia is associated with increased mortality in chronic kidney disease and kidney failure patients, and is managed in this patient
population by dietary restriction, the use of phosphate binders, dialysis, or a combination of these methods.

**Treatment of Hyperphosphatemia**

Hyperphosphatemia is generally treated with phosphate-binding antacids such as aluminum hydroxide or aluminum carbonate.

**Anesthetic Considerations**

Although specific interactions between hyperphosphatemia and anesthesia have not been described, kidney function should be assessed and hypocalcemia should be excluded.

**HYPOPHOSPHATEMIA**

Hypophosphatemia is usually the result of either a negative phosphorus balance or cellular uptake of extracellular phosphorus (an intercompartmental shift). Intercompartmental shifts of phosphorus can occur during alkalosis and following carbohydrate ingestion or insulin administration. Large doses of aluminum- or magnesium-containing antacids, severe burns, insufficient phosphorus supplementation during total parenteral nutrition, diabetic ketoacidosis, alcohol withdrawal, and prolonged respiratory alkalosis can each produce negative phosphorus balance and lead to severe hypophosphatemia (<0.3 mmol/dL or <1.0 mg/dL). In contrast to respiratory alkalosis, metabolic alkalosis rarely leads to severe hypophosphatemia.

**Clinical Manifestations of Hypophosphatemia**

Mild to moderate hypophosphatemia (1.5–2.5 mg/dL) is generally asymptomatic. In contrast, severe hypophosphatemia (<1.0 mg/dL) is associated with increased morbidity and mortality in critically ill patients. Cardiomyopathy, impaired oxygen delivery (decreased 2,3-diphosphoglycerate levels), hemolysis, impaired leukocyte function, platelet dysfunction, encephalopathy, arrhythmia, skeletal myopathy, respiratory failure, rhabdomyolysis, skeletal demineralization, metabolic acidosis, and hepatic dysfunction have all been associated with severe hypophosphatemia. However, at this time it is uncertain whether hypophosphatemia is a direct and independent contributor to these major morbidities or to mortality, or is merely a marker of illness severity.
Treatment of Hypophosphatemia

Oral phosphorus replacement is generally preferable to parenteral replacement because of the increased risk of phosphate precipitation with calcium, resulting in hypocalcemia, and also because of the increased risks of hyperphosphatemia, hypomagnesemia, and hypotension. Accordingly, intravenous replacement therapy is usually reserved for instances of symptomatic hypophosphatemia and extremely low phosphate levels (<0.32 mmol/L). In situations where oral phosphate replacement is utilized, vitamin D is required for intestinal phosphate absorption.

Anesthetic Considerations

Anesthetic management of patients with hypophosphatemia requires familiarity with its potential complications (see earlier discussion). Hyperglycemia and respiratory alkalosis should be avoided to prevent further decreases in plasma phosphorus concentration. Neuromuscular function must be monitored carefully when NMBs are given. Some patients with severe hypophosphatemia may require mechanical ventilation postoperatively because of muscle weakness.

Disorders of Magnesium Balance

Magnesium functions as a cofactor in many enzyme pathways. Only 1% to 2% of total body magnesium stores is present in the ECF compartment, with 67% contained in bone and the remaining 31% intracellular. Magnesium decreases anesthetic requirements, attenuates nociception, blunts the cardiovascular response to laryngoscopy and intubation, and potentiates NMBs. Suggested mechanisms of action include altering central nervous system neurotransmitter release, moderating adrenal medullary catecholamine release, and antagonizing the effect of calcium on vascular smooth muscle. Magnesium impairs the calcium-mediated presynaptic release of acetylcholine and may also decrease motor end-plate sensitivity to acetylcholine and alter myocyte membrane potential.

In addition to the treatment of magnesium deficiency, magnesium is used to treat preeclampsia and eclampsia, torsades de pointes, and digoxin-induced cardiac tachyarrhythmias.

NORMAL MAGNESIUM BALANCE
Magnesium intake averages 20 to 30 mEq/d (240–370 mg/d) in adults. Of that amount, only 30% to 40% is absorbed, mainly in the distal small bowel. Renal excretion is the primary route for elimination, averaging 6 to 12 mEq/d. Magnesium reabsorption by the kidneys is very efficient. Twenty-five percent of filtered magnesium is reabsorbed in the proximal tubule and 50% to 60% is reabsorbed in the thick ascending limb of the loop of Henle. Factors known to increase magnesium reabsorption in the kidneys include hypomagnesemia, PTH, hypocalcemia, ECF depletion, and metabolic alkalosis. Factors known to increase renal excretion include hypermagnesemia, acute volume expansion, aldosterone, hypercalcemia, ketoacidosis, diuretics, phosphate depletion, and alcohol ingestion.

**Plasma Magnesium Concentration**

Plasma $[\text{Mg}^{2+}]$ is closely regulated between 1.7 and 2.1 mEq/L (0.7–1 mmol/L or 1.7–2.4 mg/dL) through interaction of the gastrointestinal tract (absorption), bone (storage), and the kidneys (excretion). Approximately 50% to 60% of plasma magnesium is unbound and diffusible.

**HYPERMAGNESEMA**

Increases in plasma $[\text{Mg}^{2+}]$ are nearly always due to excessive intake (magnesium-containing antacids or laxatives: magnesium hydroxide, Milk of Magnesia), kidney impairment (GFR <30 mL/min), or both. Less common causes include adrenal insufficiency, hypothyroidism, rhabdomyolysis, and lithium administration. Magnesium sulfate therapy for preeclampsia and eclampsia can result in maternal and fetal hypermagnesemia.

**Clinical Manifestations of Hypermagnesemia**

Symptomatic hypermagnesemia typically presents with neurological, neuromuscular, and cardiac manifestations, including hyporeflexia, sedation, muscle weakness, and respiratory depression. Vasodilation, bradycardia, and myocardial depression may cause hypotension. ECG signs may include prolongation of the P–R interval and widening of the QRS complex. Severe hypermagnesemia can lead to respiratory and cardiac arrest.

**Treatment of Hypermagnesemia**
With relatively mild hypermagnesemia, all that is usually necessary is to discontinue source(s) of magnesium intake (most often antacids or laxatives). In cases of relatively high $[\text{Mg}^{2+}]$, and especially in the presence of clinical signs of magnesium toxicity, intravenous calcium can temporarily antagonize most of the effects of clinical toxicity. Forced diuresis with a loop diuretic and intravenous fluid replacement enhances urinary magnesium excretion in patients with adequate renal function. When diuretic administration with intravenous infusion is used to enhance magnesium excretion in urgent or emergent cases of magnesium toxicity, serial measurements of $[\text{Ca}^{2+}]$ and $[\text{Mg}^{2+}]$ should be obtained, a urinary catheter is required, and goal-directed hemodynamic and fluid management should be considered. Dialysis will be necessary in such patients with significant kidney impairment or kidney failure. Ventilatory or circulatory support, or both, may be necessary.

**Anesthetic Considerations**

Hypermagnesemia requires close monitoring of the ECG, blood pressure, and neuromuscular function. Potentiation of the vasodilatory and negative inotropic properties of anesthetics should be expected. Dosages of nondepolarizing NMBs should be reduced.

**HYPOMAGNESEMIA**

Hypomagnesemia is a common problem, particularly in critically ill patients, and is often associated with deficiencies of other intracellular components such as potassium and phosphorus. It is commonly found in patients undergoing major cardiothoracic or abdominal operations, and its incidence among patients in intensive care units may exceed 50%. Deficiencies of magnesium are generally the result of inadequate intake, reduced gastrointestinal absorption, increased renal excretion, or a combination of these factors (*Table 49–14*). Drugs that cause renal wasting of magnesium include ethanol, theophylline, diuretics, cisplatin, aminoglycosides, cyclosporine, amphotericin B, pentamidine, and granulocyte colony-stimulating factor. Hypomagnesemia has also been associated with long-term proton pump inhibitor (PPI) therapy, with such cases ascribed to impaired intestinal absorption of magnesium. However, the prevalence of hypomagnesemia among patients with chronic use of PPIs is low, probably less than 1%. Hypomagnesemia is common after cardiopulmonary bypass unless patients receive intraoperative supplementation, due to hemodilution and the frequent use of albumin, transfusion, and other
magnesium-lowering constituents in the priming solution.

**TABLE 49–14 Causes of hypomagnesemia.**

**Reduced gastrointestinal absorption**

- Malabsorption syndromes
- Small bowel or biliary fistulas
- Prolonged nasogastric suctioning
- Severe vomiting or diarrhea
- Chronic laxative abuse
- Chronic proton pump inhibitor (PPI) use

**Increased renal losses**

- Diuresis
- Diabetic ketoacidosis
- Hyperparathyroidism
- Hyperaldosteronism
- Hypophosphatemia
- Nephrotoxic drugs
- Postobstructive diuresis

**Multifactorial**

- Chronic alcoholism
- Protein–calorie malnutrition
- Hyperthyroidism
- Pancreatitis
- Burns

**Clinical Manifestations of Hypomagnesemia**

Most patients with hypomagnesemia are asymptomatic, but weakness, fasciculation, paresthesias, confusion, ataxia, and seizures may be encountered. Hypomagnesemia is frequently associated with both hypocalcemia (impaired PTH secretion) and hypokalemia (due to renal K⁺ wasting). Cardiac manifestations include arrhythmias and potentiation of digoxin toxicity; both are worsened by hypokalemia. Hypomagnesemia is associated with an increased
incidence of atrial fibrillation. Prolongation of the P–R and QT intervals may also be present.

**Treatment of Hypomagnesemia**

Asymptomatic hypomagnesemia can be treated orally or intramuscularly. Serious manifestations such as seizures should be treated with intravenous magnesium sulfate, 1 to 2 g (8–16 mEq or 4–8 mmol) given over 10 to 60 min.

**Anesthetic Considerations**

Although no specific anesthetic interactions are described, coexistent electrolyte disturbances such as hypokalemia, hypophosphatemia, and hypocalcemia are often present and should be corrected prior to surgery. Isolated hypomagnesemia should be corrected prior to elective procedures because of its potential to cause arrhythmias. Moreover, magnesium appears to have intrinsic antiarrhythmic properties and possibly cerebral protective effects (see Chapter 26). It is frequently administered preemptively to lessen the risk of postoperative atrial fibrillation in patients undergoing cardiac surgery.

**CASE DISCUSSION**

**Electrolyte Abnormalities Following Urinary Diversion**

A 70-year-old man with carcinoma of the bladder presents for radical cystectomy and ileal loop urinary diversion. He weighs 70 kg and has a 20-year history of hypertension. Preoperative laboratory measurements revealed normal plasma electrolyte concentrations and a BUN of 20 mg/dL with a serum creatinine of 1.5 mg/dL. The operation lasts 4 h and is performed under general anesthesia. The estimated blood loss is 900 mL. Fluid replacement consists of 3500 mL of lactated Ringer’s injection and 750 mL of 5% albumin.

One hour after admission to the postanesthesia care unit, the patient is awake, his blood pressure is 130/70 mm Hg, and he appears to be breathing well (18 breaths/min, Fio₂ = 0.4). Urinary output has been only 20 mL in the last hour. Laboratory measurements are as follows: Hb, 10.4 g/dL; plasma Na+, 133 mEq/L; K+, 3.8 mEq/L; Cl–, 104
mEq/L; total CO₂, 20 mmol/L; Pao₂, 156 mm Hg; arterial blood pH, 7.29; Paco₂, 38 mm Hg; and calculated HCO₃⁻, 18 mEq/L. (See Table 49–15 for normal ranges or common electrolytes.)

**What is the most likely explanation for the hyponatremia?**

Multiple factors tend to promote hyponatremia postoperatively, including nonosmotic ADH secretion due to surgical stress, hypovolemia, or pain; large evaporative and functional fluid losses (tissue sequestration); and the administration of hypotonic intravenous fluids. Hyponatremia is particularly common postoperatively in patients who have received relatively large amounts of lactated Ringer’s injection ([Na⁺] 130 mEq/L); the postoperative plasma [Na⁺] generally approaches 130 mEq/L in such patients. (Fluid replacement in this patient was appropriate considering basic maintenance requirements, blood loss, and the additional fluid losses usually associated with this type of surgery.)

**Why is the patient hyperchloremic and acidotic (normal arterial**
Operations for supravesical urinary diversion utilize a segment of bowel (ileum, ileocecal segment, jejunum, or sigmoid colon) that is made to function as a conduit or reservoir. The simplest and most common procedure utilizes an isolated loop of ileum as a conduit: the proximal end is anastomosed to the ureters, and the distal end is brought through the skin, forming a stoma.

Whenever urine comes in contact with bowel mucosa, the potential for significant fluid and electrolyte exchange exists. The ileum actively absorbs chloride in exchange for bicarbonate, and sodium in exchange for potassium or hydrogen ions. When chloride absorption exceeds sodium absorption, plasma chloride concentration increases, whereas plasma bicarbonate concentration decreases—a hyperchloremic metabolic acidosis is established. In addition, the colon absorbs NH₄⁺ directly from urine; the latter may also be produced by urea-splitting bacteria. Hypokalemia results if significant amounts of Na⁺ are exchanged for K⁺. Potassium losses through the conduit are increased by high urinary sodium concentrations. Moreover, a potassium deficit may be present—even in the absence of hypokalemia—because movement of K⁺ out of cells (secondary to the acidosis) can prevent an appreciable decrease in extracellular plasma [K⁺].

Are there any factors that tend to increase the likelihood of hyperchloremic metabolic acidosis following urinary diversion?

The longer the urine is in contact with bowel, the greater the chance that hyperchloremia and acidosis will occur. Mechanical problems such as poor emptying or redundancy of a conduit—along with hypovolemia—thus predispose to hyperchloremic metabolic acidosis. Preexisting renal impairment also appears to be a major risk factor and probably represents an inability to compensate for the excessive bicarbonate losses.

What treatment, if any, is required for this patient?

The ileal loop should be irrigated with saline to exclude partial obstruction and ensure free drainage of urine. Hypovolemia should be considered and treated based on goal-directed hemodynamic and fluid therapy or the response to a fluid challenge (see Chapter 51). A mild to moderate systemic acidosis (arterial pH > 7.25) is generally well tolerated by most patients. Moreover, hyperchloremic metabolic acidosis following...
ileal conduits is often transient and usually due to urinary stasis. Persistent or more severe acidosis requires treatment with sodium bicarbonate. Potassium replacement may also be required if hypokalemia is present.

**Are electrolyte abnormalities seen with other types of urinary diversion?**

Procedures employing bowel as a conduit (ileal or colonic) are less likely to result in hyperchloremic metabolic acidosis than those in which bowel functions as a reservoir. The incidence of hyperchloremic metabolic acidosis approaches 80% following ureterosigmoidostomies.

Acid–Base Management

KEY CONCEPTS

1. The strong ion difference, $\text{PCO}_2$, and total weak acid concentration best explain acid–base balance in physiological systems.

2. The bicarbonate buffer is effective against metabolic but not respiratory acid–base disturbances.

3. In contrast to the bicarbonate buffer, hemoglobin is capable of buffering both carbonic ($\text{CO}_2$) and noncarbonic (nonvolatile) acids.

4. As a general rule, $\text{PacO}_2$ can be expected to increase 0.25 to 1 mm Hg for each 1 mEq/L increase in $[\text{HCO}_3^-]$.

5. The renal response to acidemia is three-fold: (1) increased reabsorption of the filtered $[\text{HCO}_3^-]$, (2) increased excretion of titratable acids, and (3) increased production of ammonia.

6. During chronic respiratory acidosis, plasma $[\text{HCO}_3^-]$ increases approximately 4 mEq/L for each 10 mm Hg increase in $\text{PacO}_2$ above 40 mm Hg.

7. Diarrhea is a common cause of hyperchloremic metabolic acidosis.

8. The distinction between acute and chronic respiratory alkalosis is not always made, because the compensatory response to chronic respiratory alkalosis is quite variable: Plasma $[\text{HCO}_3^-]$ decreases 2 to 5 mEq/L for each 10 mm Hg decrease in $\text{PacO}_2$ below 40 mm Hg.

9. Vomiting or continuous loss of gastric fluid by gastric drainage (nasogastric suctioning) can result in marked metabolic alkalosis, extracellular volume depletion, and hypokalemia.

10. The combination of alkalemia and hypokalemia can precipitate severe atrial and ventricular arrhythmias.
Changes in temperature affect $P_{CO_2}$, $P_{O_2}$, and pH. Both $P_{CO_2}$ and $P_{O_2}$ decrease during hypothermia, but pH increases because temperature does not appreciably alter $[HCO_3^-]$ and the dissociation of water decreases (decreasing $H^+$ and increasing pH).

Nearly all biochemical reactions in the body are dependent on maintenance of a physiological hydrogen ion concentration, and alterations beyond normal hydrogen ion concentration are associated with widespread organ dysfunction. This regulation—usually referred to as acid–base balance—is of prime importance in critical illness. Changes in ventilation and perfusion, as well as infusion of electrolyte-containing solutions, are common during anesthesia and can rapidly alter acid–base balance.

Our understanding of acid–base balance is evolving. In the past, we focused on the concentration of hydrogen ions $[H^+]$, $CO_2$ balance, and the base excess/deficit. We now understand that the strong ion difference (SID), $P_{CO_2}$, and total weak acid concentration ($A_{TOT}$) best explain acid–base balance in physiological systems.

This chapter examines acid–base physiology and the perioperative care implications of common disturbances. Clinical measurements of blood gases and their interpretation are reviewed.

**Definitions**

**ACID–BASE CHEMISTRY**

**Hydrogen Ion Concentration & pH**

In any aqueous solution, water molecules reversibly dissociate into hydrogen and hydroxide ions:

$$H_2O \leftrightarrow H^+ + OH^-$$

This process is described by the dissociation constant, $K_W$:

$$K_W = [H^+] \times [OH^-] = 10^{-14}$$
The concentration of water is omitted from the denominator of this expression because it does not vary appreciably and is already included in the constant. Therefore, given \([H^+]\) or \([OH^-]\), the concentration of the other ion can be readily calculated.

**Example:** If \([H^+] = 10^{-8}\) nEq/L, then \([OH^-] = 10^{-14} \div 10^{-8} = 10^{-6}\) nEq/L.

Arterial \([H^+]\) is normally 40 nEq/L, or \(40 \times 10^{-9}\) mol/L. Hydrogen ion concentration is more commonly expressed as pH, which is defined as the negative logarithm (base 10) of \([H^+]\) (Figure 50–1). Normal arterial pH is therefore \(-\log (40 \times 10^{-9}) = 7.40\). Hydrogen ion concentrations between 16 and 160 nEq/L (pH 6.8–7.8) are compatible with life.

**FIGURE 50–1** The relationship between pH and \([H^+]\). Note that between a pH of 7.10 and 7.50, the relationship between pH and \([H^+]\) is nearly linear. (Reproduced with permission from Narins RG, Emmett M. Simple and mixed acid–base disorders: A practical approach. *Medicine*. 1980 May;59(3):161-187.)

Like most dissociation constants, \(K_w\) is affected by changes in temperature. Thus, the electroneutrality point for water occurs at a pH of 7.0 at 25°C, but at about a pH of 6.8 at 37°C; temperature-related changes may be important during
hypothermia (see Chapter 22).

Because physiological fluids are complex aqueous solutions, SID, the \( P_{CO_2} \), and \( A_{TOT} \) are other factors that affect the dissociation of water into \( H^+ \) and \( OH^- \).

**Acids & Bases**

An *acid* is usually defined as a chemical species that can act as a proton (\( H^+ \)) donor, whereas a *base* is a species that can act as a proton acceptor (Brönsted–Lowry definitions). In physiological solutions, it is probably better to use Arrhenius’ definitions: An acid is a compound that contains hydrogen and reacts with water to form hydrogen ions. A base is a compound that produces hydroxide ions in water. Using these definitions, the SID becomes important, as other ions in solutions (cations and anions) will affect the dissociation constant for water, and, therefore, the hydrogen ion concentration. A *strong acid* is a substance that readily and almost irreversibly gives up an \( H^+ \) and increases \([H^+]\), whereas a *strong base* avidly binds \( H^+ \) and decreases \([H^+]\). In contrast, *weak acids* reversibly donate \( H^+ \), whereas *weak bases* reversibly bind \( H^+ \); both weak acids and bases tend to have less of an effect on \([H^+]\) (for a given concentration of the parent compound) than do strong acids and bases. *Biological compounds are either weak acids or weak bases.*

For a solution containing the weak acid \( HA \), where

\[
HA \leftrightarrow H^+ + A^- 
\]

a dissociation constant, \( K \), can be defined as follows:

\[
K = \frac{[H^+][A^-]}{[HA]} \quad \text{or} \quad [H^+] = \frac{K[HA]}{[A^-]}
\]

The negative logarithmic form of the latter equation is called the *Henderson–Hasselbalch equation:*

\[
pH = pK + \log \left( \frac{[A^-]}{[HA]} \right)
\]

From this equation, it is apparent that the pH of this solution is related to the ratio of the dissociated anion to the undissociated acid.
This approach works well with pure water: The concentration of \([H^+]\) must equal \([OH^-]\). But physiological solutions are far more complex. Even in such a complex solution, the \([H^+]\) can be predicted using three variables: the SID, the \(P_{CO_2}\), and \(A_{TOT}\).

**Strong Ion Difference**

The SID is the sum of all the strong, completely or almost completely dissociated cations (Na\(^+\), K\(^+\), Ca\(^{2+}\), Mg\(^{2+}\)) minus the strong anions (Cl\(^-\), lactate\(^-\), etc; **Figure 50–2**). Although we can calculate the SID, because the laws of electroneutrality must be observed, if there is a SID, other unmeasured ions must be present. \(P_{CO_2}\) is an independent variable, assuming ventilation is ongoing.

The conjugate base of HA is A\(^-\) and is composed mostly of phosphates and proteins that do not change independent of the other two variables. A\(^-\) plus AH is an independent variable because its value is not determined by any other variable. Note that \([H^+]\) is not a strong ion (water does not completely dissociate), but it can, does, and must change in response to any change in SID, \(P_{CO_2}\), or \(A_{TOT}\) to comply with the laws of electroneutrality and conservation of mass. Hydrogen ions are created or consumed based on changes in the dissociation of water.

**FIGURE 50–2** The strong ion difference (SID). SID\(_a\), apparent strong ion difference. SID\(_e\), effective strong ion difference. The strong ion gap (SIG) is the difference between SID\(_a\) and SID\(_e\) and represents the anion gap. (Reproduced with permission from Greenbaum J, Nirmalan M. Acid-base balance: Stewart’s physiochemical approach. *Curr*
Conjugate Pairs & Buffers

As previously discussed, when the weak acid HA is in solution, HA can act as an acid by donating an $H^+$, and $A^-$ can act as a base by taking up $H^+$. $A^-$ is therefore often referred to as the *conjugate base* of HA. A similar concept can be applied for weak bases. Consider the weak base B, where

$$B + H^+ \leftrightarrow BH^+$$

BH$^+$ is therefore the conjugate acid of B.

A *buffer* is a solution that contains a weak acid and its conjugate base or a weak base and its conjugate acid (conjugate pairs). Buffers minimize any change in $[H^+]$ by readily accepting or giving up hydrogen ions. It is readily apparent that buffers are most efficient in minimizing changes in the $[H^+]$ of a solution (ie, $[A^-] = [HA]$) when pH = pK. Moreover, the conjugate pair must be present in significant quantities in solution to act as an effective buffer.

CLINICAL DISORDERS

A clear understanding of acid–base disorders and compensatory physiological responses requires precise terminology (*Table 50–1*). The suffix “-osis” is used here to denote any pathological process that alters arterial pH. Thus, any disorder that tends to reduce pH to a less than normal value is an *acidosis*, whereas one tending to increase pH is termed an *alkalosis*. If the disorder primarily affects $[HCO_3^-]$, it is termed *metabolic*. If the disorder primarily affects $PaCO_2$, it is termed *respiratory*. Secondary compensatory responses (discussed in the next section) should be referred to as just that and not as an “-osis.” For example, one might refer to a metabolic acidosis with respiratory compensation.

**TABLE 50–1  Defining acid–base disorders.**
When only one pathological process occurs by itself, the acid–base disorder is considered to be simple (Figure 50–3). The presence of two or more primary processes indicates a mixed acid–base disorder.

<table>
<thead>

</tr>
</tbody>
</table>

When only one pathological process occurs by itself, the acid–base disorder is considered to be simple (Figure 50–3). The presence of two or more primary processes indicates a mixed acid–base disorder.

The suffix “-emia” is used to denote the net effect of all primary processes and compensatory physiological responses (described next) on arterial blood pH. Because arterial blood pH is normally between 7.35 and 7.45 in adults, the term acidemia signifies a pH less than 7.35, whereas alkalemia signifies a pH greater than 7.45.
Compensatory Mechanisms

Physiological responses to changes in [H+] are characterized by three phases: (1) immediate chemical buffering, (2) respiratory compensation (whenever possible), and (3) a slower, but more effective, renal compensatory response that may nearly normalize arterial pH even if the underlying pathological process remains present.

BODY BUFFERS

Physiologically important buffers in humans include bicarbonate (H$_2$CO$_3$/HCO$_3^-$), hemoglobin (HbH/Hb$^-$), other intracellular proteins (PrH/Pr$^-$), phosphates (H$_2$PO$_4^-$/HPO$_4^{2-}$), and ammonia (NH$_3$/NH$_4^+$). The effectiveness of these buffers in the various fluid compartments is related to their concentration. Bicarbonate is the most important buffer in the extracellular fluid compartment. Hemoglobin, though restricted inside red blood cells, also functions as an important buffer in blood. Other proteins probably play a major role in buffering the intracellular fluid compartment. Phosphate and ammonium ions are important urinary buffers.

Buffering of the extracellular compartment can also be accomplished by the exchange of extracellular H$^+$ for Na$^+$ and Ca$^{2+}$ ions from bone and by the exchange of extracellular H$^+$ for intracellular K$^+$. Acid loads can demineralize bone and release alkaline compounds (CaCO$_3$ and CaHPO$_4$). Alkaline loads (NaHCO$_3$) increase the deposition of carbonate in bone.

Buffering by plasma bicarbonate is almost immediate, whereas that due to interstitial bicarbonate requires 15 to 20 min. In contrast, buffering by intracellular proteins and bone is slower (2–4 h). Up to 50% to 60% of acid loads may ultimately be buffered by bone and intracellular buffers.

The Bicarbonate Buffer

Although in the strictest sense, the bicarbonate buffer consists of H$_2$CO$_3$ and HCO$_3^-$, CO$_2$ tension (P$_{CO_2}$) may be substituted for H$_2$CO$_3$ because:

$$H_2O + CO_2 \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$
This hydration of CO₂ is catalyzed by carbonic anhydrase. If adjustments are made in the dissociation constant for the bicarbonate buffer and if the solubility coefficient for CO₂ (0.03 mEq/L) is taken into consideration, the Henderson–Hasselbalch equation for bicarbonate can be written as follows:

\[
pH = pK' + \log \left( \frac{[HCO_3^-]}{0.03 \text{ PaCO}_2} \right)
\]

where \( pK' = 6.1 \).

Note that its \( pK' \) is well removed from the normal arterial pH of 7.40, which means that bicarbonate would not be expected to be an efficient extracellular buffer (see earlier discussion). The bicarbonate system is, however, important for two reasons: (1) Bicarbonate (\( HCO_3^- \)) is present in relatively high concentrations in extracellular fluid, and (2) more importantly, \( \text{PaCO}_2 \) and plasma [\( HCO_3^- \)] are closely regulated by the lungs and the kidneys, respectively. The ability of these two organs to alter the [\( HCO_3^- \)]/\( \text{PaCO}_2 \) ratio allows them to exert important influences on arterial pH.

A simplified and more practical derivation of the Henderson–Hasselbalch equation for the bicarbonate buffer is as follows:

\[
[H^+] = 24 \times \frac{\text{PaCO}_2}{[HCO_3^-]}
\]

This equation is very useful clinically because pH can be readily converted to [\( H^+ \)] (Table 50–2). Note that below 7.40, [\( H^+ \)] increases 1.25 nEq/L for each 0.01 decrease in pH; above 7.40, [\( H^+ \)] decreases 0.8 nEq/L for each 0.01 increase in pH.

**TABLE 50–2** The relationship between pH and [\( H^+ \)].

**Example:** If arterial pH = 7.28 and Paco₂ = 24 mm Hg, what should the plasma [HCO₃⁻] be?

\[
[H^+] = 40 + [(40 - 28) \times 1.25] = 55 \text{ nEq/L}
\]

Therefore,

\[
55 = 24 \times \frac{24}{[\text{HCO}_3^-]} \quad \text{and} \quad [\text{HCO}_3^-] = \frac{(24 \times 24)}{55} = 10.5 \text{ mEq/L}
\]

**It should be emphasized that the bicarbonate buffer is effective against metabolic but not respiratory acid–base disturbances.** If 3 mEq/L of a strong nonvolatile acid, such as HCl, is added to extracellular fluid, the following reaction takes place:
3 mEq/L of H⁺ 24 mEq/L of HCO₃⁻ → H₂CO₃

+ H₂O + 3 mEq/L of CO₂ + 21 mEq/L of HCO₃⁻

Note that HCO₃⁻ reacts with H⁺ to produce CO₂. Moreover, the CO₂ generated is normally eliminated by the lungs such that Paco₂ does not change. Consequently, [H⁺] = 24 × 40 ÷ 21 = 45.7 nEq/L, and pH = 7.34. Furthermore, the decrease in [HCO₃⁻] reflects the amount of nonvolatile acid added.

In contrast, an increase in CO₂ tension (volatile acid) has a minimal effect on [HCO₃⁻]. If, for example, Paco₂ increases from 40 to 80 mm Hg, the dissolved CO₂ increases only from 1.2 mEq/L to 2.2 mEq/L. Moreover, the equilibrium constant for the hydration of CO₂ is such that an increase of this magnitude minimally drives the reaction to the left:

H₂O + CO₂ ↔ H₂CO₃ ↔ H⁺ + HCO₃⁻

If the valid assumption is made that [HCO₃⁻] does not appreciably change, then

\[ [H^+] = \frac{(24 \times 80)}{24} = 80 \text{ nEq/L} \quad \text{and} \quad \text{pH} = 7.10 \]

[H⁺] therefore increases by 40 nEq/L, and because HCO₃⁻ is produced in a 1:1 ratio with H⁺, [HCO₃⁻] also increases by 40 nEq/L. Thus, extracellular [HCO₃⁻] increases negligibly, from 24 mEq/L to 24.000040 mEq/L. Therefore, the bicarbonate buffer is not effective against increases in Paco₂, and changes in [HCO₃⁻] do not reflect the severity of a respiratory acidosis.

**Hemoglobin as a Buffer**

Hemoglobin is rich in histidine, which is an effective buffer from pH 5.7 to 7.7 (pKₐ 6.8). Hemoglobin is the most important noncarbonic buffer in intravascular fluid. Simplistically, hemoglobin may be thought of as existing in red blood cells in equilibrium as a weak acid (HHb) and a potassium salt (KHb). In contrast to the bicarbonate buffer, hemoglobin is capable of buffering both carbonic (CO₂) and noncarbonic (nonvolatile) acids:
\[ H^+ + KHb \leftrightarrow HHb + K^+ \text{ and} \]
\[ H_2CO_3 + KHb \leftrightarrow HHb + HCO_3^- \]

**RESPIRATORY COMPENSATION**
Changes in alveolar ventilation responsible for the respiratory compensation of PaCO₂ are mediated by chemoreceptors within the brainstem and the carotid and aortic bodies (see Chapter 23). These receptors respond to changes in cerebrospinal spinal fluid pH. Minute ventilation increases 1 to 4 L/min for every (acute) 1 mm Hg increase in PaCO₂. In fact, the lungs are responsible for eliminating the approximately 15 mEq of CO₂ produced every day as a byproduct of carbohydrate and fat metabolism. Respiratory compensatory responses are also important in defending against marked changes in pH during metabolic disturbances.

**Respiratory Compensation During Metabolic Acidosis**
Decreases in arterial blood pH stimulate medullary respiratory centers. The resulting increase in alveolar ventilation lowers PaCO₂ and tends to restore arterial pH toward normal. The respiratory response to lower the PaCO₂ occurs rapidly but may not reach a predictably steady state until 12 to 24 h; pH is never completely restored to normal. PaCO₂ normally decreases 1 to 1.5 mm Hg below 40 mm Hg for every 1 mEq/L decrease in plasma [HCO₃⁻].

**Respiratory Compensation During Metabolic Alkalosis**
Increases in arterial blood pH depress respiratory centers. The resulting alveolar hypoventilation tends to elevate PaCO₂ and restore arterial pH toward normal. The respiratory response to metabolic alkalosis is generally less predictable than the respiratory response to metabolic acidosis. Hypoxemia, as a result of progressive hypoventilation, eventually activates oxygen-sensitive chemoreceptors; the latter stimulates ventilation and limits the compensatory respiratory response. Consequently, PaCO₂ usually does not increase above 55 mm Hg in response to metabolic alkalosis. As a general rule, PaCO₂ can be
expected to increase 0.25 to 1 mm Hg for each 1 mEq/L increase in [HCO₃⁻].

**RENA L COMPENSATION**

The ability of the kidneys to control the amount of HCO₃⁻ reabsorbed from filtered tubular fluid, form new HCO₃⁻, and eliminate H⁺ in the form of titratable acids and ammonium ions (see Chapter 30) allows them to exert a major influence on pH during both metabolic and respiratory acid–base disturbances. The kidneys are responsible for eliminating the approximately 1 mEq/kg per day of sulfuric acid, phosphoric acid, uric acid, and incompletely oxidized organic acids that are normally produced by the metabolism of dietary and endogenous proteins, nucleoproteins, and organic phosphates (from phosphoproteins and phospholipids). Incomplete metabolisms of fatty acids and glucose produces keto acids and lactic acid. Endogenous bases are produced during the metabolism of some anionic amino acids (eg, glutamate and aspartate) and other organic compounds (eg, citrate, acetate, and lactate), but the quantity is insufficient to offset the endogenous acid production.

**Renal Compensation During Acidosis**

The renal response to acidemia is three-fold: (1) increased reabsorption of the filtered HCO₃⁻, (2) increased excretion of titratable acids, and (3) increased production of ammonia. Although these mechanisms are probably activated immediately, their effects are generally not appreciable for 12 to 24 h and may not be maximal for up to 5 days.

**A. Increased Reabsorption of HCO₃⁻**

Bicarbonate reabsorption is shown in Figure 50–4. CO₂ within renal tubular cells combines with water in the presence of carbonic anhydrase. The carbonic acid (H₂CO₃) formed rapidly dissociates into H⁺ and HCO₃⁻. Bicarbonate ion then enters the bloodstream while the H⁺ is secreted into the renal tubule, where it reacts with filtered HCO₃⁻ to form H₂CO₃. Carbonic anhydrase associated with the luminal brush border catalyzes the dissociation of H₂CO₃ into CO₂ and H₂O. The CO₂ thus formed can diffuse back into the renal tubular cell to replace the CO₂ originally consumed. The proximal tubules normally reabsorb 80% to 90% of the filtered bicarbonate load along with sodium, whereas the distal
tubules are responsible for the remaining 10% to 20%. Unlike the proximal H\(^+\) pump, the H\(^+\) pump in the distal tubule is not necessarily linked to sodium reabsorption and is capable of generating steep H\(^+\) gradients between tubular fluid and tubular cells. Urinary pH can decrease to as low as 4.4 (compared with a pH of 7.40 in plasma).

**FIGURE 50–4** Reclamation of filtered HCO\(_3^−\) by the proximal renal tubules.

**B. Increased Excretion of Titratable Acids**
After all of the HCO\(_3^−\) in tubular fluid is reclaimed, the H\(^+\) secreted into the tubular lumen can combine with HPO\(_4^{2−}\) to form H\(_2\)PO\(_4^−\) (**Figure 50–5**); the latter is not readily reabsorbed because of its charge and is therefore eliminated.
in urine. The net result is that $\text{H}^+$ is excreted from the body as $\text{H}_2\text{PO}_4^-$, and the $\text{HCO}_3^-$ that is generated in the process can enter the bloodstream. With a $\text{pK}$ of 6.8, the $\text{H}_2\text{PO}_4^-/\text{HPO}_4^{2-}$ pair is normally an ideal urinary buffer. When urinary pH approaches 4.4, however, all of the phosphate reaching the distal tubule is in the $\text{H}_2\text{PO}_4^-$ form; $\text{HPO}_4^{2-}$ ions are no longer available for eliminating $\text{H}^+$.

**FIGURE 50–5** Formation of a titratable acid in urine.

**C. Increased Formation of Ammonia**

After complete reabsorption of $\text{HCO}_3^-$ and consumption of the phosphate buffer, the $\text{NH}_3/\text{NH}_4^+$ pair becomes the most important urinary buffer (Figure 50–6). Deamination of glutamine within the mitochondria of proximal tubular cells is
the principal source of NH$_3$ production in the kidneys. Acidemia markedly increases renal NH$_3$ production. The ammonia formed is then able to passively cross the cell’s luminal membrane, enter the tubular fluid, and react with H$^+$ to form NH$_4^+$. Unlike NH$_3$, NH$_4^+$ does not readily penetrate the luminal membrane and is therefore trapped within the tubules. Thus, excretion of NH$_4^+$ in urine effectively eliminates H$^+$.

**FIGURE 50–6** Formation of ammonia in urine.

**Renal Compensation During Alkalosis**

The tremendous amount of HCO$_3^-$ normally filtered and subsequently
reabsorbed allows the kidneys to rapidly excrete large amounts of bicarbonate, if necessary (see Chapter 49). As a result, the kidneys are highly effective in protecting against metabolic alkalosis, which therefore generally occurs only in association with concomitant sodium deficiency or mineralocorticoid excess. Sodium depletion decreases extracellular fluid volume and enhances Na\(^+\) reabsorption in the proximal tubule. To maintain neutrality, the Na\(^+\) ion is brought across with a Cl\(^-\) ion. As Cl\(^-\) ions decrease in number (<10 mEq/L of urine), HCO\(_3^-\) must be reabsorbed. Increased H\(^+\) secretion in exchange for augmented Na\(^+\) reabsorption favors HCO\(_3^-\) formation with metabolic alkalosis. Similarly, increased mineralocorticoid activity augments aldosterone-mediated Na\(^+\) reabsorption in exchange for H\(^+\) secretion in the distal tubules. The resulting increase in HCO\(_3^-\) formation can initiate or propagate metabolic alkalosis. Metabolic alkalosis is commonly associated with increased mineralocorticoid activity, even in the absence of sodium and chloride depletion.

**Base Excess**

*Base excess* is defined as the amount of acid or base (expressed in mEq/L) that must be added for blood pH to return to 7.40 and Paco\(_2\) to return to 40 mm Hg at full O\(_2\) saturation and 37°C. Moreover, it adjusts for noncarbonic buffering in the blood. Simplistically, *base excess represents the metabolic component of an acid–base disturbance*. A positive value indicates metabolic alkalosis, whereas a negative value reveals metabolic acidosis. Base excess is usually derived from a nomogram and requires measurement of hemoglobin concentration.

**Acidosis**

**PHYSIOLOGICAL EFFECTS OF ACIDEMIA**

Biochemical reactions are very sensitive to changes in [H\(^+\)]. [H\(^+\)] is strictly regulated (36–43 nmol/L), as H\(^+\) ions have high charge densities and “large” electric fields that can affect the strength of hydrogen bonds that are present on most physiological molecules. The overall effects of acidemia represent the balance between the direct biochemical effects of H\(^+\) and the effects of acidemia-induced sympathoadrenal activation. With severe acidosis (pH <7.20), direct myocardial and smooth muscle depression reduces cardiac contractility and peripheral vascular resistance, resulting in progressive hypotension. Severe
acidosis can lead to tissue hypoxia, despite a rightward shift in hemoglobin affinity for oxygen. Both cardiac and vascular smooth muscle become less responsive to endogenous and exogenous catecholamines, and the ventricular fibrillation threshold is decreased. The movement of K\(^+\) out of cells in exchange for increased extracellular H\(^+\) results in hyperkalemia that is also potentially lethal. *Plasma [K+] increases approximately 0.6 mEq/L for each 0.10 decrease in pH.*

Central nervous system depression is more prominent with respiratory acidosis than with metabolic acidosis. This effect is often termed CO\(_2\) narcosis. Unlike CO\(_2\), H\(^+\) ions do not readily penetrate the blood–brain barrier.

**RESPIRATORY ACIDOSIS**

Respiratory acidosis is defined as a primary increase in PaCO\(_2\). This increase drives the reaction

\[
\text{H}_2\text{O} + \text{CO}_2 \leftrightarrow \text{H}_2\text{CO}_3 \leftrightarrow \text{H}^+ + \text{HCO}_3^- \\
\]

to the right, leading to an increase in [H\(^+\)] and a decrease in arterial pH. For the reasons described above, [HCO\(_3^-\)] is minimally affected.

PaCO\(_2\) represents the balance between CO\(_2\) production and CO\(_2\) elimination:

\[
\text{PaCO}_2 = \frac{\text{CO}_2 \text{ production}}{\text{Alveolar ventilation}}
\]

CO\(_2\) is a byproduct of fat and carbohydrate metabolism—and muscle activity, body temperature, and thyroid hormone activity can all have major influences on CO\(_2\) production. Because CO\(_2\) production does not appreciably vary under most circumstances, respiratory acidosis is usually the result of alveolar hypoventilation (*Table 50–3*). In patients with a limited capacity to increase alveolar ventilation, however, increased CO\(_2\) production can precipitate respiratory acidosis.

**TABLE 50–3  Differential diagnosis of respiratory acidosis.**
Alveolar hypoventilation
- Central nervous system depression
  - Drug-induced
  - Sleep disorders
  - Obesity hypoventilation (Pickwickian) syndrome
  - Cerebral ischemia
  - Cerebral trauma
- Neuromuscular disorders
  - Myopathies
  - Neuropathies
- Chest wall abnormalities
  - Flail chest
  - Kyphoscoliosis
- Pleural abnormalities
  - Pneumothorax
  - Pleural effusion
- Airway obstruction
  - Upper airway
    - Foreign body
    - Tumor
    - Laryngospasm
    - Sleep disorders
  - Lower airway
    - Severe asthma
    - Chronic obstructive pulmonary disease
    - Tumor
- Parenchymal lung disease
  - Pulmonary edema
    - Cardiogenic
    - Noncardiogenic
  - Pulmonary emboli
  - Pneumonia
  - Aspiration
  - Interstitial lung disease
  - Ventilator malfunction

Increased CO₂ production
- Large caloric loads
- Malignant hyperthermia
- Intensive shivering
- Prolonged seizure activity
- Thyroid storm
- Extensive thermal injury (burns)
**Acute Respiratory Acidosis**

The compensatory response to acute (6–12 h) elevations in $\text{Paco}_2$ is limited. Buffering is primarily provided by hemoglobin and the exchange of extracellular $\text{H}^+$ for $\text{Na}^+$ and $\text{K}^+$ from bone and the intracellular fluid compartment (see earlier discussion). The renal response to retain more bicarbonate is acutely very limited. As a result, plasma $[\text{HCO}_3^-]$ increases only about 1 mEq/L for each 10 mm Hg increase in $\text{Paco}_2$ above 40 mm Hg.

**Chronic Respiratory Acidosis**

Renal compensation in respiratory acidosis is appreciable only after 12 to 24 h and may not be maximal until 3 to 5 days have elapsed. During chronic respiratory acidosis, plasma $[\text{HCO}_3^-]$ increases approximately 4 mEq/L for each 10 mm Hg increase in $\text{Paco}_2$ above 40 mm Hg.

**Treatment of Respiratory Acidosis**

Respiratory acidosis is treated by reversing the imbalance between $\text{CO}_2$ production and alveolar ventilation. In most instances, this is accomplished by increasing alveolar ventilation. Measures aimed at reducing $\text{CO}_2$ production are useful only in specific instances (eg, dantrolene for malignant hyperthermia, muscle paralysis for status epilepticus, antithyroid medication for thyroid storm, or reduced caloric intake in patients receiving excessive enteral or parenteral nutrition). Potential temporizing measures aimed at improving alveolar ventilation (in addition to controlled mechanical ventilation) include bronchodilation, reversal of narcosis, or improving lung compliance via diuresis. Severe acidosis (pH <7.20), $\text{CO}_2$ narcosis, and respiratory muscle fatigue are indications for mechanical ventilation. An increased inspired oxygen concentration is also usually necessary, as coexistent hypoxemia is common. Intravenous NaHCO$_3$ is rarely necessary, unless pH is less than 7.10 and HCO$_3^-$ is less than 15 mEq/L. Sodium bicarbonate therapy will transiently increase $\text{Paco}_2$:

$$\text{H}^+ + \text{HCO}_3^- \rightarrow \text{CO}_2 + \text{H}_2\text{O}$$
Buffers that do not produce CO₂, such as Carbicarb or tromethamine (THAM), are theoretically attractive alternatives; however, there is almost no evidence showing that they have greater efficacy than bicarbonate. Carbicarb™ is a mixture of 0.3 M sodium bicarbonate and 0.3 M sodium carbonate; buffering by this mixture mainly produces sodium bicarbonate instead of CO₂. Tromethamine has the added advantage of lacking sodium and may be a more effective intracellular buffer.

Patients with chronic respiratory acidosis require special consideration. When such patients develop acute ventilatory failure, the goal of therapy should be to return PaCO₂ to the patient’s “normal” baseline. Normalizing the patient’s PaCO₂ to 40 mm Hg will produces the equivalent of a respiratory alkalosis (see later discussion). Oxygen therapy must also be carefully controlled, because the respiratory drive in these patients may be dependent on hypoxemia, not PaCO₂. “Normalization” of PaCO₂ or relative hyperoxia can precipitate severe hypoventilation.

**METABOLIC ACIDOSIS**

Metabolic acidosis is defined as a primary decrease in [HCO₃⁻]. Pathological processes can initiate metabolic acidosis by one of three mechanisms: (1) consumption of HCO₃⁻ by a strong nonvolatile acid, (2) renal or gastrointestinal wasting of bicarbonate, or (3) rapid dilution of the extracellular fluid compartment with a bicarbonate-free fluid.

A fall in plasma [HCO₃⁻] without a proportionate reduction in PaCO₂ decreases arterial pH. The pulmonary compensatory response in a simple metabolic acidosis (see preceding discussion) characteristically does not reduce PaCO₂ to a level that completely normalizes pH but nevertheless can produce marked hyperventilation (*Kussmaul’s respiration*).

Table 50–4 lists disorders that can cause metabolic acidosis. Note that differential diagnosis of metabolic acidosis may be facilitated by calculation of the *anion gap*.

**TABLE 50–4** Differential diagnosis of metabolic acidosis.
Increased anion gap

Increased production of endogenous nonvolatile acids
  Renal failure
  Ketoacidosis
  Diabetic
  Starvation
  Lactic acidosis
  Mixed
    Nonketotic hyperosmolar coma
    Alcoholic
  Inborn errors of metabolism
Ingestion of toxin
  Salicylate
  Methanol
  Ethylene glycol
  Paraldehyde
  Toluene
  Sulfur
  Rhabdomyolysis

Normal anion gap (hyperchloremic)

Increased gastrointestinal losses of HCO$_3^-$
  Diarrhea
  Anion exchange resins (cholestyramine)
  Ingestion of CaCl$_2$, MgCl$_2$
  Fistulas (pancreatic, biliary, or small bowel)
  Ureterosigmoidostomy or obstructed ileal loop
Increased renal losses of HCO$_3^-$
  Renal tubular acidosis
  Carbonic anhydrase inhibitors
  Hypoaldosteronism
Dilutional
  Large amount of bicarbonate-free fluids (eg, 0.9% NaCl)
Total parenteral nutrition (Cl$^-$ salts of amino acids)
Increased intake of chloride-containing acids
  Ammonium chloride
  Lysine hydrochloride
  Arginine hydrochloride
The Anion Gap

The anion gap in plasma is most commonly defined as the difference between the major measured cations and the major measured anions:

$$\text{Anion gap} = \text{Major plasma cations} - \text{Major plasma anions}$$

Or

$$\text{Anion gap} = ([\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-]))$$

Some practitioners also include plasma $K^+$ in the calculation. Using normal values,

$$\text{Anion gap} = 140 - (104 + 24) = 12 \text{ mEq/L}$$

(Normal range = 7 – 14 mEq/L)

In reality, an anion gap cannot exist because electroneutrality must be maintained in the body; the sum of all anions must equal the sum of all cations. Therefore,

$$\text{Anion gap} = \text{Unmeasured anions} - \text{Unmeasured cations}$$

“Unmeasured cations” include $K^+$, $Ca^{2+}$, and $Mg^{2+}$, whereas “unmeasured anions” include all organic anions (including plasma proteins), phosphates, and sulfates. Plasma albumin normally accounts for the largest fraction of the anion gap (approximately 11 mEq/L). The anion gap decreases by 2.5 mEq/L for every 1 g/dL reduction in plasma albumin concentration. Any process that increases “unmeasured anions” or decreases “unmeasured cations” will increase the anion gap. Conversely, any process that decreases “unmeasured anions” or increases “unmeasured cations” will decrease the anion gap.

Mild elevations of plasma anion gap up to 20 mEq/L may not be helpful diagnostically during acidosis, but values greater than 30 mEq/L usually indicate the presence of a high anion gap acidosis. Metabolic alkalosis can also produce a high anion gap because of extracellular volume depletion, an increased charge on albumin, and a compensatory increase in lactate production. A low plasma anion gap may be encountered with hypoalbuminemia, bromide or lithium
intoxication, and multiple myeloma.

**High Anion Gap Metabolic Acidosis**

Metabolic acidosis with an increased anion gap is characterized by an increase in relatively strong nonvolatile acids. These acids dissociate into $H^+$ and their respective anions; the $H^+$ consumes $HCO_3^-$ to produce $CO_2$, whereas their anions (conjugate bases) accumulate and take the place of $HCO_3^-$ in extracellular fluid (hence the anion gap increases). Nonvolatile acids can be endogenously produced or ingested.

**A. Failure to Excrete Endogenous Nonvolatile Acids**

Endogenously produced organic acids are normally eliminated by the kidneys in urine (as described earlier). Glomerular filtration rates below 20 mL/min (kidney injury or failure) typically result in progressive metabolic acidosis from the accumulation of these acids.

**B. Increased Endogenous Nonvolatile Acid Production**

Severe tissue hypoxia following hypoxemia, hypoperfusion (ischemia), or an inability to utilize oxygen (cyanide poisoning) can result in *lactic acidosis*. Lactic acid is the end product of the anaerobic metabolism of glucose (glycolysis) and can rapidly accumulate under these conditions. Decreased utilization of lactate by the liver, and, to a lesser extent by the kidneys, is less commonly responsible for lactic acidosis; causes include hypoperfusion, alcoholism, and liver disease. Lactate levels can be readily measured and are normally 0.3 to 1.3 mEq/L. Acidosis resulting from D-lactic acid, which is not recognized by $\alpha$-lactate dehydrogenase (and not measured by routine assays), may be encountered in patients with short bowel syndromes; D-lactic acid is formed by colonic bacteria from dietary glucose and starch and is absorbed systemically.

An absolute or relative lack of insulin can result in hyperglycemia and progressive ketoacidosis from the accumulation of $\beta$-hydroxybutyric and acetoacetic acids (*diabetic ketoacidosis*). Ketoacidosis may also be seen following starvation or alcoholic binges. The pathophysiology of the acidosis often associated with severe alcoholic intoxication and nonketotic hyperosmolar coma is complex and may represent a buildup of lactic, keto, or other unknown acids.
Some inborn errors of metabolism, such as maple syrup urine disease, methylmalonic aciduria, propionic acidemia, and isovaleric acidemia, produce a high anion gap metabolic acidosis as a result of accumulation of abnormal amino acids.

C. Ingestion of Exogenous Nonvolatile Acids

Ingestion of large amounts of salicylates may result in metabolic acidosis. Salicylic acid and other acid intermediates rapidly accumulate and produce a high anion gap acidosis. Because salicylates also produce direct respiratory stimulation, most adults develop mixed metabolic acidosis with superimposed respiratory alkalosis. Ingestion of methanol (methyl alcohol) frequently produces acidosis and retinitis. Symptoms are typically delayed until the slow oxidation of methanol by alcohol dehydrogenase produces formic acid, which is highly toxic to the retina. The high anion gap represents the accumulation of many organic acids, including acetic acid. The toxicity of ethylene glycol is also the result of the action of alcohol dehydrogenase to produce glycolic acid. Glycolic acid, the principal cause of the acidosis, is further metabolized to form oxalic acid, which may be deposited in the renal tubules and produce acute kidney injury.

Normal Anion Gap Metabolic Acidosis

Metabolic acidosis associated with a normal anion gap is typically characterized by hyperchloremia. Plasma [Cl\(^-\)] increases to take the place of the HCO\(_3^-\) ions that are lost. Hyperchloremic metabolic acidosis most commonly results from abnormal gastrointestinal or renal losses of HCO\(_3^-\), or from excessive intravenous administration of 0.9% NaCl solution.

Calculation of the anion gap in urine can be helpful in diagnosing a normal anion gap acidosis.

\[
\text{Urine anion gap} = ([\text{Na}^+] + [\text{K}^+]) - [\text{Cl}^-]
\]

The urine anion gap is normally positive or close to zero. The principal unmeasured urinary cation is normally NH\(_4^+\), which should increase (along with Cl\(^-\)) during a metabolic acidosis; the latter results in a negative urinary anion gap. Impairment of H\(^+\) or NH\(_4^+\) secretion, as occurs in kidney failure or renal tubular acidosis (discussed below), results in a positive urine anion gap despite systemic acidosis.
A. Increased Gastrointestinal Loss of HCO₃⁻

Diarrhea is a common cause of hyperchloremic metabolic acidosis. Diarrheal fluid contains 20 to 50 mEq/L of HCO₃⁻. Small bowel, biliary, and pancreatic fluids are all rich in HCO₃⁻. Loss of large volumes of these fluids can lead to hyperchloremic metabolic acidosis. Patients with ureterosigmoidostomies and those with ileal loop neobladders that are too long or that become partially obstructed frequently develop hyperchloremic metabolic acidosis. The ingestion of chloride-containing anion-exchange resins (cholestyramine) or large amounts of calcium or magnesium chloride can result in increased absorption of chloride and loss of bicarbonate ions. The nonabsorbable resins bind bicarbonate ions, whereas calcium and magnesium combine with bicarbonate to form insoluble salts within the intestines.

B. Increased Renal Loss of HCO₃⁻

Renal wasting of HCO₃⁻ can occur as a result of failure to reabsorb filtered HCO₃⁻ or to secrete adequate amounts of H⁺ in the form of titratable acid or ammonium ion. These defects are encountered in patients taking carbonic anhydrase inhibitors, such as acetazolamide, and in those with renal tubular acidosis.

Renal tubular acidosis (RTA) is a disease of systemic acidosis resulting from inadequate renal compensation for systemic acid production. The kidneys are unable to adequately acidify the urine, and urinary pH is inappropriately high relative to the systemic acidemia. Kidney function is otherwise normal. RTA involves a defect in distal renal tubular H⁺ secretion (type 1 RTA), proximal renal tubular reabsorption of filtered HCO₃⁻ (type 2 RTA), or both (type 3 RTA). Type 4 RTA is the result of hypoaldosteronism or renal insensitivity to aldosterone.

C. Other Causes of Hyperchloremic Acidosis

Dilutional hyperchloremic acidosis may occur when extracellular volume is rapidly expanded with a bicarbonate-free, chloride-rich fluid such as normal saline. Plasma [HCO₃⁻] decreases in proportion to the amount of fluid infused as extracellular HCO₃⁻ is diluted, and this fall in [HCO₃⁻] is compensated by a rise in [Cl⁻]. This is a reason to prefer balanced salt solutions over 0.9% saline for fluid resuscitation. Amino acid infusions (parenteral hyperalimentation) contain
organic cations in excess of organic anions and can produce hyperchloremic metabolic acidosis because chloride is commonly used as the anion for the cationic amino acids. Lastly, the administration of excessive quantities of chloride-containing acids, such as ammonium chloride or arginine hydrochloride (usually given to treat a metabolic alkalosis), can cause hyperchloremic metabolic acidosis.

**Treatment of Metabolic Acidosis**

Several general measures can be undertaken to control the severity of acidemia until the underlying processes are corrected. Any respiratory component of the acidemia should be corrected. Respiration should be controlled, if necessary; a $\text{Paco}_2$ in the low 30s may be desirable to partially return pH to normal. If arterial blood pH remains below 7.20, alkali therapy, usually in the form of a 7.5% $\text{NaHCO}_3$ solution may be necessary. $\text{Paco}_2$ may transiently rise as $\text{HCO}_3^-$ is consumed by acids, emphasizing the need to control ventilation in severe acidemia. The amount of $\text{NaHCO}_3$ given is decided empirically as a fixed dose (1 mEq/kg) or is derived from the base excess and the calculated bicarbonate space (discussed next). In either case, serial blood gas measurements are mandatory to avoid complications (eg, overshoot alkalosis and sodium overload) and to guide further therapy. Raising arterial pH above 7.25 is usually sufficient to overcome the adverse physiological effects of the acidemia. Profound or refractory acidemia may require acute hemodialysis with a bicarbonate dialysate.

The routine use of large amounts of $\text{NaHCO}_3$ in treating cardiac arrest and low flow states is not recommended. Paradoxical intracellular acidosis may occur, particularly when CO$_2$ elimination is impaired, because the CO$_2$ formed readily enters cells, but the bicarbonate ion does not. Alternate buffers that do not produce CO$_2$, such as Carbicarb or tromethamine (THAM), may be theoretically preferable, but are unproven clinically.

Specific therapy for diabetic ketoacidosis includes replacement of the existing fluid deficit resulting from a hyperglycemic osmotic diuresis first, as well as insulin, potassium, phosphate, and magnesium. The treatment of lactic acidosis should be directed first at restoring adequate oxygenation and tissue perfusion. Alkalization of the urine with $\text{NaHCO}_3$ to a pH greater than 7.0 increases elimination of salicylate following salicylate poisoning. Treatment options for ethanol or ethylene glycol intoxication include ethanol infusion or fomepizole administration, which competitively inhibit alcohol dehydrogenase and
hemodialysis or hemofiltration.

**Bicarbonate Space**

The *bicarbonate space* is defined as the volume to which $\text{HCO}_3^-$ will distribute when administered intravenously. Although this theoretically should equal the extracellular fluid space (approximately 25% of body weight), in reality, it ranges anywhere between 25% and 60% of body weight, depending on the severity and duration of the acidosis. This variation is at least partly related to the amount of intracellular and bone buffering that has taken place.

**Example:** Calculate the amount of NaHCO$_3$ necessary to correct a base deficit (BD) of –10 mEq/L for a 70-kg man with an estimated HCO$_3^-$ space of 30%:

\[
\text{NaHCO}_3 = \text{BD} \times 30\% \times \text{body weight in L}
\]

\[
\text{NaHCO}_3 = –10 \text{ mEq/L} \times 30\% \times 70 \text{ L} = 210 \text{ mEq}
\]

In practice, only 50% of the calculated dose (e.g., 105 mEq) is usually given, after which another blood gas is measured.

**ANESTHETIC CONSIDERATIONS IN PATIENTS WITH ACIDOSIS**

Acidemia can potentiate the depressant effects of most sedatives and anesthetic agents on the central nervous and circulatory systems. Because most opioids are weak bases, acidosis can increase the fraction of the drug in the nonionized form and facilitate opioid penetration into the brain, potentiating its sedative effect. The circulatory depressant effects of both volatile and intravenous anesthetics can also be exaggerated. Moreover, any agent that rapidly decreases sympathetic tone can potentially allow unopposed circulatory depression in the setting of acidosis. Halothane is more arrhythmogenic in the presence of acidosis. Succinylcholine should generally be avoided in acidotic patients with hyperkalemia to prevent further increases in plasma $[\text{K}^+]$.

**Alkalosis**
PHYSIOLOGICAL EFFECTS OF ALKALOSIS

Alkalosis increases the affinity of hemoglobin for oxygen and shifts the oxygen dissociation curve to the left, making it more difficult for hemoglobin to give up oxygen to tissues. Movement of H\(^+\) out of cells in exchange for the movement of extracellular K\(^+\) into cells can produce hypokalemia. Alkalosis increases the number of anionic binding sites for Ca\(^{2+}\) on plasma proteins and can therefore decrease ionized plasma [Ca\(^{2+}\)], leading to circulatory depression and neuromuscular irritability. Respiratory alkalosis reduces cerebral blood flow. In the lungs, respiratory alkalosis increases bronchial smooth muscle tone (bronchoconstriction), but decreases pulmonary vascular resistance.

RESPIRATORY ALKALOSIS

Respiratory alkalosis is defined as a primary decrease in PaCO\(_2\). The mechanism is usually an inappropriate increase in alveolar ventilation relative to CO\(_2\) production. Table 50–5 lists the most common causes of respiratory alkalosis. The distinction between acute and chronic respiratory alkalosis is not always made, because the compensatory response to chronic respiratory alkalosis is quite variable: Plasma [HCO\(_3^−\)] usually decreases 2 to 5 mEq/L for each 10 mm Hg decrease in PaCO\(_2\) below 40 mm Hg.

**TABLE 50–5  Differential diagnosis of respiratory alkalosis.**
Treatment of Respiratory Alkalosis

Correction of the underlying process is the only treatment for respiratory alkalosis. For severe alkalemia (arterial pH >7.60), intravenous hydrochloric acid, arginine chloride, or ammonium chloride may be indicated (see later discussion).

**METABOLIC ALKALOSIS**

*Metabolic alkalosis* is defined as a primary increase in plasma $[\text{HCO}_3^-]$. Most cases of metabolic alkalosis can be divided into (1) those associated with NaCl
deficiency and extracellular fluid depletion, often described as chloride-sensitive, and (2) those associated with enhanced mineralocorticoid activity, commonly referred to as chloride-resistant (Table 50–6).

**Chloride-Sensitive Metabolic Alkalosis**
Depletion of extracellular fluid causes the renal tubules to avidly reabsorb Na⁺. Because not enough Cl⁻ is available to accompany all of the Na⁺ ions reabsorbed, increased H⁺ secretion must take place to maintain electroneutrality. In effect, HCO₃⁻ ions that might otherwise have been excreted are reabsorbed, resulting in metabolic alkalosis. Physiologically, maintenance of extracellular fluid volume is therefore given priority over acid–base balance. Because secretion of K⁺ ion can also maintain electroneutrality, potassium secretion is also enhanced. Moreover, hypokalemia augments H⁺ secretion (and HCO₃⁻ reabsorption) and will also propagate metabolic alkalosis. Indeed, severe hypokalemia alone can cause alkalosis. Urinary chloride concentrations during a chloride-sensitive metabolic alkalosis are characteristically low (<10 mEq/L).

**Diuretic therapy is the most common cause of chloride-sensitive metabolic alkalosis.** Diuretics, such as furosemide, ethacrynic acid, and thiazides, increase Na⁺, Cl⁻, and K⁺ excretion, resulting in NaCl depletion, hypokalemia, and usually mild metabolic alkalosis. Loss of gastric fluid is also a common cause of chloride-sensitive metabolic alkalosis. Vomiting or continuous loss of gastric fluid by gastric drainage (nasogastric suctioning) can result in marked metabolic alkalosis, extracellular volume depletion, and hypokalemia. Gastric secretions contain 25 to 100 mEq/L of H⁺, 40 to 160 mEq/L of Na⁺, about 15 mEq/L of K⁺, and about 200 mEq/L of Cl⁻. Rapid normalization of PaCO₂ after plasma [HCO₃⁻] has risen in chronic respiratory acidosis results in metabolic alkalosis (posthypercapnic alkalosis; see previous section). Infants being fed formulas containing Na⁺ without chloride readily develop metabolic alkalosis because of the increased H⁺ (or K⁺) secretion that must accompany sodium absorption.

**Chloride-Resistant Metabolic Alkalosis**

Increased mineralocorticoid activity commonly results in metabolic alkalosis, even when it is not associated with extracellular volume depletion. Inappropriate increases in mineralocorticoid activity cause sodium retention and expansion of extracellular fluid volume. Increased H⁺ and K⁺ secretion takes place to balance enhanced mineralocorticoid-mediated sodium reabsorption, resulting in metabolic alkalosis and hypokalemia. Urinary chloride concentrations are typically greater than 20 mEq/L in such cases.
Other Causes of Metabolic Alkalosis

Metabolic alkalosis is rarely encountered in patients given even large doses of NaHCO$_3$ unless renal excretion of HCO$_3^-$ is impaired. The administration of large amounts of blood products and some plasma protein–containing colloid solutions frequently results in metabolic alkalosis because citrate, lactate, and acetate contained in these fluids are converted by the liver into HCO$_3^-$. Patients receiving high doses of sodium penicillin (particularly carbenicillin) can develop metabolic alkalosis. Because penicillins act as nonabsorbable anions in the renal tubules, increased H$^+$ (or K$^+$) secretion must accompany sodium absorption. For reasons that are not clear, hypercalcemia that results from nonparathyroid causes (milk-alkali syndrome and bone metastases) is also often associated with metabolic alkalosis.

Treatment of Metabolic Alkalosis

As with other acid–base disorders, correction of metabolic alkalosis is never complete until the underlying disorder is corrected. When ventilation is controlled, any respiratory component contributing to alkalemia should be corrected by decreasing minute ventilation to normalize PaCO$_2$. The treatment of choice for chloride-sensitive metabolic alkalosis is administration of intravenous saline (NaCl) and potassium (KCl). H$_2$-blocker therapy is useful when excessive loss of gastric fluid is a factor. Acetazolamide may also be useful in edematous patients. Alkalosis associated with primary increases in mineralocorticoid activity readily responds to aldosterone antagonists (spironolactone). When arterial blood pH is greater than 7.60, treatment with intravenous hydrochloric acid (0.1 mol/L), ammonium chloride (0.1 mol/L), arginine hydrochloride, or hemodialysis should be considered.

ANESTHETIC CONSIDERATIONS IN PATIENTS WITH ALKALEMIA

Cerebral ischemia can occur from marked reduction in cerebral blood flow during respiratory alkalosis, particularly during hypotension. The combination of alkalemia and hypokalemia can precipitate severe atrial and ventricular arrhythmias. Reports of effects of alkalemia on neuromuscular blockers are inconsistent.
**DIAGNOSIS OF ACID–BASE DISORDERS**

Interpretation of acid–base status from analysis of blood gases requires a systematic approach. A recommended approach follows (see Figure 50–3):

1. Examine arterial pH: Is acidemia or alkalemia present?
2. Examine $\text{Paco}_2$: Is the change in $\text{Paco}_2$ consistent with a respiratory component?
3. If the change in $\text{Paco}_2$ does not explain the change in arterial pH, does the change in $[\text{HCO}_3^-]$ indicate a metabolic component?
4. Make a tentative diagnosis (see Table 50–1).
5. Compare the change in $[\text{HCO}_3^-]$ with the change in $\text{Paco}_2$. Does a compensatory response exist (Table 50–7)? Because arterial pH is related to the ratio of $\text{Paco}_2$ to $[\text{HCO}_3^-]$, both respiratory and renal compensatory mechanisms are always such that $\text{Paco}_2$ and $[\text{HCO}_3^-]$ change in the same direction. A change in opposite directions implies a mixed acid–base disorder.

**TABLE 50–7** Normal compensatory responses in acid–base disturbances.
6. If the compensatory response is more or less than expected, by definition, a mixed acid–base disorder exists.

7. Calculate the plasma anion gap in the case of metabolic acidosis.

8. Measure urinary chloride concentration in the case of metabolic alkalosis.

An alternative approach that is rapid, though less precise, is to correlate changes in pH with changes in CO\textsubscript{2} or HCO\textsubscript{3}\textsuperscript{-}. For a respiratory disturbance, every 10 mm Hg change in CO\textsubscript{2} should change arterial pH by approximately 0.08 U in the opposite direction. During metabolic disturbances, every 6 mEq change in HCO\textsubscript{3}\textsuperscript{-} also changes arterial pH by 0.1 in the same direction. If the change in pH is greater or less than predicated, a mixed acid–base disorder is likely to be present.

### MEASUREMENT OF BLOOD GAS TENSIONS & pH

Values obtained by routine blood gas measurement include oxygen and carbon dioxide tensions (P\textsubscript{O\textsubscript{2}} and P\textsubscript{CO\textsubscript{2}}), pH, [HCO\textsubscript{3}\textsuperscript{-}], base excess, hemoglobin, and the
percentage oxygen saturation of hemoglobin. As a rule, only Po₂, Pco₂, and pH are measured. Hemoglobin and percentage oxygen saturation are measured with a cooximeter. [HCO₃⁻] is derived using the Henderson–Hasselbalch equation and base excess from the Siggaard–Andersen nomogram.

**Sample Source & Collection**

Arterial blood samples are most commonly utilized clinically, though capillary or venous blood can be used if the limitations of such samples are recognized. Oxygen tension in venous blood (normally 40 mm Hg) reflects tissue extraction, not pulmonary function. Venous Pco₂ is usually 4 to 6 mm Hg higher than Paco₂. Consequently, venous blood pH is usually 0.05 U lower than arterial blood pH. Despite these limitations, venous blood is often useful in determining acid–base status. Capillary blood represents a mixture of arterial and venous blood, and the values obtained reflect this fact. Samples are usually collected in heparin-coated syringes and should be analyzed as soon as possible. Air bubbles should be eliminated, and the sample should be capped and placed on ice to prevent significant uptake of gas from blood cells or loss of gases to the atmosphere. Although heparin is highly acidic, excessive heparin in the sample syringe usually lowers pH only minimally, but decreases Pco₂ in direct proportion to percentage dilution and has a variable effect on Po₂.

**Temperature Correction**

Changes in temperature affect Pco₂, Po₂, and pH. Decreases in temperature lower the partial pressure of a gas in solution—even though the total gas content does not change—because gas solubility is inversely proportionate to temperature. Both Pco₂ and Po₂ therefore decrease during hypothermia, but pH increases because temperature does not appreciably alter [HCO₃⁻] and the dissociation of water decreases (decreasing H⁺ and increasing pH). Because blood gas tensions and pH are always measured at 37°C, controversy exists over whether to correct the measured values to the patient’s actual temperature. “Normal” values at temperatures other than 37°C are not known. Many clinicians use the measurements at 37°C directly (α-stat), regardless of the patient’s actual temperature (see Chapter 22).
A Complex Acid–Base Disturbance

A 1-month-old male infant with an anorectal malformation undergoes anoplasty. Postoperatively, he is found to be in congestive heart failure resulting from coarctation of the aorta. He is noted to have tachypnea, decreased urinary output, poor peripheral perfusion, hepatomegaly, and cardiomegaly. Following tracheal intubation, the infant is placed on a ventilator (pressure support ventilation, fraction of inspired oxygen \([\text{Fio}_2] = 1.0\)). Initial arterial blood gas, hemoglobin, and electrolyte measurements are as follows:

- \(\text{Paco}_2 = 11\) mm
- \(\text{pH} = 7.47\)
- \(\text{Pao}_2 = 209\) mm Hg

Calculated \([\text{HCO}_3^-] = 7.7\) mEq/L

Base deficit (BD) = \(-14.6\) mEq/L

Hemoglobin (Hb) = 9.5 g/Dl

- \([\text{Na}^+] = 135\) mEq/L
- \([\text{Cl}^-] = 95\) mEq/L
- \([\text{K}^+] = 5.5\) mEq/L
- \([\text{Total CO}_2] = 8\) mEq/L

Note that the \([\text{total CO}_2]\) normally measured with electrolytes includes both plasma \([\text{HCO}_3^-]\) and dissolved \(\text{CO}_2\) in plasma.

**What is the acid–base disturbance?**

Using the approach described earlier, the patient clearly has an alkalosis (pH > 7.45), which is at least partly respiratory in origin (\(\text{Paco}_2 < 40\) mm Hg). Because \(\text{Paco}_2\) has decreased by nearly 30 mm Hg, we would expect \([\text{HCO}_3^-]\) to be 18 mEq/L:

\[
(40 - 10) \times \frac{2\text{mEq/L}}{10} = 6\text{mEq/L below 24 mEq/L}
\]

In fact, the patient’s \([\text{HCO}_3^-]\) is nearly 10 mEq/L less than that! The
patient therefore also has a mixed acid–base disturbance: primary respiratory alkalosis and primary metabolic acidosis. Note that the difference between the patient’s [HCO₃⁻] and the [HCO₃⁻] expected for a pure respiratory alkalosis roughly corresponds to the base excess.

**What are likely causes of these disturbances?**

The respiratory alkalosis is probably the result of congestive heart failure, whereas the metabolic acidosis results from lactic acidosis secondary to poor perfusion. The latter is suggested by the calculated plasma anion gap:

\[
\text{Anion gap} = 135 - (95 + 8) = 32 \text{ mEq/L}
\]

The lactate level was in fact measured and found to be elevated at 14.4 mEq/L. It is probable that fluid overload precipitated the congestive heart failure.

**What treatment is indicated?**

Treatment should be directed at the primary process (ie, the congestive heart failure). The patient was treated with diuresis and inotropes.

Following diuresis, the patient’s tachypnea has improved, but perfusion still seems to be poor. Repeat laboratory measurements are as follows (Fio₂ = 0.5):

- \( \text{Paco}_2 = 23 \text{ mm Hg} \)
- \( \text{pH} = 7.52 \)
- \( \text{Pao}_2 = 136 \text{ mm Hg} \)
- Calculated \( [\text{HCO}_3^-] = 18 \text{ mEq/L} \)
- BD = -3.0 mEq/L
- Hb = 10.3 g/dL
- \( [\text{Na}^+] = 137 \text{ mEq/L} \)
- \( [\text{Cl}^-] = 92 \text{ mEq/L} \)
- \( [\text{K}^+] = 3.9 \text{ mEq/L} \)
- \( [\text{Total CO}_2] = 18.5 \text{ mEq/L} \)

**What is the acid–base disturbance?**

Respiratory alkalosis is still present, whereas the BD has improved. Note
that the hemoglobin concentration has increased slightly, but [K+] has
decreased as a result of the diuresis. With the new PaCO₂, the expected
[HCO₃⁻] should be 20.6 mEq/L:

\[
(40 - 10) \times \frac{2 \text{mEq/L}}{10} = 3.4 \text{ mEq/L below 24 mEq/L}
\]

Therefore, the patient still has metabolic acidosis because the [HCO₃⁻] is
2 mEq/L less. Note again that this difference is close to the given BD and
that the anion gap is still high:

\[
\text{Anion gap} = 137 - (92 + 18) = 27
\]

The repeat lactate measurement is now 13.2 mEq/L.
The high anion gap and lactate level explain why the patient is still not
doing well and indicate that a new process is masking the severity of the
metabolic acidosis (which is essentially unchanged).

Given the clinical course, it is likely that the patient now has a triple
acid–base disorder: respiratory alkalosis, metabolic acidosis, and now
metabolic alkalosis. The latter probably resulted from hypovolemia
secondary to excessive diuresis (chloride-sensitive metabolic alkalosis).
Note also that the metabolic alkalosis is nearly equal in magnitude to the
metabolic acidosis.

The patient was subsequently given packed red blood cells in saline, and
within 24 h all three disorders began to improve:

- PaCO₂ = 35 mm Hg
- pH = 7.51
- PaO₂ = 124 mm Hg
- Calculated [HCO₃⁻] = 26.8 mEq/L
- Base excess = +5.0 mEq/L
- Hb = 15 g/dL
- [Na⁺] = 136 mEq/L
- [Cl⁻] = 91 mEq/L
- [K⁺] = 3.2 mEq/L
- [Total CO₂] = 27 mEq/L
- Lactate = 2.7 mEq/L
Outcome

The respiratory alkalosis and the metabolic acidosis have now resolved, and the metabolic alkalosis is now most prominent.

Intravenous KCl replacement and a small amount of saline were judiciously given, followed by complete resolution of metabolic alkalosis. The patient subsequently underwent surgical correction of the coarctation.

SUGGESTED READINGS

Yessayan L, Yee J, Finak S, et al. Continuous renal replacement therapy for the
management of acid-base and electrolyte imbalances in acute kidney injury. 
Although the intravascular half-life of a crystalloid solution is 20 to 30 min, most colloid solutions have intravascular half-lives between 3 and 6 h.

Patients with a normal hematocrit should generally be transfused only after losses greater than 10% to 20% of their blood volume. The timing of transfusion initiation is based on the patient’s surgical procedure, comorbid conditions, and rate of blood loss.

The most severe transfusion reactions are due to ABO incompatibility; naturally acquired antibodies can react against the transfused (foreign) antigens, activate complement, and result in intravascular hemolysis.

In anesthetized patients, an acute hemolytic reaction is manifested by a rise in temperature, unexplained tachycardia, hypotension, hemoglobinuria, diffuse oozing in the surgical field, or a combination of these findings.

Allogeneic transfusion of blood products may diminish immunoresponsiveness and promote inflammation.

Immunocompromised and immunosuppressed patients (eg, premature infants, organ transplant recipients, and cancer patients) are particularly susceptible to severe transfusion-related cytomegalovirus (CMV) infections. Ideally, such patients should receive only CMV-negative units.

The most common cause of nonsurgical bleeding following massive blood transfusion is dilutional thrombocytopenia.

Clinically important hypocalcemia, causing cardiac depression, will not
Occur in most normal patients unless the transfusion rate exceeds 1 unit every 5 min, and intravenous calcium salts should rarely be required in the absence of measured hypocalcemia.

Once normal tissue perfusion is restored, any metabolic acidosis typically resolves, and metabolic alkalosis commonly occurs as citrate and lactate contained in transfusions and resuscitation fluids are converted to bicarbonate by the liver.

Almost all patients undergoing surgical procedures require venous access for administration of intravenous fluids and medication, and some patients will require transfusion of blood components. The anesthesia provider should be able to assess intravascular volume with sufficient accuracy to correct existing fluid or electrolyte deficits and replace ongoing losses. Errors in fluid and electrolyte replacement or transfusion may result in morbidity or death.

**Evaluation of Intravascular Volume**

Intravascular volume can be estimated using patient history, physical examination, and laboratory analysis, often with the aid of sophisticated hemodynamic monitoring techniques. Regardless of the method employed, serial evaluations are necessary to confirm initial impressions and to guide fluid, electrolyte, and blood component therapy. Multiple modalities complement one another, because all parameters are indirect, nonspecific measures of volume; reliance upon any one parameter may lead to erroneous conclusions.

**PATIENT HISTORY**

The patient history may reveal recent oral intake, persistent vomiting or diarrhea, gastric suction, significant blood loss or wound drainage, intravenous fluid and blood administration, and recent hemodialysis if the patient has kidney failure.

**PHYSICAL EXAMINATION**

Indications of hypovolemia include abnormal skin turgor, dehydration of mucous membranes, thready peripheral pulses, increased resting heart rate and decreased blood pressure, orthostatic heart rate and blood pressure changes from the supine to sitting or standing positions, and decreased urinary flow rate (Table 51–1).
Unfortunately, many medications administered during anesthesia, as well as the neuroendocrine stress response to operative procedures, frequently alter these signs and render them unreliable in the immediate postoperative period. Intraoperatively, in addition to heart rate and blood pressure, the fullness of a peripheral pulse, urinary flow rate, and indirect signs, such as the blood pressure response to positive-pressure ventilation and to vasodilating or negative inotropic effects of anesthetics, are often used for guidance.

**TABLE 51–1 Signs of fluid loss (hypovolemia).**

\*bpm, beats per minute

Pitting edema—presacral in the bedridden patient or pretibial in the ambulatory patient—and increased urinary flow are signs of excess extracellular water and likely hypervolemia in patients with normal cardiac, hepatic, and renal function. Late signs of hypervolemia in settings such as congestive heart failure may include tachycardia, tachypnea, elevated jugular pulse pressure, pulmonary crackles, wheezing, cyanosis, and pink, frothy pulmonary secretions.

**LABORATORY EVALUATION**

Several laboratory measurements may be used as surrogates of intravascular volume and adequacy of tissue perfusion, including serial hematocrits, arterial blood pH, urinary specific gravity or osmolality, urinary sodium or chloride concentration, serum sodium, and the blood urea nitrogen (BUN)-to-serum creatinine ratio. However, because these measurements are only indirect indices of intravascular volume, they are affected by many perioperative factors, and because laboratory results are often delayed, they often cannot be relied upon intraoperatively. Laboratory signs of dehydration may include rising hematocrit and hemoglobin, progressive metabolic acidosis (including lactic acidosis), urinary specific gravity greater than 1.010, urinary sodium less than 10 mEq/L, urinary osmolality greater than 450 mOsm/L, hypernatremia, and BUN-to-
creatinine ratio greater than 10:1. The hemoglobin and hematocrit are usually unchanged in patients with acute hypovolemia secondary to acute blood loss because there is insufficient time for extravascular fluid to shift into the intravascular space. Ultrasound can reveal a nearly collapsed vena cava or incompletely filled cardiac chambers. Radiographic indicators of volume overload include increased pulmonary vascular and interstitial markings (Kerley “B” lines), diffuse alveolar infiltrates, or both.

HEMODYNAMIC MEASUREMENTS

Hemodynamic monitoring is discussed in Chapter 5. Central venous pressure (CVP) monitoring has been used when volume status is difficult to assess by other means or when rapid or major alterations are expected. However, static CVP readings do not provide accurate or reliable indication of volume status.

Pulmonary artery pressure monitoring has been used in settings where CVP readings do not correlate with the clinical assessment or when the patient has primary or secondary right ventricular dysfunction; the latter is usually due to pulmonary or left ventricular disease, respectively. Pulmonary artery occlusion pressure (PAOP) readings of less than 8 mm Hg may indicate hypovolemia in patients with normal left ventricular compliance; however, values less than 15 mm Hg may be associated with relative hypovolemia in patients with poor ventricular compliance. PAOP measurements greater than 18 mm Hg are elevated and may imply left ventricular volume overload. The normal relationship between PAOP and left ventricular end-diastolic volume is altered by the presence of mitral valve disease, severe aortic stenosis, or a left atrial myxoma or thrombus, as well as by increased thoracic and pulmonary airway pressures (see Chapters 5, 20, 21, and 22). All PAOP measurements should be obtained at end expiration and interpreted in the context of the clinical setting. Finally, one should recognize that multiple studies have failed to show that pulmonary artery pressure monitoring leads to improved outcomes in critically ill patients, and that echocardiography provides a much more accurate and less invasive estimate of cardiac filling and function.

Intravascular volume status is often difficult to assess, and noninvasive fluid therapy guidance utilizing arterial pulse contour analysis and estimation of stroke volume variation (eg, LIDCOUnity, Vigileo FloTrak), esophageal Doppler, transesophageal echocardiography, or transthoracic echocardiography) should be considered when accurate determination of hemodynamic and fluid status is important. Stroke volume variation (SVV) is calculated as follows:
The maximum, minimum, and mean SV are calculated for a set period of time by the various measuring devices. During spontaneous ventilation the blood pressure decreases on inspiration. During positive pressure ventilation the opposite occurs. Normal SVV is less than 10% to 15% for patients on controlled ventilation. Patients with greater degrees of SVV are likely to be responsive to fluid therapy. In addition to providing more accurate assessment of volume and hemodynamic status than that obtained with CVP monitoring, these noninvasive modalities avoid multiple risks associated with central venous and pulmonary artery catheters. Consequently, we infrequently employ pulmonary artery catheters to guide hemodynamic therapy.

### Intravenous Fluids

Intravenous fluid therapy may consist of infusions of crystalloids, colloids, or a combination of both. Crystalloid solutions are aqueous solutions of ions (salts) with or without glucose, whereas colloid solutions also contain high-molecular-weight substances such as proteins or large glucose polymers. Colloid solutions help maintain plasma colloid oncotic pressure (see Chapter 49) and for the most part remain intravascular, whereas crystalloid solutions rapidly equilibrate with and distribute throughout the entire extracellular fluid space.

Controversy remains regarding the use of colloid versus crystalloid fluids for surgical patients. Proponents of colloids justifiably argue that by maintaining plasma oncotic pressure, colloids are more efficient (ie, a smaller volume of colloids than crystalloids is required to produce the same effect) in restoring normal intravascular volume and cardiac output. Crystalloid proponents, on the other hand, maintain that the crystalloid solutions are equally effective when given in appropriate amounts. Concerns that colloids may enhance the formation of pulmonary edema fluid in patients with increased pulmonary capillary permeability are unfounded (see Chapter 23). Several generalizations can be made:

1. Crystalloids, when given in sufficient amounts, are just as effective as colloids in restoring intravascular volume.

2. Replacing an intravascular volume deficit with crystalloids generally requires three to four times the volume needed when using colloids.

3. Surgical patients may have an extracellular fluid deficit that exceeds the
intravascular deficit.

4. Severe intravascular fluid deficits can be more rapidly corrected using colloid solutions.

5. The rapid administration of large amounts of crystalloids (>4–5 L) is often associated with tissue edema.

Tissue edema secondary to excessive fluid administration can impair oxygen transport, tissue healing, and return of bowel function following surgery and may increase the risk of surgical site infection.

**CRYSTALLOID SOLUTIONS**

Crystalloids are often considered as the initial resuscitation fluid in patients with hemorrhagic and septic shock, in burn patients, in patients with head injury (to maintain cerebral perfusion pressure), and in patients undergoing plasmapheresis and hepatic resection. Colloids may be included in resuscitation efforts following initial administration of crystalloid solutions depending upon anesthesia provider preferences and institutional protocols.

A wide variety of solutions is available, and choice is according to the type of fluid loss being replaced. For losses primarily involving water, replacement is with hypotonic solutions, and if losses involve both water and electrolytes, replacement is with isotonic electrolyte solutions. Glucose is provided in some solutions to maintain tonicity, or prevent ketosis and hypoglycemia due to fasting, or based on tradition. Children are prone to developing hypoglycemia (<50 mg/dL) following 4- to 8-h fasts.

Because most intraoperative fluid losses are isotonic, isotonic crystalloid solutions such as normal saline or balanced electrolyte solutions (low-\([\text{Cl}^-]\) crystalloids, which have preserved ionic “balance” by replacing \([\text{Cl}^-]\) with lactate, gluconate, or acetate) such as lactated Ringer’s solution or PlasmaLyte are most commonly used for replacement (Table 51–2). Normal saline, when given in large volumes, produces hyperchloremic metabolic acidosis because of its high chloride content and lack of bicarbonate (see Chapter 50). In addition, chloride-rich crystalloids such as normal saline may contribute to perioperative acute kidney injury. Therefore, we prefer balanced salt solutions for most intraoperative uses. Normal saline is the preferred solution for hypochloremic metabolic alkalosis and for diluting packed red blood cells prior to transfusion. Five percent dextrose in water (\(D_5W\)) is used for
replacement of pure water deficits and as a maintenance fluid for patients on sodium restriction. Hypertonic 3% saline is employed in therapy of severe symptomatic hyponatremia (see Chapter 49). Hypotonic solutions must be administered slowly to avoid inducing hemolysis.

**COLLOID SOLUTIONS**

The osmotic activity of high-molecular-weight substances in colloids tends to maintain these solutions intravascularly. Although the intravascular half-life of a crystalloid solution is 20 to 30 min, most colloid solutions have intravascular half-lives between 3 and 6 h. The relatively greater cost and occasional complications associated with colloids may limit their use. Generally accepted indications for colloids include (1) fluid resuscitation in patients with severe intravascular fluid deficits (eg, hemorrhagic shock) prior to the arrival of blood for transfusion, and (2) fluid resuscitation in the presence of severe hypoalbuminemia or conditions associated with large protein losses such as burns. For burn patients, colloids are not included in most initial resuscitation protocols, but may be considered following initial resuscitation with more extensive burn injuries during subsequent operative procedures.

Many clinicians also use colloid solutions in conjunction with crystalloids.
when fluid replacement needs exceed 3 to 4 L prior to transfusion. It should be noted that colloid solutions are prepared in normal saline (Cl\(^-\) 145–154 mEq/L) and thus can also cause hyperchloremic metabolic acidosis (see earlier discussion). Some clinicians suggest that during anesthesia, maintenance (and other) fluid requirements be provided with crystalloid solutions and blood loss be replaced on a milliliter-per-milliliter basis with colloid solutions (including blood products).

Several colloid solutions are generally available. All are derived from either plasma proteins or synthetic glucose polymers and are supplied in isotonic electrolyte solutions.

Blood-derived colloids include albumin (5% and 25% solutions) and plasma protein fraction (5%). Both are heated to 60°C for at least 10 h to minimize the risk of transmitting hepatitis and other viral diseases. Plasma protein fraction contains α- and β-globulins in addition to albumin and has occasionally resulted in hypotensive allergic reactions. Synthetic colloids include gelatins and dextrose starches. Gelatins (eg, Gelofusine) are associated with histamine-mediated allergic reactions and are not available in the United States. Dextran is a complex polysaccharide available as dextran 70 (Macrodex) and dextran 40 (Rheomacrodex), which have average molecular weights of 70,000 and 40,000, respectively. Dextran is used as a volume expander but also reduces blood viscosity, von Willebrand factor antigen, platelet adhesion, and red blood cell aggregation. Because of these latter properties, it is used by microsurgeons to improve microcirculatory flow and decrease risk of microthrombus formation. Infusions exceeding 20 mL/kg per day can interfere with blood typing, may prolong bleeding time, and have been associated with bleeding complications. Dextran has been associated with acute kidney injury and failure and should not be administered to patients with a history of kidney disease or to those at risk for acute kidney injury (eg, elderly or critically ill). Anaphylactoid and anaphylactic reactions have been reported. Dextran 1 (Promit) may be administered prior to dextran 40 or dextran 70 to prevent severe anaphylactic reactions; it acts as a hapten and binds any circulating dextran antibodies.

Hetastarch (hydroxyethyl starch) is available in multiple formulations that are designated by concentration, molecular weight, degree of starch substitution (on a molar basis), and ratio of hydroxylation between the C2 and the C6 positions. Thus, in some countries a wide variety of formulations are available with concentrations between 6% and 10%, molecular weights between 200 and 670, and degree of molar substitution between 0.4 and 0.7. Smaller starch molecules are eliminated by the kidneys, whereas large molecules must first be broken
down by amylase. Hetastarch is highly effective as a plasma expander and is less expensive than albumin. Allergic reactions are rare, but anaphylactoid and anaphylactic reactions have been reported. Hetastarch can decrease von Willebrand factor antigen levels, may prolong the prothrombin time, and has been associated with hemorrhagic complications. It is potentially nephrotoxic and should not be administered to patients at risk for acute kidney injury, including those who are elderly, critically ill, or have a history of kidney disease. However, its perioperative use in patients who are not critically ill or are not at increased risk of acute kidney injury remains controversial and is subject to a great deal of current debate.

---

Perioperative Fluid Therapy

Perioperative fluid therapy includes replacement of normal losses (maintenance requirements), of preexisting fluid deficits, and of surgical wound losses including blood loss.

NORMAL MAINTENANCE REQUIREMENTS

In the absence of oral intake, fluid and electrolyte deficits can rapidly develop as a result of continued urine formation, gastrointestinal secretions, sweating, and insensible losses from the skin and lungs. Normal maintenance requirements can be estimated from Table 51–3.

**TABLE 51–3** Estimating maintenance fluid requirements.¹

¹Example: What are the maintenance fluid requirements for a 25-kg child?
Answer: 40 + 20 + 5 = 65 mL/h.

PREEXISTING DEFICITS
Patients presenting for surgery after a traditional overnight fast without any fluid intake will have a preexisting deficit proportionate to the duration of the fast. The deficit can be estimated by multiplying the normal maintenance rate by the length of the fast. For the average 70-kg person fasting for 8 h, this amounts to \((40 + 20 + 50) \text{ mL/h} \times 8 \text{ h}, \) or 880 mL. In fact, the real deficit is less as a result of renal conservation—after all, how many of us would feel the need to consume nearly 1 L of fluid upon awakening after 8 h of sleep? However, current anesthesia practice often allows oral fluids up to 2 h prior to an elective procedure, and the preoperative regimen may include preoperative carbohydrate fluid loading (see Chapters 18 and 48). Such patients will present for surgical or procedural care with essentially no fluid deficit, as will the hospitalized patient who has received intravenous maintenance fluids preoperatively.

Abnormal fluid losses frequently contribute to preoperative deficits. Preoperative bleeding, vomiting, nasogastric suction, diuresis, and diarrhea are often contributory. Losses (actually, redistribution; see next section) due to fluid sequestration by traumatized or infected tissues, coagulopathy-related occult hematoma formation, or ascites can also be substantial. Increased insensible losses due to hyperventilation, fever, and sweating are often overlooked.

 Ideally, deficits should be replaced preoperatively in surgical patients, and the fluids administered should be similar in composition to the fluids lost (Table 51–4).

### SURGICAL FLUID LOSSES

#### Blood Loss

One of the most important, yet difficult, tasks in anesthesia practice is to monitor and estimate blood loss. Although estimates are complicated by occult bleeding
into the wound or under the surgical drapes, accuracy is important to guide fluid therapy and transfusion.

The most commonly used method for estimating blood loss is measurement of blood in the surgical suction container and visual estimation of the blood on surgical sponges (“4 by 4’s”) and laparotomy pads (“lap sponges”). A fully soaked “4 × 4” is generally considered to hold 10 mL of blood, whereas a soaked “lap” may hold 100 to 150 mL. More accurate estimates are obtained if sponges and “laps” are weighed before and after use, which is especially important during pediatric procedures. Use of irrigating solutions complicates estimates, but their volume should be noted and an attempt made to compensate. Serial hematocrits or hemoglobin concentrations reflect the ratio of RBCs to plasma, not necessarily blood loss, and rapid fluid shifts and intravenous replacement affect such measurements.

**Other Fluid Losses**

Many surgical procedures are associated with obligatory losses of fluids other than blood. Such losses are due mainly to evaporation and internal redistribution of body fluids. Evaporative losses are most significant with large wounds, especially burns, and are proportional to the surface area exposed and to the duration of the surgical procedure.

Internal redistribution of fluids—often called *third-spacing*—can cause massive fluid shifts and severe intravascular depletion in patients with peritonitis, burns, and similar situations characterized by inflamed or infected tissue. Traumatized, inflamed, or infected tissue can sequester large amounts of fluid in the interstitial space and can translocate fluid across serosal surfaces (ascites) or into bowel lumen. Shifting of intravascular fluid into the interstitial space (edema) is especially important; protein-free fluid shift across an intact vascular barrier into the interstitial space is exacerbated by hypervolemia (water and sodium excess), and pathological alteration of the vascular barrier allows protein-rich fluid shift.

**INTRAOPERATIVE FLUID REPLACEMENT**

Intraoperative fluid therapy should include supplying basic fluid requirements and replacing residual preoperative deficits as well as intraoperative losses (blood loss, fluid redistribution, and evaporation). Selection of the type of intravenous solution depends on the surgical procedure and the expected blood loss. For minor procedures involving minimal or no blood loss, minimal or no
fluid is often administered other than for drug delivery and for maintenance of intravenous line patency. For all other procedures, a balanced crystalloid such as lactated Ringer’s solution or Plasmalyte is generally used for maintenance requirements.

**Goal-Directed Fluid Therapy**

The concept of *goal-directed fluid therapy* (GDFT) arose from a 1983 study by Shoemaker and colleagues that demonstrated lower mortality in critically ill patients in whom tissue oxygen delivery was optimized through “physiological goals” related to cardiac output and fluid administration. The current concept of GDFT has many variations but in general assumes no need for maintenance fluid administration, instead using hemodynamic variables such as stroke volume, cardiac output, cardiac index, and mean arterial blood pressure to determine volume responsiveness and to guide fluid administration by bolus. Some anesthesiologists also incorporate the use of inotropes and vasopressors in their GDFT regimens. GDFT has been widely incorporated into enhanced recovery protocols, but studies of GDFT have been inconsistent to date, with some investigators reporting fewer postoperative complications and shorter hospital lengths of stay. Inconsistent reports of GDFT results may be due to inconsistent GDFT regimens, or to the possibility that not all operations (eg, those with less physiological trespass, such as laparoscopic or robotic procedures) require GDFT. The precise role of GDFT in perioperative care related to various surgical procedures is currently the subject of intense scrutiny.

**Replacing Blood Loss**

Ideally, blood loss should be replaced with sufficient crystalloid or colloid solutions to maintain normovolemia until the danger of anemia outweighs the risks of transfusion. At that point, further blood loss is replaced with transfusion of red blood cells to maintain hemoglobin concentration (or hematocrit) at an acceptable level. There are no mandatory transfusion triggers. The point where the benefits of transfusion outweigh its risks must be considered on an individual basis.

Below a hemoglobin concentration of 7 g/dL, the resting cardiac output increases to maintain a normal oxygen delivery. An increased hemoglobin concentration may be appropriate for older and sicker patients with cardiac or pulmonary disease, particularly when there is clinical evidence (eg, a reduced mixed venous oxygen saturation and a persisting tachycardia) that transfusion
would be beneficial.

In settings other than massive trauma, most clinicians administer lactated Ringer’s solution or Plasmalyte in approximately three to four times the volume of the blood lost, or colloid in a 1:1 ratio, until the transfusion trigger point is reached. At that time, blood is replaced unit-for-unit as it is lost, with reconstituted packed red blood cells (see Chapter 39).

The transfusion point can be determined preoperatively from the hematocrit and by estimating total blood volume (Table 51–5). Patients with a normal hematocrit should generally be transfused only after losses greater than 10% to 20% of their blood volume. The timing of transfusion initiation is based on the patient’s surgical procedure, comorbid conditions, and rate of blood loss. The amount of blood loss necessary for the hematocrit to fall to 30% can be calculated as follows:

**TABLE 51–5 Average blood volumes.**

<table>
<thead>

</tr>
</tbody>
</table>

1. Estimate blood volume from Table 51–5.
2. Estimate the red blood cell volume (RBCV) at the preoperative hematocrit (RBCV<sub>preop</sub>).
3. Estimate RBCV at a hematocrit of 30% (RBCV<sub>30%</sub>), assuming normal blood volume is maintained.
4. Calculate the RBCV lost when the hematocrit is 30%; RBCV<sub>lost</sub> = RBCV<sub>preop</sub> – RBCV<sub>30%</sub>.
5. Allowable blood loss = RBCV<sub>lost</sub> × 3.
**Example:** An 85-kg woman has a preoperative hematocrit of 35%. How much blood loss will decrease her hematocrit to 30%?

Estimated blood volume = $65 \text{ mL/kg} \times 85 \text{ kg} = 5525 \text{ mL}.

\[
\begin{align*}
\text{RBCV}_{35\%} &= 5525 \times 35\% = 1934 \text{ mL}.
\text{RBCV}_{30\%} &= 5525 \times 30\% = 1658 \text{ mL}.
\text{Red cell loss at 30\%} &= 1934 - 1658 = 276 \text{ mL}.
\text{Allowable blood loss} &= 3 \times 276 \text{ mL} = 828 \text{ mL}.
\end{align*}
\]

Therefore, transfusion should be considered only when this patient’s blood loss exceeds 800 mL. **Increasingly, transfusions are not recommended until the hematocrit decreases to 24% or lower (hemoglobin <8.0 g/dL), but it is necessary to take into account the potential for further blood loss, rate of blood loss, and comorbid conditions (eg, cardiac disease).**

Clinical guidelines for transfusion commonly used include the following: (1) transfusing 1 unit of red blood cells will increase hemoglobin 1 g/dL and the hematocrit 2% to 3% in adults; and (2) a 10-mL/kg transfusion of red blood cells will increase hemoglobin concentration by 3 g/dL and the hematocrit by 10%.

**Replacing Redistributive & Evaporative Losses**

Because redistributive and evaporative losses are primarily related to wound size and the extent of surgical dissections and manipulations, procedures can be classified according to the degree of tissue trauma. These additional fluid losses can be replaced according to **Table 51–6**, based on whether tissue trauma is minimal, moderate, or severe. These values are only guidelines, and actual needs vary considerably from patient to patient. Fluid replacement can also be guided by a GDT regimen.

**TABLE 51–6** Redistributive and evaporative surgical fluid losses.
Transfusion

BLOOD GROUPS

Human red cell membranes are estimated to contain at least 300 different antigenic determinants, and at least 20 separate blood group antigen systems are known. Fortunately, only the ABO and the Rh systems are important in the majority of blood transfusions. Individuals often produce antibodies (alloantibodies) to the alleles they lack within each system. Such antibodies are responsible for the most serious reactions to transfusions. Antibodies may occur spontaneously or in response to sensitization from a previous transfusion or pregnancy.

The ABO System

ABO blood group typing is determined by the presence or absence of A or B red blood cell (RBC) surface antigens: Type A blood has A RBC antigen, type B blood has B RBC antigen, type AB blood has both A and B RBC antigens, and type O blood has neither A nor B RBC antigen present. Almost all individuals not having A or B antigen “naturally” produce antibodies, mainly immunoglobulin (Ig) M, against those missing antigens within the first year of life.

The Rh System

There are approximately 46 Rhesus group red cell surface antigens, and patients with the D Rhesus antigen are considered Rh-positive. Approximately 85% of
the white population and 92% of the black population has the D antigen, and individuals lacking this antigen are called *Rh-negative*. In contrast to the ABO groups, Rh-negative patients usually develop antibodies against the D antigen only after an Rh-positive transfusion or with pregnancy, in the situation of an Rh-negative mother delivering an Rh-positive baby.

**Other Red Blood Cell Antigen Systems**

Other red cell antigen systems include Lewis, P, Ii, MNS, Kidd, Kell, Duffy, Lutheran, Xg, Sid, Cartright, YK, Ss, and Chido Rodgers. Fortunately, with some exceptions (Kell, Kidd, Duffy, and Ss), alloantibodies against these antigens rarely cause serious hemolytic reactions.

**COMPATIBILITY TESTING**

The purpose of compatibility testing is to predict and to prevent antigen–antibody reactions resulting from red cell transfusions.

**ABO–Rh Testing**

- The most severe transfusion reactions are due to ABO incompatibility; naturally acquired antibodies can react against the transfused (foreign) antigens, activate complement, and result in intravascular hemolysis. The patient’s red cells are tested with serum known to have antibodies against A and against B to determine blood type. Because of the almost universal prevalence of natural ABO antibodies, confirmation of blood type is then made by testing the patient’s serum against red cells with a known antigen type.

  The patient’s red cells are also tested with anti-D antibodies to determine Rh status. If the subject is Rh-negative, the presence of anti-D antibody is checked by mixing the patient’s serum against Rh-positive red cells. The probability of developing anti-D antibodies after a single exposure to the Rh antigen is 50% to 70%.

**Antibody Screen**

The purpose of this test is to detect in the serum the presence of the antibodies that are most commonly associated with non-ABO hemolytic reactions. The test (also known as the *indirect Coombs test*) requires 45 min and involves mixing the patient’s serum with red cells of known antigenic composition; if specific
antibodies are present, they will coat the red cell membrane, and subsequent addition of an antiglobulin antibody will result in red cell agglutination. Antibody screens are routinely done on all donor blood and are frequently done for a potential recipient instead of a crossmatch (described next).

**Crossmatch**

A crossmatch mimics the transfusion: Donor red cells are mixed with recipient serum. **Crossmatching serves three functions:** (1) it confirms ABO and Rh typing, (2) it detects antibodies to the other blood group systems, and (3) it detects antibodies in low titers or those that do not agglutinate easily.

**Type & Crossmatch versus Type & Screen**

In the situation of negative antibody screen without crossmatch, the incidence of serious hemolytic reaction with ABO- and Rh-compatible transfusion is less than 1:10,000. Crossmatching, however, assures optimal safety and detects the presence of less common antibodies not usually tested for in a screen. Because of the expense and time involved (45 min), crossmatches are often now performed before the need to transfuse only when the patient’s antibody screen is positive, when the probability of transfusion is high, or when the patient is considered at risk for alloimmunization.

**EMERGENCY TRANSFUSIONS**

When a patient is exsanguinating, the urgent need to transfuse may arise prior to completion of a crossmatch, screen, or even blood typing. **If the patient’s blood type is known, an abbreviated crossmatch, requiring less than 5 min, will confirm ABO compatibility.** If the recipient’s blood type and Rh status are not known with certainty and transfusion must be started before determination, type O Rh-negative (universal donor) red cells may be used. Red blood cells, fresh frozen plasma, and platelets are often transfused in a balanced ratio (1:1:1) in massive transfusion protocols and in trauma damage control resuscitation (see later discussion and Chapter 39).

**BLOOD BANK PRACTICES**

Blood donors are screened to exclude medical conditions that might adversely affect the donor or the recipient. Once the blood is collected, it is typed, screened
for antibodies, and tested for hepatitis B, hepatitis C, syphilis, and human immunodeficiency virus. A preservative–anticoagulant solution is added. The most commonly used solution is **CPDA-1**, which contains citrate as an anticoagulant (by binding calcium), phosphate as a buffer, dextrose as a red cell energy source, and adenosine as a precursor for adenosine triphosphate (ATP) synthesis. CPDA-1-preserved blood can be stored for 35 days, after which the viability of the red cells rapidly decreases. Alternatively, use of either AS-1 (Adsol) or AS-3 (Nutrice) extends the shelf-life to 6 weeks.

Nearly all units collected are separated into their component parts (ie, red cells, platelets, and plasma), and whole blood units are rarely available for transfusion in civilian practice. When centrifuged, 1 unit of whole blood yields approximately 250 mL of packed red blood cells (PRBCs) with a hematocrit of 70%; following the addition of saline preservative, the volume of a unit of PRBCs often reaches 350 mL. Red cells are normally stored at 1°C to 6°C but may be frozen in a hypertonic glycerol solution for up to 10 years. The latter technique is usually reserved for storage of blood with rare phenotypes.

The supernatant is centrifuged to yield platelets and plasma. The unit of platelets obtained generally contains 50 to 70 mL of plasma and can be stored at 20°C to 24°C for 5 days. The remaining plasma supernatant is further processed and frozen to yield fresh frozen plasma; rapid freezing helps prevent inactivation of the labile coagulation factors V and VIII. Slow thawing of fresh frozen plasma yields a gelatinous precipitate (cryoprecipitate) that contains high concentrations of factor VIII and fibrinogen. Once separated, cryoprecipitate can be refrozen for storage. One unit of blood yields about 200 mL of plasma, which is frozen for storage; once thawed, it must be transfused within 24 h. Most platelets are now obtained from donors by apheresis, and a single platelet apheresis unit is equivalent to the amount of platelets derived from 6 to 8 units of whole blood.

The use of leukocyte-reduced (leukoreduction) blood products has been rapidly adopted by many countries, including the United States, in order to decrease the risk of transfusion-related febrile reactions, infections, and immunosuppression.

**INTRAOPERATIVE TRANSFUSION PRACTICES**

**Packed Red Blood Cells**

Blood transfusions should usually be given as PRBCs, which allows optimal
utilization of blood bank resources. Surgical patients require volume as well as red cells, and crystalloid or colloid can be infused simultaneously through a second intravenous line for volume replacement.

Prior to transfusion, each unit should be carefully checked against the blood bank slip and the recipient’s identity bracelet. The transfusion tubing should contain a 170-μm filter to trap any clots or debris. Blood for intraoperative transfusion should be warmed to 37°C during infusion, particularly when more than 2 to 3 units will be transfused; failure to do so can result in profound hypothermia. The additive effects of hypothermia and the typically low levels of 2,3-diphosphoglycerate (2,3-DPG) in stored blood can cause a marked leftward shift of the hemoglobin–oxygen dissociation curve (see Chapter 23) and, at least theoretically, promote tissue hypoxia.

Fresh Frozen Plasma

Fresh frozen plasma (FFP) contains all plasma proteins, including most clotting factors. **Transfusions of FFP are indicated in the treatment of isolated factor deficiencies, the reversal of warfarin therapy, and the correction of coagulopathy associated with liver disease.** Each unit of FFP generally increases the level of each clotting factor by 2% to 3% in adults. The initial therapeutic dose is usually 10 to 15 mL/kg. The goal is to achieve 30% of the normal coagulation factor concentration. Administration of FFP and platelets in treatment of coagulopathy is optimally guided by point-of-care coagulation analysis, such as thromboelastography (TEG) or rotational thromboelastometry (ROTEM).

FFP may also be used in patients who have received massive blood transfusions (see later discussion and Chapter 39) and continue to bleed following platelet transfusions. Patients with antithrombin III deficiency or thrombotic thrombocytopenic purpura also benefit from FFP transfusions.

Each unit of FFP carries the same infectious risk as a unit of whole blood. In addition, occasional patients may become sensitized to plasma proteins. ABO-compatible units are usually given but are not mandatory. As with red cells, FFP should generally be warmed to 37°C prior to transfusion.

Platelets

Platelet transfusions should be given to patients with thrombocytopenia or dysfunctional platelets in the presence of bleeding. Prophylactic platelet transfusions are also indicated in patients with platelet counts below 10,000 to
20,000 × 10^9/L because of an increased risk of spontaneous hemorrhage.

Platelet counts less than 50,000 × 10^9/L are associated with increased blood loss during surgery, and such thrombocytopenic patients often receive prophylactic platelet transfusions prior to surgery or invasive procedures. Vaginal delivery and minor surgical procedures may be performed in patients with normal platelet function and counts greater than 50,000 × 10^9/L. Administration of a single unit of platelets may be expected to increase the platelet count by 5000 to 10,000 × 10^9/L, and with administration of a platelet apheresis unit, by 30,000 to 60,000 × 10^9/L.

ABO-compatible platelet transfusions are desirable but not necessary. Transfused platelets generally survive only 1 to 7 days following transfusion. ABO compatibility may increase platelet survival. Rh sensitization can occur in Rh-negative recipients due to the presence of a few red cells in Rh-positive platelet units. Moreover, anti-A or anti-B antibodies in the 70 mL of plasma in each platelet unit can cause a hemolytic reaction against the recipient’s red cells when a large number of ABO-incompatible platelet units is given. Administration of Rh immunoglobulin to Rh-negative individuals can protect against Rh sensitization following Rh-positive platelet transfusions.

**Granulocyte Transfusions**

Granulocyte transfusions, prepared by leukapheresis, may be indicated in neutropenic patients with bacterial infections not responding to antibiotics. Transfused granulocytes have a very short circulatory life span, so that daily transfusions of 10^10 granulocytes are usually required. Irradiation of these units decreases the incidence of graft-versus-host reactions, pulmonary endothelial damage, and other problems associated with transfusion of leukocytes (see next section), but may adversely affect granulocyte function. The availability of granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) has greatly reduced the need for granulocyte transfusions.

**Indications for Procoagulant Transfusions**

Blood products can be misused in surgical settings. Use of a transfusion algorithm, particularly for components such as plasma, platelets, and cryoprecipitate, and particularly when the algorithm is guided by appropriate laboratory testing, will reduce unnecessary transfusion of these precious and
costly (but dangerous) resources (see Chapter 22). Following military experience, major civilian trauma care units commonly transfuse blood products in equal ratios early in severe trauma resuscitation efforts in order to preempt or correct trauma-induced coagulopathy. This balanced approach to transfusion of blood products, 1:1:1 (one unit of FFP and one unit of platelets with each unit of PRBCs), is termed damage control resuscitation (see Chapter 39).

Complications of Blood Transfusion

IMMUNE COMPLICATIONS

Immune complications following blood transfusions are primarily due to sensitization of the recipient to donor red cells, white cells, platelets, or plasma proteins. Less commonly, the transfused cells or serum may mount an immune response against the recipient.

1. Hemolytic Reactions

Hemolytic reactions usually involve specific destruction of the transfused red cells by the recipient’s antibodies. Less commonly, hemolysis of a recipient’s red cells occurs as a result of transfusion of red cell antibodies. Incompatible units of platelet concentrates, FFP, clotting factor concentrates, or cryoprecipitate may contain small amounts of plasma with anti-A or anti-B (or both) alloantibodies. Transfusions of large volumes of such units can lead to intravascular hemolysis. Hemolytic reactions are commonly classified as either acute (intravascular) or delayed (extravascular).

Acute Hemolytic Reactions

Acute intravascular hemolysis is usually due to ABO blood incompatibility, and the reported frequency is approximately 1:38,000 transfusions. The most common cause is misidentification of a patient, blood specimen, or transfusion unit, a risk that is not abolished with autologous blood transfusion. These reactions are often severe, and may occur after infusion of as little as 10 to 15 mL of ABO-incompatible blood. The risk of a fatal hemolytic reaction is about 1 in 100,000 transfusions. In awake patients, symptoms include chills, fever, nausea, and chest and flank pain. In anesthetized patients, an acute hemolytic reaction may be manifested by a rise in temperature, unexplained tachycardia, hypotension, hemoglobinuria, diffuse oozing in
the surgical field, or a combination of these findings. Disseminated intravascular coagulation, shock, and kidney acute failure can develop rapidly. The severity of a reaction often depends upon the volume of incompatible blood that has been administered.

Management of hemolytic reactions can be summarized as follows:

1. If a hemolytic reaction is suspected, the transfusion should be stopped immediately and the blood bank should be notified.
2. The unit should be rechecked against the blood slip and the patient’s identity bracelet.
3. Blood should be drawn to identify hemoglobin in plasma, to repeat compatibility testing, and to obtain coagulation studies and a platelet count.
4. A urinary bladder catheter should be inserted, and the urine should be checked for hemoglobin.
5. Forced diuresis should be initiated with mannitol and intravenous fluids, and with a loop diuretic if necessary.

Delayed Hemolytic Reactions

A delayed hemolytic reaction—also called extravascular hemolysis—is generally mild and is caused by antibodies to non-D antigens of the Rh system or to foreign alleles in other systems such as the Kell, Duffy, or Kidd antigens. Following an ABO and Rh D-compatible transfusion, patients have a 1% to 1.6% chance of forming antibodies directed against foreign antigens in these other systems. By the time significant amounts of these antibodies have formed (weeks to months), the transfused red cells have been cleared from the circulation. Moreover, the titer of these antibodies subsequently decreases and may become undetectable. Reexposure to the same foreign antigen during a subsequent red cell transfusion, however, triggers an anamnestic antibody response against the foreign antigen. The hemolytic reaction is therefore typically delayed 2 to 21 days after transfusion, and symptoms are generally mild, consisting of malaise, jaundice, and fever. The patient’s hematocrit typically fails to rise, or rises only transiently, in spite of the transfusion and the absence of bleeding. The serum unconjugated bilirubin increases as a result of hemoglobin breakdown.

Diagnosis of delayed antibody-mediated hemolytic reactions may be facilitated by the antiglobulin (Coombs) test. The direct Coombs test detects the
presence of antibodies on the membrane of red cells. In this setting, however, this test cannot distinguish between recipient antibodies coated on donor red cells and donor antibodies coated on recipient red cells. The latter requires a more detailed reexamination of pretransfusion specimens from both the patient and the donor.

The treatment of delayed hemolytic reactions is primarily supportive. The frequency of delayed hemolytic transfusion reactions is estimated to be approximately 1:12,000 transfusions. Pregnancy (exposure to fetal red cells) can also be responsible for the formation of alloantibodies to red cells.

2. **Nonhemolytic Immune Reactions**

Nonhemolytic immune reactions are due to sensitization of the recipient to the donor’s white cells, platelets, or plasma proteins; the risk of these reactions may be minimized by the use of leukoreduced blood products.

**Febrile Reactions**

White cell or platelet sensitization is typically manifested as a febrile reaction. Such reactions are relatively common (1–3% of transfusion episodes) and are characterized by an increase in temperature without evidence of hemolysis. Patients with a history of repeated febrile reactions should receive leukoreduced transfusions only.

**Urticarial Reactions**

Urticarial reactions are usually characterized by erythema, hives, and itching without fever. They are relatively common (1% of transfusions) and are thought to be due to sensitization of the patient to transfused plasma proteins. Urticarial reactions can be treated with antihistaminic drugs (H₁ and perhaps H₂ blockers) and steroids.

**Anaphylactic Reactions**

Anaphylactic reactions are rare (approximately 1:150,000 transfusions). These severe reactions may occur after only a few milliliters of blood has been given, typically in IgA-deficient patients with anti-IgA antibodies who receive IgA-containing blood transfusions. The prevalence of IgA deficiency is estimated to be 1:600 to 1:800 in the general population. Such reactions require treatment
with epinephrine, fluids, corticosteroids, and H₁ and H₂ blockers. Patients with IgA deficiency should receive thoroughly washed packed red cells, deglycerolized frozen red cells, or IgA-free blood units.

**Transfusion-Related Acute Lung Injury**

*Transfusion-related acute lung injury* (TRALI) presents as acute hypoxia and noncardiac pulmonary edema occurring within 6 h of blood product transfusion. It may occur as frequently as 1:5000 transfused units, and with transfusion of any blood component, but especially platelets and FFP. Treatment is similar to that for acute respiratory distress syndrome (see Chapter 58), with the important difference that TRALI may resolve within a few days with supportive therapy. The incidence of TRALI, until recently the leading cause of transfusion-related death, has markedly declined with the recognition that the presence of HLA antibodies in donor plasma is the principal TRALI risk factor (see Chapter 39).

**Transfusion-Associated Circulatory Overload**

*Transfusion-associated circulatory overload* (TACO) occurs when blood products are administered at a rate greater than the patient’s cardiac output, usually in a massive hemorrhage resuscitation scenario. This is most likely to occur when the provider administering blood products has not recognized that the source of bleeding has been successfully controlled. Communication in this situation is critical between the team members resuscitating the patient with blood products and those attempting to control the hemorrhage (see Chapter 39). **TACO has replaced TRALI as the leading transfusion-related risk for trauma patients.**

**Graft-Versus-Host Disease**

This type of reaction may be seen in immunocompromised patients. Cellular blood products contain lymphocytes capable of mounting an immune response against the compromised recipient. Use of special leukocyte filters alone does not reliably prevent graft-versus-host disease; irradiation of red cell, granulocyte, and platelet transfusions effectively eliminates lymphocytes without altering the efficacy of such transfusions.

**Post-Transfusion Purpura**
Post-transfusion purpura is a potentially fatal thrombocytopenic disorder that occurs, rarely, following blood or platelet transfusion. It results from development of platelet alloantibodies that destroy the patient’s own platelets. The platelet count typically drops precipitously 5 to 10 days following transfusion. Treatment may include intravenous IgG and plasmapheresis.

Transfusion-Related Immunomodulation

- Allogeneic transfusion of blood products may diminish immunoresponsiveness and promote inflammation. Post-transfusion immunosuppression is clearly evident in kidney transplant recipients, in whom preoperative blood transfusion improves graft survival. Recent studies suggest that perioperative transfusion may increase the risk of postoperative bacterial infection, cancer recurrence, and mortality, all of which emphasize the need to avoid unnecessary blood product administration.

INFECTIONOUS COMPLICATIONS

Viral Infections

A. Hepatitis
The incidence of post-transfusion viral hepatitis varies greatly, from approximately 1:200,000 transfusions (for hepatitis B) to approximately 1:1,900,000 (for hepatitis C). Most acute cases are anicteric. Hepatitis C is the more serious infection; most cases progress to chronic hepatitis, with cirrhosis developing in 20% of chronic carriers and hepatocellular carcinoma developing in up to 5% of chronic carriers.

B. Acquired Immunodeficiency Syndrome (AIDS)
All blood is tested for the presence of anti-HIV-1 and anti-HIV-2 antibodies. The requirement for donor blood testing by the U.S. Food and Drug Administration (FDA) has decreased the risk of transfusion-transmitted HIV to approximately 1:1,900,000 transfusions.

C. Other Viral Infections
Cytomegalovirus (CMV) and Epstein–Barr virus usually cause asymptomatic or mild systemic illness. Some individuals infected with these viruses become asymptomatic infectious carriers; the white cells in blood units from such donors
are capable of transmitting either virus. Immunocompromised and immunosuppressed patients (eg, premature infants, organ transplant recipients, and cancer patients) are particularly susceptible to severe transfusion-related CMV infections. Ideally, such patients should receive only CMV-negative units. However, recent studies indicate that the risk of CMV transmission from transfusion of leukoreduced blood products is equivalent to CMV test-negative units. Human T-cell lymphotropic viruses 1 and 2 (HTLV-1 and HTLV-2) are leukemia and lymphoma viruses, respectively, that have been reported to be transmitted by blood transfusion; the former has also been associated with myelopathy. Parvovirus transmission has been reported following transfusion of coagulation factor concentrates and can result in transient aplastic crises in immunocompromised hosts. West Nile virus infection may result in encephalitis with a fatality rate of up to 10%, and transmission of this virus by transfusion has been reported.

Parasitic Infections

Parasitic diseases that can be transmitted by transfusion include malaria, toxoplasmosis, and Chagas disease. Such cases are very rare in developed countries.

Bacterial Infections

Bacterial contamination of blood products is the second leading cause of transfusion-associated mortality. The prevalence of positive bacterial cultures in blood products ranges from 1:2000 for platelets to 1:7000 for PRBCs and may be due to transient donor bacteremia or to inadequate antisepsis during phlebotomy. The prevalence of sepsis due to blood transfusion ranges from 1:25,000 for platelets to 1:250,000 for PRBCs. Both gram-positive (Staphylococcus) and gram-negative (Yersinia and Citrobacter) bacteria can contaminate blood transfusions and transmit disease. To avoid the possibility of significant bacterial contamination, blood products should be administered over a period shorter than 4 h. Specific bacterial diseases rarely transmitted by blood transfusions from donors include syphilis, brucellosis, salmonellosis, yersiniosis, and various rickettsioses.

MASSIVE BLOOD TRANSFUSION

Massive transfusion is most often defined as the need to transfuse the patient’s
total estimated blood volume in less than 24 h, or one-half the patient’s total estimated blood volume in 1 h. For most adult patients, the total estimated blood volume is the equivalent of 10 to 20 units. The approach to massive transfusion (and to lesser degrees of transfusion) after trauma injury has been greatly influenced by recent military experience in which outcomes have improved with concurrent transfusion of packed red cells, FFP, and platelets to avoid dilutional coagulopathy (see Chapter 39).

Coagulopathy

The most common cause of nonsurgical bleeding following massive blood transfusion is dilutional thrombocytopenia, although clinically significant dilution of coagulation factors may also occur. Point-of-care coagulation studies and platelet counts should guide platelet and FFP transfusion. Although most clinicians will be familiar with “routine” coagulation tests (eg, prothrombin time [PT], activated partial thromboplastin time [aPTT], international normalized ratio [INR], platelet count, fibrinogen), multiple studies show that viscoelastic analysis of whole blood clotting (thromboelastography, rotation thromboelastometry, or Sonoclot analysis) is more useful in resuscitation, liver transplantation, and cardiac surgical settings.

Citrate Toxicity

Calcium binding by the citrate preservative can rise in importance following transfusion of large volumes of blood or blood products. Clinically important hypocalcemia, causing cardiac depression, will not occur in most normal patients unless the transfusion rate exceeds 1 unit every 5 min, and intravenous calcium salts should rarely be required in the absence of measured hypocalcemia. Because citrate metabolism is primarily hepatic, patients with hepatic disease or dysfunction (and possibly hypothermic patients) may demonstrate hypocalcemia and require calcium infusion during massive transfusion, as may small children and others with relatively impaired parathyroid–vitamin D function.

Hypothermia

Massive blood transfusion is an absolute indication for warming all blood products and intravenous fluids to normal body temperature. Ventricular arrhythmias progressing to fibrillation often occur at temperatures close to 30°C, and hypothermia will hamper cardiac resuscitation. The customary use of rapid
infusion devices with efficient heat transfer capability has decreased the incidence of transfusion-related hypothermia.

**Acid–Base Balance**

Although stored blood is acidic due to the citric acid anticoagulant and accumulation of red cell metabolites (carbon dioxide and lactic acid), metabolic acidosis due to transfusion is uncommon because citric acid and lactic acid are rapidly metabolized to bicarbonate by the normal liver. However, in the situation of massive blood transfusion, acid–base status is largely dependent upon tissue perfusion, rate of blood transfusion, and citrate metabolism. Once normal tissue perfusion is restored, any metabolic acidosis typically resolves, and metabolic alkalosis commonly occurs as citrate and lactate contained in transfusions and resuscitation fluids are converted to bicarbonate by the liver.

**Serum Potassium Concentration**

The extracellular concentration of potassium in stored blood steadily increases with time. The amount of extracellular potassium transfused with each unit is typically less than 4 mEq per unit. Hyperkalemia can develop regardless of the age of the blood when transfusion rates exceed 100 mL/min. The treatment of hyperkalemia is discussed in Chapter 49. In contrast, hypokalemia is commonly encountered postoperatively, particularly in association with metabolic alkalosis (see Chapters 49 and 50).

**Alternative Strategies for Management of Blood Loss During Surgery**

**AUTOLOGOUS TRANSFUSION**

Patients undergoing some elective surgical procedures with a high probability for transfusion can donate their own blood for use during that surgery. Collection is usually started 4 to 5 weeks prior to the procedure. The patient is usually allowed to donate a unit as long as the hematocrit is at least 34% or hemoglobin at least 11 g/dL. A minimum of 72 h is required between donations to ensure plasma volume has returned to normal. With iron supplementation and erythropoietin therapy, at least 3 or 4 units can usually be collected prior to operation. Autologous blood transfusions probably do not adversely affect
survival in patients undergoing operations for cancer. Although autologous transfusions likely reduce the risk of infection and transfusion reactions, they are not risk-free. Risks include those of immunological reactions due to clerical errors in collection, labeling, and administration; bacterial contamination; and improper storage. Allergic reactions can occur due to allergens (eg, ethylene oxide) that dissolve into the blood from collection and storage equipment.

BLOOD SALVAGE & REINFUSION

This technique is used widely during cardiac, major vascular, and orthopedic surgery (see Chapter 22). The shed blood is aspirated intraoperatively into a reservoir and mixed with heparin. After a sufficient amount of blood is collected, the red cells are concentrated and washed to remove debris and anticoagulant and then reinfused into the patient. The concentrates obtained usually have hematocrits of 50% to 60%. To be used effectively, this technique requires blood losses greater than 1000 to 1500 mL. Contraindications to blood salvage and reinfusion include septic contamination of the wound and perhaps malignancy. Newer, simpler systems allow reinfusion of shed blood without centrifugation.

NORMOVOLEMIC HEMODILUTION

Acute normovolemic hemodilution relies on the premise that if the concentration of red cells is decreased, total red cell loss is reduced when large amounts of blood are shed; moreover, cardiac output remains normal because intravascular volume is maintained. One or 2 units of blood are typically removed just prior to surgery from a large-bore intravenous catheter and replaced with crystalloid and colloids so that the patient remains normovolemic but has a hematocrit of 21% to 25%. The blood that is removed is stored in a CPD bag at room temperature (up to 6 h) to preserve platelet function; the blood is given back to the patient after the blood loss, or sooner if necessary. The use of normovolemic hemodilution is now rare because of progressive improvements in transfusion safety.

DONOR-DIRECTED TRANSFUSIONS

Patients can request donated blood from family members or friends known to be ABO compatible. Most blood banks discourage this practice and generally require donation at least 7 days prior to surgery in order to process the donated blood and confirm compatibility. Studies comparing the safety of donor-directed
units to that of random donor units have found either no difference or that random units from blood banks are safer than directed units.

CASE DISCUSSION

A Patient with Sickle Cell Disease
A 24-year-old woman with a history of sickle cell anemia presents with abdominal pain and is scheduled for cholecystectomy.

What is sickle cell anemia?

Sickle cell anemia is a hereditary hemolytic anemia resulting from the formation of an abnormal hemoglobin (HbS). HbS differs structurally from the normal adult hemoglobin (HbA) only in the substitution of valine for glutamic acid at the sixth position of the β chain. Functionally, sickle hemoglobin has less affinity for oxygen (P₅₀ = 31 mm Hg) as well as less solubility. Upon deoxygenation, HbS readily polymerizes and precipitates inside RBCs, causing them to sickle. Sickle cell patients produce variable amounts (2–20%) of fetal hemoglobin (HbF), and it is likely that cells with large amounts of HbF are somewhat protected from sickling. The continuous destruction of irreversibly sickled cells leads to anemia, and hematocrits are typically 18% to 30% due to the extravascular hemolysis. RBC survival is reduced to 10 to 15 days, compared with up to 120 days in normal individuals.

What is the difference between sickle cell anemia and sickle cell trait?

When the genetic defect for adult hemoglobin is present on both the maternally and paternally derived chromosomes (No. 11), the patient is homozygous for HbS and has sickle cell anemia (HbSS). When only one chromosome has the sickle gene, the patient is heterozygous and has sickle cell trait (HbAS). Patients with the sickle trait produce variable amounts of HbA (55–60%) and HbS (35–40%). Unlike those with HbSS, they are generally not anemic, are asymptomatic, and have a normal life span. Sickling occurs only under extreme hypoxemia or in low-flow states. Sickling is particularly apt to occur in the renal medulla; indeed, many
patients with the sickle trait have impaired renal concentrating ability. Patients with HbAS may have renal medullary, splenic, and pulmonary infarcts.

Sickle cell anemia is primarily a disease of individuals of Central African ancestry. Approximately 0.2% to 0.5% of African Americans are homozygous for the sickle gene and approximately 8% to 10% are heterozygous. Sickle cell anemia is found less commonly in patients of Mediterranean ancestry.

What is the pathophysiology?

Conditions favoring the formation of deoxyhemoglobin (eg, hypoxemia, acidosis, intracellular hypertonicity or dehydration, increased 2,3-DPG levels, or increased temperature) can precipitate sickling in patients with HbSS. Hypothermia may also be detrimental because of associated vasoconstriction (see below). Intracellular polymerization of HbS distorts red cells, makes them less pliable and more “sticky,” increasing blood viscosity. Sickling may initially be reversible but eventually becomes irreversible in some RBCs. Formation of red cell aggregates in capillaries can obstruct tissue microcirculation, and a vicious cycle is established in which circulatory stasis leads to localized hypoxia, which, in turn, causes more sickling.

With what symptoms do patients with sickle cell anemia usually present?

Patients with HbSS generally first develop symptoms in infancy, when levels of HbF decline. The disease is characterized by both acute episodic crises and chronic and progressive features (Table 51–7). Children display retarded growth and have recurrent infections. Recurrent splenic infarction leads to splenic atrophy and functional asplenism by adolescence. Patients usually die from recurrent infections or kidney failure. Chronic abdominal, bone, and joint pain is typical, often complicated by repeated, acutely painful sickling crises, and patients frequently require chronic opioid therapy. Because of issues related to analgesic tolerance and addiction, these patients often benefit from management by pain specialists. Crises are often precipitated by infection, cold weather, dehydration, or other forms of stress. Crises may be divided into three types:

1. **Vasoocclusive crises:** Depending on the vessels involved, these acute episodes can result in micro- or macroinfarctions. Most painful crises are thought to be due to microinfarcts in various tissues. Clinically, they present as acute abdominal, chest, back, or joint pain. Differentiation between surgical and nonsurgical causes of abdominal pain is difficult. Most patients form pigmented gallstones by adulthood, and many present with acute cholecystitis. Vasoocclusive phenomena in larger vessels can produce thromboses resulting in splenic, cerebral, pulmonary, hepatic, renal, and, less commonly, myocardial infarctions.

2. **Aplastic crisis:** Profound anemia (Hb 2–3 g/dL) can rapidly occur when red cell production in the bone marrow is exhausted or suppressed. Infections and folate deficiency may play a major role. Some patients also develop leukopenia.

3. **Splenic sequestration crisis:** Sudden pooling of blood in the spleen can occur in infants and young children and can cause life-threatening hypotension. The mechanism is thought to be partial or complete occlusion of venous drainage from the spleen.

**How is sickle cell anemia diagnosed?**

RBCs from patients with sickle cell anemia readily sickle following addition of an oxygen-consuming reagent (metabisulfite) or a hypertonic ionic solution (solubility test). Confirmation requires hemoglobin electrophoresis.

**What would be the best way to prepare patients with sickle cell anemia for surgery?**

Optimal preoperative preparation includes the following: patients should be well hydrated, infections should be controlled, and the hemoglobin concentration should be at an acceptable level. Preoperative transfusion must be individualized for the patient and to the surgical procedure. Partial exchange transfusions before major surgical procedures are usually advocated, which decrease blood viscosity, increase blood oxygen-carrying capacity, and decrease likelihood of sickling. The goal of such transfusions is generally to achieve a hematocrit of 35% to 40% with 40% to 50% normal hemoglobin (HbA). Chronic management of sickle cell disease has been revolutionized by the introduction of hydroxyurea.
Are there any special intraoperative considerations?

Conditions that might promote hemoglobin desaturation or low-flow states should be avoided. Every effort must be made to avoid hypothermia, hyperthermia, acidosis, and even mild degrees of hypoxemia, hypotension, or hypovolemia, and generous hydration and a relatively high (>50%) inspired oxygen tension are important. The principal compensatory mechanism for impaired tissue oxygen delivery in these patients is increased cardiac output, which should be maintained intraoperatively. GDFT may be useful. Mild alkalosis may help avoid sickling, but even moderate degrees of respiratory alkalosis may have an adverse effect on cerebral blood flow. Tourniquet use, other than brief, should be avoided.

Are there any special postoperative considerations?

Most perioperative deaths occur in the postoperative period, and the same management principles applied intraoperatively should be utilized following surgery. Hypoxemia and pulmonary complications (particularly acute chest syndrome) are major risk factors. Supplemental oxygen; optimal hemodynamic, fluid, and pain and symptom management; and pulmonary physiotherapy with early mobilization all help minimize the risk of these complications.

What is the pathophysiology of thalassemia?

Thalassemia is a hereditary defect in the production of one or more of the normal subunits of hemoglobin. Patients with thalassemia may be able to produce normal HbA but have reduced amounts of α- or β-chain production; the severity of this defect depends on the subunit affected and the degree to which hemoglobin production is affected. Symptoms range from absent to severe. Patients with α-thalassemia produce reduced amounts of the α subunit, whereas patients with β-thalassemia produce reduced amounts of the β subunit. The formation of hemoglobins with abnormal subunit composition can alter the red cell membrane and lead to variable degrees of hemolysis as well as ineffective hematopoiesis. The latter can result in hypertrophy of the bone marrow and often an abnormal skeleton. Maxillary hypertrophy may make tracheal intubation difficult. Thalassemias are most common in patients of Southeast Asian, African, Mediterranean, and Indian ancestry.

What is the significance of sickle cell anemia and thalassemia
in the same patient?

The combination of HbS and thalassemia, most commonly sickle β-thalassemia, has a variable and unpredictable effect on disease severity.

What is hemoglobin C disease?

Substitution of lysine for glutamic acid at position 6 on the β subunit results in hemoglobin C (HbC). Approximately 0.05% of African Americans carry the gene for HbC. Patients homozygous for HbC generally have only a mild hemolytic anemia and splenomegaly and rarely develop significant complications. The tendency for HbC to crystallize in hypertonic environments is probably responsible for the hemolysis and characteristically produces target cells on the peripheral blood smear.

What is the significance of the genotype HbSC?

Nearly 0.1% of African Americans are simultaneously heterozygous for both HbS and HbC (HbSC). These patients generally have a mild to moderate hemolytic anemia. Some patients occasionally have painful crises, splenic infarcts, and hepatic dysfunction. Eye manifestations similar to those associated with HbSS disease are particularly prominent. Women with HbSC have a high rate of complications during the third trimester of pregnancy and delivery.

What is hemoglobin E?

Hemoglobin E is the result of a single substitution on the β chain and is the second most common hemoglobin variant worldwide. It is most often encountered in patients from Southeast Asia. Although oxygen-binding affinity is normal, the substitution impairs production of β chains (similar to β-thalassemia). Homozygous patients have marked microcytosis and prominent target cells, but are not usually anemic and lack any other manifestations.

What is the hematologic significance of glucose-6-phosphate dehydrogenase (G6PD) deficiency?

RBCs are normally well-protected against oxidizing agents. The sulfhydryl groups on hemoglobin are protected by reduced glutathione. The latter is regenerated by NADPH (reduced nicotinamide adenine dinucleotide phosphate), which itself is regenerated by glucose metabolism
in the hexose monophosphate shunt. G6PD is a critical enzyme in this pathway. A defect in this pathway results in an inadequate amount of reduced glutathione, which can potentially result in the oxidation and precipitation of hemoglobin in red cells (seen as Heinz bodies) and hemolysis.

Abnormalities in G6PD are relatively common, with over 400 variants described. Clinical manifestations are variable, depending on the functional significance of the enzyme abnormality. Up to 15% of African American males have the common, clinically significant, A<sup>−</sup> variant. A second variant is common in individuals of eastern Mediterranean ancestry, and a third in individuals of Chinese ancestry. Because the locus for the enzyme is on the X chromosome, abnormalities are X-linked traits, with males being primarily affected. G6PD activity decreases as RBCs age; therefore, aging red cells are most susceptible to oxidation. This decay is markedly accelerated in patients with the Mediterranean variant, but only moderately so in patients with the A<sup>−</sup> variant.

Most patients with G6PD deficiency are not anemic but can develop hemolysis following stresses such as viral and bacterial infections, or after administration of certain drugs (Table 51–8). Hemolytic episodes can be precipitated by metabolic acidosis (eg, diabetic ketoacidosis) and may present with hemoglobinuria and hypotension. Such episodes are generally self-limited because only the older population of RBCs is destroyed. Mediterranean variants may be associated with chronic hemolytic anemia of varying severity and may include the classic feature of marked sensitivity to fava beans.

**TABLE 51–8** Drugs to avoid in patients with G6PD<sup>1</sup> deficiency.
Management of G6PD deficiency is primarily preventive, avoiding factors known to promote or exacerbate hemolysis. Measures aimed at preserving kidney function (see above) are indicated in patients who develop hemoglobinuria.

Thermoregulation, Hypothermia, & Malignant Hyperthermia

KEY CONCEPTS

1. When there is no attempt to actively warm an anesthetized patient, core temperature usually decreases 1°C to 2°C during the first hour of general anesthesia (phase one), followed by a more gradual decline during the ensuing 3 to 4 h (phase two), eventually reaching a point of steady state.

2. In the normal, unanesthetized patient the hypothalamus maintains core body temperature within very narrow tolerances, termed the interthreshold range, with the threshold for sweating and vasodilation at one extreme and the threshold for vasoconstriction and shivering at the other.

3. Anesthetics inhibit central thermoregulation by interfering with these hypothalamic reflex responses.

4. Postoperative hypothermia should be treated with a forced-air warming device, if available; alternately (but less satisfactorily) warming lights or heating blankets can be used to restore body temperature to normal.

5. Nearly 50% of patients who experience an episode of malignant hyperthermia (MH) have had at least one previous uneventful exposure to anesthesia during which they received a recognized triggering agent. Why MH fails to occur after every exposure to a triggering agent is unclear.

6. The earliest signs of MH during anesthesia include muscle rigidity, tachycardia, unexplained hypercarbia, and increased temperature.

7. Susceptibility to MH may be increased in several musculoskeletal diseases. These include central-core disease, multi-minicore myopathy, and King–Denborough syndrome.
Treatment of an MH episode is directed at terminating the episode and treating complications such as hyperthermia and acidosis. The mortality rate for MH, even with prompt treatment, ranges from 5% to 30%. First and most importantly, the triggering agent must be stopped; second, dantrolene must be given immediately.

Dantrolene, a hydantoin derivative, directly interferes with muscle contraction by inhibiting calcium ion release from the sarcoplasmic reticulum. The dose is 2.5 mg/kg intravenously every 5 min until the episode is terminated (upper limit, 10 mg/kg). Dantrolene should be continued for 24 h after initial treatment.

Propofol, etomidate, benzodiazepines, ketamine, thiopental, methohexital, opiates, droperidol, nitrous oxide, nondepolarizing muscle relaxants, and all local anesthetics are safe for use in MH-susceptible patients.

THERMOREGULATION & HYPOTHERMIA

Anesthesia and surgery predispose patients to hypothermia, usually defined as a body temperature less than 36°C. Unintentional perioperative hypothermia is more common in patients at the extremes of age, and in those undergoing abdominal surgery or procedures of long duration, especially with cold ambient operating room temperatures; it will occur in nearly every such patient unless steps are taken to prevent this complication.

Hypothermia (in the absence of shivering) reduces metabolic oxygen requirements and can be protective during cerebral or cardiac ischemia. Nevertheless, hypothermia has multiple deleterious physiological effects (Table 52–1). In fact, unintended perioperative hypothermia has been associated with an increased mortality rate.

TABLE 52–1 Deleterious effects of hypothermia.
Core temperature is normally the same as the central venous blood temperature (except during periods of relatively rapid temperature change as can occur during and after extracorporeal perfusion). When there is no attempt to actively warm an anesthetized patient, core temperature usually decreases 1°C to 2°C during the first hour of general anesthesia (phase one), followed by a more gradual decline during the ensuing 3 to 4 h (phase two), eventually reaching a point of steady state (phase three). With general, epidural, or spinal anesthesia most of the initial decrease in temperature during phase one is explained by redistribution of heat from warm “central” compartments (eg, abdomen, thorax) to cooler peripheral tissues (eg, arms, legs) from anesthetic-induced vasodilation. Actual heat loss from the patient to the environment is a minor contributor. Continuous heat loss to the environment is the primary driver for the slower decline during phase two. At steady state, heat loss equals metabolic heat production (Figure 52–1).
Unintentional hypothermia during general anesthesia follows a typical pattern: a steep drop in core temperature during the first hour (phase one, redistribution), followed by a gradual decline during the next 3 to 4 h (phase two, heat loss), eventually reaching a steady state (phase three).

In the normal unanesthetized patient the hypothalamus maintains core body temperature within very narrow tolerances, termed the *interthreshold range*, with the threshold for sweating and vasodilation at one extreme and the threshold for vasoconstriction and shivering at the other. Increasing core temperature a fraction of a degree induces sweating and vasodilation, whereas a minimally reduced core temperature triggers vasoconstriction and shivering. Anesthetic agents inhibit central thermoregulation by interfering with these hypothalamic reflex responses. For example, isoflurane produces a dose-dependent decrease in the threshold temperature that triggers vasoconstriction (3°C decrease for each percent of inhaled isoflurane). Both general and neuraxial anesthetics increase the interthreshold range, albeit by different mechanisms. Spinal and epidural anesthetics, like general anesthetics, lead to hypothermia by causing vasodilation and internal redistribution of heat. The thermoregulatory impairment from conduction anesthesia that allows continued heat loss is likely also due to altered perception by the hypothalamus of temperature in the anesthetized dermatomes.

**Intraoperative Considerations**

A cold ambient temperature in the operating room, prolonged exposure of a large
wound, and the use of large amounts of room-temperature intravenous fluids or high flows of unhumidified gases can contribute to hypothermia. **Prewarming the patient for half an hour with convective forced-air warming blankets prevents phase one hypothermia by eliminating the central–peripheral temperature gradient.** Methods to minimize phase two hypothermia from heat loss during anesthesia include use of forced-air warming blankets and warm-water blankets, heated humidification of inspired gases, warming of intravenous fluids, and increasing ambient operating room temperature. Passive insulators such as heated cotton blankets or so-called space blankets have limited utility unless virtually the entire body is covered.

**Postoperative Considerations**

Shivering can occur in postanesthesia care units (PACUs) or critical care units as a result of actual hypothermia or neurological aftereffects of general anesthetic agents. Shivering is also common immediately postpartum. Shivering in such instances represents the body’s effort to increase heat production and raise body temperature and may be associated with intense vasoconstriction. Emergence from even brief general anesthesia is sometimes also associated with shivering. Although shivering can be part of nonspecific neurological signs (posturing, clonus, or the Babinski sign) sometimes observed during emergence, shivering is typically associated with hypothermia and volatile anesthetics. Shivering appears to be more common after longer durations of surgery and the use of greater concentrations of a volatile agent. Occasionally, shivering is intense enough to cause hyperthermia (38–39°C) and metabolic acidosis, both of which promptly resolve when the shivering stops. Both spinal and epidural anesthesia lower the shivering threshold and vasoconstrictive response to hypothermia; shivering may also be encountered in the PACU following regional anesthesia. Other causes of shivering should be excluded, such as sepsis, drug allergy, or a transfusion reaction. Intense shivering may increase oxygen consumption, CO₂ production, and cardiac output. These physiological effects are often poorly tolerated by patients with preexisting cardiac or pulmonary impairment.

Postoperative shivering may increase oxygen consumption as much as fivefold, may decrease arterial oxygen saturation, and may be associated with an increased risk of myocardial ischemia. Although postoperative shivering can be effectively treated with small intravenous doses of meperidine (12.5–25 mg) in adults, the better option is to reduce the likelihood of shivering by maintaining normothermia. Shivering in intubated and mechanically ventilated patients can
also be controlled with sedation and a muscle relaxant pending normothermia and dissipation of all effects of anesthesia.

Postoperative hypothermia should be treated with a forced-air warming device, if available; alternately (but less satisfactorily) warming lights or heating blankets can be used. In addition to an increased incidence of myocardial ischemia, hypothermia has been associated with arrhythmias, increased transfusion requirements, and increased duration of muscle relaxant effects, the latter of which can be especially harmful in the recently extubated patient.

**MALIGNANT HYPERTHERMIA**

Malignant hyperthermia (MH) is a rare (1:15,000 in pediatric patients and 1:40,000 in adult patients) genetic hypermetabolic muscle disease, the characteristic phenotypical signs and symptoms of which most commonly appear with exposure to inhaled general anesthetics or succinylcholine (triggering agents). MH may occasionally present more than an hour after emergence from an anesthetic, and rarely may occur without exposure to known triggering agents. Most cases have been reported in young males; almost none have been reported in infants, and few have been reported in the elderly. Nevertheless, all ages and both sexes may be affected. The incidence of MH varies greatly from country to country and even among different geographic localities within the same country, reflecting varying gene pools. The upper Midwest appears to have the greatest incidence of MH in the United States.

**Pathophysiology**

A halogenated anesthetic agent alone may trigger an episode of MH (Table 52–2). In many of the early reported cases, both succinylcholine and a halogenated anesthetic agent were used and so-called masseter muscle rigidity was observed. However, succinylcholine is less frequently used in modern practice, and about half of the cases in the past decade were associated with a volatile anesthetic as the only triggering agent. Whether succinylcholine is a trigger in the absence of a volatile agent is now controversial. Nearly 50% of patients who experience an episode of MH have had at least one previous uneventful exposure to anesthesia during which they received a recognized triggering agent. Why MH fails to occur after every exposure to a triggering agent is unclear. Investigations into the biochemical causes of MH reveal an uncontrolled increase in intracellular calcium in skeletal muscle. The sudden release of calcium from sarcoplasmic reticulum removes the inhibition of troponin, resulting in sustained muscle
contraction. Markedly increased adenosine triphosphatase activity results in an uncontrolled hypermetabolic state with significantly increased oxygen consumption and CO₂ production, producing severe lactic acidosis and hyperthermia.

Most patients with an episode of MH have relatives who have had a similar episode or who have an abnormal halothane–caffeine contracture test (see later discussion). The complexity of genetic inheritance patterns in families reflects the fact that MH can be associated with a variety of different mutations. The major focus of investigations into the genetic mechanisms of MH has been on the gene for the ryanodine (Ryr₁) receptor, located on chromosome 19. Ryr₁ is a calcium channel responsible for calcium release from the sarcoplasmic reticulum and it plays an important role in muscle depolarization. Most investigators believe that MH results from abnormalities in this channel. The great majority of families in which there is susceptibility to MH harbor one of the known mutations of Ryr₁.

**Clinical Manifestations**

- The earliest signs of MH during anesthesia include muscle rigidity, tachycardia, unexplained hypercarbia, and increased temperature (Table 52–3). Two or more of these signs greatly increase the likelihood that the clinical signs are the result of MH. The hypercarbia (due to increased CO₂ production) results in tachypnea when muscle relaxants are not used. Overactivity of the sympathetic nervous system produces tachyarrhythmias, hypertension, and
mottled cyanosis. Hyperthermia may be an early sign, and when it occurs, core temperature can rise as much as 1°C every 5 min. Generalized muscle rigidity is not always present. Hypertension may be rapidly followed by hypotension if cardiac depression occurs. Dark-colored urine reflects myoglobinemia and myoglobinuria.

Laboratory testing typically reveals mixed metabolic and respiratory acidosis with a marked base deficit, hyperkalemia, hypermagnesemia, and reduced mixed-venous oxygen saturation. Some case reports describe isolated respiratory acidosis early in the course of an episode of MH. Serum ionized calcium concentration is variable: It may initially increase before a later decrease. Patients typically have increased serum myoglobin, creatine kinase (CK), lactic dehydrogenase, and aldolase levels. When peak serum CK levels (the maximum
is usually measured 12–18 h after anesthesia) exceed 20,000 IU/L the diagnosis is strongly suspected. It should be noted that succinylcholine administration to some normal patients without MH may cause serum myoglobin and CK levels to increase markedly.

Much of the problem in diagnosing MH arises from its variable presentation. An unanticipated doubling or tripling of end-tidal CO₂ (in the absence of a ventilatory change) is an early and sensitive indicator of MH. If the patient survives the initial presentation, acute kidney failure and disseminated intravascular coagulation (DIC) can rapidly ensue. Other complications of MH include cerebral edema with seizures and hepatic failure. Most MH deaths are due to DIC and organ failure due to delayed or no treatment with dantrolene.

Susceptibility to MH may be increased in several musculoskeletal diseases. These include central-core disease, multi-minicore myopathy, and King–Denborough syndrome. Duchenne and other muscular dystrophies, nonspecific myopathies, heat stroke, and osteogenesis imperfecta have been associated with MH-like symptoms in some reports; however, their association with MH is controversial. Other possible clues to susceptibility include a family history of anesthetic complications, or a history of unexplained fevers or muscular cramps. There are several reports of MH episodes occurring in patients with a history of exercise-induced rhabdomyolysis. Prior uneventful anesthetics and absence of a positive family history are notoriously unreliable predictors of lack of susceptibility to MH. Any patient who develops masseter muscle rigidity during induction of anesthesia should be considered potentially susceptible to MH.

**Intraoperative Considerations**

Treatment of an MH episode is directed at terminating the episode and treating complications such as hyperthermia and acidosis. The mortality rate for MH, even with prompt treatment, ranges from 5% to 30%. Table 52-4 illustrates a standard protocol for management of MH.

**TABLE 52–4  Protocol for immediate treatment of malignant hyperthermia.**¹
1. Discontinue volatile anesthetic and succinylcholine. Notify the surgeon. Call for help.
2. Mix dantrolene sodium with sterile distilled water and administer 2.5 mg/kg intravenously as soon as possible.
3. Administer bicarbonate for metabolic acidosis.
4. Institute cooling measures (lavage, cooling blanket, cold intravenous solutions).
5. Treat severe hyperkalemia with dextrose, 25–50 g intravenously, and regular insulin, 10–20 units intravenously (adult dose).
6. Administer antiarrhythmic agents if needed despite correction of hyperkalemia and acidosis.
7. Monitor end-tidal CO₂ tension, electrolytes, blood gases, creatine kinase, serum myoglobin, core temperature, urinary output and color, and coagulation status.
8. If necessary, consult on-call physicians at the 24-hour MHAUS hotline, 1-800-644-9737.

A. Acute Treatment Measures
First and most importantly, volatile agents and succinylcholine must be discontinued immediately. Even trace amounts of anesthetics released from soda lime, breathing tubes, and breathing bags may be detrimental. The patient should be hyperventilated with 100% oxygen to counteract the effects of uncontrolled CO₂ production and increased oxygen consumption.

B. Dantrolene Therapy
The mainstay of therapy for MH is immediate administration of intravenous dantrolene. Its safety and efficacy mandate its immediate use in this potentially life-threatening situation. Dantrolene, a hydantoin derivative, directly interferes with muscle contraction by binding the RyR₁ receptor channel and inhibiting calcium ion release from the sarcoplasmic reticulum. The dose is 2.5 mg/kg intravenously every 5 min until the episode is terminated (upper limit, 10 mg/kg). “Conventional” dantrolene is packaged as 20 mg of lyophilized powder to be dissolved in 60 mL of sterile water, thus, reconstitution of the initial dose can be unavoidably time consuming. A new, more costly formulation is available in which 250 mg can be reconstituted in 5 mL, making it an attractive option for

¹Data from the MHAUS protocol available at https://www.mhaus.org/healthcare-professionals/mhaus-recommendations/.
the “initial” dose of dantrolene given as an emergency treatment when MH is first diagnosed (Table 52–5). The effective half-life of dantrolene is about 6 h.

1Personal Communication from Rodney Stiltner, VCU Health System, Richmond, VA; 23 Apr 2018.

After initial control of symptoms, 1 mg/kg of dantrolene intravenously is recommended every 6 h for 24 to 48 h to prevent relapse (MH can recur within 24 h of an initial episode). Dantrolene is a relatively safe drug that is also used to decrease temperature in patients with thyroid “storm” and neuroleptic malignant syndrome. Although its use in chronic therapy for spastic disorders has been associated with hepatic dysfunction, the most serious complication following acute administration is generalized muscle weakness that may result in respiratory insufficiency or aspiration pneumonia. Dantrolene can cause phlebitis in small peripheral veins and should be given through a central venous line if one is available. Following administration of dantrolene, most patients revert to normal acid–base status promptly and no further pharmacological treatment is necessary.

**C. Correction of Acid–Base/Electrolyte Imbalances**

Persisting metabolic acidosis should be treated with intravenous sodium bicarbonate, recognizing that this treatment will worsen the hypercarbia.
Hyperkalemia should be treated with glucose, insulin, and diuresis. There is no useful role for intravenous calcium salts in treatment of MH. Antiarrhythmic agents, vasopressors, and inotropes should be administered if indicated. Calcium channel blockers should not be given to patients receiving dantrolene because this combination appears to promote hyperkalemia. Furosemide may be used to establish diuresis and prevent acute kidney failure, which may develop as a consequence of myoglobinuria. Dantrolene contains a considerable amount of mannitol (3 g per 20-mg bottle); thus furosemide or bumetanide should be used in preference to mannitol for diuresis.

**D. Cooling the Patient**

If fever is present, cooling measures should be instituted immediately. Surface cooling with ice packs over major arteries, cold air convection, and cooling blankets are used. Iced saline lavage of the stomach and any open body cavities (eg, in patients undergoing abdominal surgery) should also be instituted. Use of hypothermic cardiopulmonary bypass may be appropriate if other measures fail.

**E. Management of the Patient with Isolated Masseter Muscle Rigidity**

Masseter muscle rigidity, or trismus, is a forceful contraction of the jaw musculature that prevents full mouth opening. This must be distinguished from incomplete jaw relaxation due to inadequate dosing or inadequate delay after dosing of muscle relaxants. Both myotonia and MH can cause masseter spasm. The two disorders can be differentiated by the medical history, neurological examination, and electromyography. The historical incidence of masseter muscle rigidity following administration of succinylcholine with halothane to pediatric patients was 1% or more; fortunately, only a small fraction of these patients actually developed MH. Isolated masseter muscle rigidity is now of mostly historical interest given the rare combination of halothane and succinylcholine in current pediatric practice. When this occurs and there is no other sign of MH, most anesthesiologists would allow surgery to continue using non-triggering anesthetic agents. Elevated serum CK levels after an episode of masseter muscle rigidity may indicate an underlying myopathy.

**Postoperative Considerations**

**A. Confirmation of the Diagnosis**
Patients who have survived an unequivocal episode of MH are considered susceptible. If the diagnosis remains in doubt postoperatively, testing is indicated. Baseline CK may be elevated chronically in 50% to 70% of people at risk for MH but is not diagnostic. A halothane-caffeine contracture test will require that a fresh biopsy specimen of living skeletal muscle be exposed to a caffeine, halothane, or combination caffeine–halothane bath. The halothane–caffeine contracture test may have a 10% to 20% false-positive rate, but the false-negative rate is close to zero. Very few centers worldwide perform this test, and there are only two such sites remaining in the United States. More commonly (and much more conveniently) genetic testing of patients and first-degree relatives is performed.

Both European and North American MH registries have been established to help physicians identify and treat patients with suspected MH, as well as provide standardization for diagnosis and testing. The Malignant Hyperthermia Association of the United States (MHAUS, telephone 1-800-986-4287) operates a 24-hour hotline (1-800-644-9737) and a web site (http://www.mhaus.org). This web site has a useful and frequently updated section on the genetic testing and diagnosis of patients suspected of having MH.

1. Differential diagnosis—Several disorders may superficially resemble MH (Table 52–6). However, MH is associated with greater degrees of metabolic acidosis and venous desaturation than any of these other conditions. In current practice, the most common condition confused with MH is hypercarbia from CO₂ insufflation for laparoscopy. This condition can result in an unexpected increase in end-tidal CO₂ with accompanying tachycardia. Surgery and anesthesia can precipitate thyroid storm in undiagnosed or poorly controlled hyperthyroid patients. The signs of thyroid storm include tachycardia, tachyarrhythmias (particularly atrial fibrillation), hyperthermia (often ≥40°C), hypotension, and in some cases congestive heart failure. In contrast to MH, hypokalemia is very common. Also unlike the typical intraoperative presentation of MH, thyroid storm generally develops postoperatively (see Chapter 35). Pheochromocytoma is associated with dramatic increases in heart rate and blood pressure but not with an increase in CO₂ production, end-tidal CO₂, or temperature (see Chapter 35). Cardiac arrhythmias or ischemia may also be prominent. Rarely such patients may have hyperthermia (>38°C), which is generally thought to be due to increased heat production from catecholamine-mediated increases in metabolic rate together with decreased heat elimination from intense vasoconstriction. Sepsis shares several characteristics with MH,
including fever, tachypnea, tachycardia, and metabolic acidosis (see Chapter 57). Sepsis can be difficult to diagnose if there is no obvious primary site of infection.

**TABLE 52–6** Differential diagnosis of hyperthermia in the intraoperative and immediate postoperative periods.

Less commonly, drug-induced hyperthermia may be encountered in the perioperative period. In these cases, the drugs appear to markedly increase serotonin activity in the brain, causing hyperthermia, confusion, shivering, diaphoresis, hyperreflexia, and myoclonus. Drug combinations associated with this serotonin syndrome include monoamine oxidase inhibitors (MAOIs) and meperidine, and MAOIs and selective serotonin reuptake inhibitors (SSRIs). Hyperthermia can also be caused by some illicit drugs, including 3,4-methylenedioxymethamphetamine (MDMA or “ecstasy’), “crack” cocaine, amphetamines, phencyclidine (PCP), and lysergic acid diethylamine (LSD).

Iatrogenic hyperthermia is also a possibility, particularly in pediatric patients. Common sources of excessive heat in the operating room include humidifiers on ventilators, warming blankets, heat lamps, and increased ambient temperature. Injuries to the brainstem, hypothalamus, or nearby regions can be associated with marked hyperthermia.

2. **Neuroleptic malignant syndrome (NMS)**—NMS is characterized by hyperthermia, muscle rigidity with extrapyramidal signs (dyskinesia), altered consciousness, and autonomic lability in patients receiving antidopaminergic agents. The syndrome is caused by an imbalance of neurotransmitters in the central nervous system. It can occur either during drug therapy with antidopaminergic agents (eg, phenothiazines, butyrophenones, thioxanthenes, or
metoclopramide) or less commonly following the withdrawal of dopaminergic agonists (levodopa or amantadine) in patients with Parkinson disease. Thus, it appears to involve abnormal central dopaminergic activity, as opposed to the altered peripheral calcium release seen in MH. These differing mechanisms probably explain why nondepolarizing relaxants reverse the rigidity of NMS, but not the rigidity associated with MH.

NMS does not appear to be inherited and typically takes hours to weeks to develop; the majority of episodes develop within 2 weeks of a dose adjustment. Hyperthermia generally tends to be mild, and appears to be proportional to the amount of rigidity. Autonomic dysfunction results in tachycardia, labile blood pressure, diaphoresis, increased secretions, and urinary incontinence. Muscle rigidity can produce dyspnea and respiratory distress and, together with the increased secretions, can promote aspiration pneumonia. CK levels are typically elevated; some patients may develop rhabdomyolysis resulting in myoglobinemia, myoglobinuria, and kidney failure.

Mild forms of NMS promptly resolve after withdrawal of the causative drug (or reinstitution of antiparkinsonian therapy). Initial treatment of more severe forms of NMS should include oxygen therapy and endotracheal intubation for respiratory distress or altered consciousness. Marked muscle rigidity can be controlled with muscle paralysis, dantrolene, or a dopaminergic agonist (amantadine, bromocriptine, or levodopa), depending on the severity and acuity of the syndrome. Resolution of the muscle rigidity usually decreases body temperature.

This syndrome is considered a separate entity from MH; nevertheless, some clinicians believe that NMS may predispose patients to MH and recommend that patients with NMS should not receive succinylcholine or a volatile anesthetic. In contrast to patients with NMS, patients susceptible to MH can safely receive phenothiazines.

B. Prophylaxis, Postanesthesia Care, and Discharge

Propofol, etomidate, benzodiazeines, ketamine, thiopental, methohexitol, opiates, droperidol, nitrous oxide, nondepolarizing muscle relaxants, and all local anesthetics are safe for use in MH-susceptible patients. An adequate supply of dantrolene should always be available wherever general anesthesia is provided. Prophylactic administration of intravenous dantrolene to susceptible patients is not appropriate if a nontriggering anesthetic is administered.

For MH-susceptible patients, the consensus is that the vaporizers should be removed from the anesthesia workstation (or fixed in an “off” position) and the
machine should be flushed with 10 L/min of fresh gas (air or oxygen) for at least 5 min. This step should reduce concentrations of volatile anesthetics to less than 1 part per million. Additionally, the CO₂ absorbent and circle system (or other anesthetic circuit) hoses should be changed. **Manufacturers of modern anesthesia machines make differing recommendation (based on the design of their machine) for how to prepare their machines to manage MH-susceptible patients. We strongly recommend that the reader review the specific recommendations for the anesthesia machine(s) at their hospital.**

MH-susceptible patients who have undergone an uneventful procedure with a nontriggering anesthetic can be discharged from the PACU or ambulatory surgery unit when they meet standard criteria. There are no reported cases of MH-susceptible patients experiencing MH after receiving a nontriggering anesthetic during uneventful surgery.

CHAPTER 53

Nutrition in Perioperative & Critical Care

KEY CONCEPTS

1. The fit, previously well-nourished patient undergoing elective surgery could be fasted for up to a week postoperatively without apparent adverse effect on outcomes, provided that fluid and electrolyte needs are met. On the other hand, it is well established in multiple studies that malnourished patients benefit from nutritional repletion via either enteral or parenteral routes prior to surgery.

2. The indications for total parenteral nutrition (TPN) are narrow, including those patients who cannot absorb enteral solutions (small bowel obstruction, short gut syndrome, etc); partial parenteral nutrition may be indicated to supplement enteral nutrition (EN) when EN cannot fully provide for nutritional needs.

3. TPN will generally require a venous access line with its catheter tip in the superior vena cava. The line or port through which the TPN solution will be infused should be dedicated to this purpose, if at all possible, and strict aseptic techniques should be employed for insertion and care of the catheter.

4. In the patient with critical illness, discontinuing an EN infusion may require multiple potentially dangerous adjustments in insulin infusions and maintenance of intravenous fluid rates. Meanwhile, the evidence is sparse that EN infusions delivered through an appropriately sited gastrointestinal feeding tube increases the risk of aspiration pneumonitis.

5. Regardless of whether the TPN infusion is continued, reduced, replaced with 10% dextrose, or stopped, blood glucose monitoring will be needed during all but short, minor surgical procedures.
Issues related to nutrition tend to be far removed from the usual concerns of the surgical anesthesiologist, other than those related to whether patient listed for elective surgery has fasted for whatever interval one’s institution or colleagues insist upon (this highly controversial issue is also considered in Chapter 19). On the other hand, appropriate nutritional support has been recognized to be of key importance for favorable outcomes in patients with critical illness, a large fraction of whom will require procedural services. Severe malnutrition causes widespread organ dysfunction and increases the risk of perioperative morbidity and mortality. Nutritional repletion may improve wound healing, restore immune competence, and reduce morbidity and mortality rates in critically ill patients. Nutritional support is a key element of an enhanced recovery program (these issues are dealt with in Chapter 48).

This chapter does not provide a complete review of nutrition in the patient undergoing surgery or with critical illness, but rather offers the framework for providing basic nutritional support in such patients. We consider, for example, whether enteral nutrition (EN) or parenteral nutrition (PN) will best meet the needs of an individual patient. This chapter also briefly reviews the conditions under which the ongoing nutritional needs of patients may come into conflict with anesthetic preferences and dogmas, such as the duration that patients must not receive EN before undergoing general anesthesia.

**BASIC NUTRITIONAL NEEDS**

Maintenance of normal body mass, composition, structure, and function requires intake of water, energy substrates, and specific nutrients. Ions and compounds that cannot be synthesized from other nutrients are characterized as “essential.” Relatively few essential nutrients are required to form the thousands of compounds that make up the body. Known essential nutrients include 8 to 10 amino acids, 2 fatty acids, 13 vitamins, and approximately 16 minerals.

Energy is normally derived from dietary or endogenous carbohydrates, fats, and protein. Metabolic breakdown of these substrates yields the adenosine triphosphate required for normal cellular function. Dietary fats and carbohydrates normally supply most of the body’s energy requirements. Dietary proteins provide amino acids for protein synthesis; however, when their supply exceeds requirements, amino acids also function as energy substrates. The metabolic pathways of carbohydrate, fat, and amino acid substrates overlap, such that some interconversions can occur (see Figure 33–4). Excess amino acids can
be converted to carbohydrate or fatty acid precursors. Excess carbohydrates are stored as glycogen in the liver and skeletal muscle. When glycogen stores are saturated (200–400 g in adults), excess carbohydrate is converted to fatty acids and stored as triglycerides, primarily in fat cells.

During starvation, the protein content of essential tissues is spared. As blood glucose concentration begins to fall during fasting, insulin secretion decreases and counterregulatory hormones (eg, glucagon) increase. Hepatic and, to a lesser extent, renal glycogenolysis and gluconeogenesis are enhanced. As glycogen supplies are depleted (within 24 h), gluconeogenesis from amino acids becomes increasingly important. Only neural tissue, renal medullary cells, and erythrocyes continue to utilize glucose—in effect, sparing tissue proteins. Lipolysis is enhanced, and fats become the principal energy source. Glycerol from triglycerides enters the glycolytic pathway, and fatty acids are broken down to acetylcoenzyme A (acetyl-CoA). Excess acetyl-CoA results in the formation of ketone bodies (ketosis). Some fatty acids can contribute to gluconeogenesis. If starvation is prolonged, the brain, kidneys, and muscle also begin to utilize ketone bodies efficiently.

The previously well-nourished patient undergoing elective surgery could be fasted for up to a week postoperatively, provided fluid and electrolyte needs are met. Whether early postoperative nutritional support influences outcomes likely relates to the degree of preoperative malnutrition, number of nutrient deficiencies, and severity of the illness, injury, or surgical procedure. The optimal timing and amount of nutrition support following acute illness remain unknown. On the other hand, malnourished patients likely benefit from nutritional repletion prior to and after surgery.

Modern surgical practice has evolved to an expectation of an accelerated (“enhanced”) recovery. Enhanced recovery programs generally include early enteral feeding, even in patients undergoing surgery on the gastrointestinal tract, so prolonged periods of postoperative starvation are no longer common practice. Such protocols often specify a carbohydrate drink the night before surgery and again shortly before operation. Previously well-nourished patients should receive nutritional support after no more than 5 days of postsurgical starvation, and those with ongoing critical illness or severe malnutrition should be given nutritional support immediately. The healing of wounds requires energy, protein, lipids, electrolytes, trace elements, and vitamins. Depletion of any of these substrates may delay wound healing and predispose to complications, such as infection. Nutrient depletion may also delay optimal muscle function, which is important for supporting increased respiratory demands and early mobilization of the
The resting metabolic rate can be measured (but often inaccurately) using indirect calorimetry (known as a metabolic cart) or by estimating energy expenditure using standard nomograms (such as the Harris–Benedict equation) to approximate the daily energy requirements. Alternatively, a simple and practical approach assumes that patients require 25 to 30 kcal/kg daily. The weight is usually taken as the ideal body weight or adjusted body weight. One determines the daily requirements to ensure that patients are not unnecessarily overfed, recognizing that nutritional requirements can increase greatly above basal levels with certain conditions (eg, burns). Thus, obese patients require an estimation of ideal body weight to prevent overfeeding.

**HOW TO FEED THE PATIENT**

After total parenteral nutrition (TPN) was established as a feasible approach for feeding patients lacking a functional gut, physicians extended the practice of TPN to many circumstances where “logic” or “clinical experience” suggested that it would be better than EN. In the past, one such indication was acute pancreatitis: In the 1970s, many clinicians thought that a period of TPN would put the gut and pancreas at “rest,” allowing for weight gain and resolution of pain. Unfortunately, both “logic” and “clinical experience” were incorrect. Now, the worldwide consensus expressed in clinical practice guidelines is that patients with acute pancreatitis (and indeed all others with functioning guts) will have worse outcomes if TPN is provided, rather than EN. Today, the indications for TPN are narrow and include patients who cannot absorb enteral solutions (small bowel obstruction, short gut syndrome, etc); partial PN may be indicated to supplement EN when EN cannot fully provide for nutritional needs. In the latter circumstance, recent evidence supports delaying supplemental PN in previously well-nourished patients. Earlier initiation of supplemental PN in previously well-nourished patients, as had been supported by 2009 European guidelines, resulted in worse outcomes in a large randomized clinical trial; however, smaller randomized clinical trials have suggested findings to the contrary. The divergent results from these recent trials may be associated with the type of parenteral formulations being used, types of patients being studied, timing of PN administration, and treatment in the control groups. Thus, further studies are needed to better define patients who may benefit from PN, as well as the optimal timing of nutritional support and formulations for feeding. In short, EN should be the primary mode of nutritional support, and PN should be used when EN is not indicated, not tolerated, or not sufficient.
There was a time when nearly every physician who took care of critically ill patients was in the position of frequently ordering TPN for patients. This is no longer the case, given that EN is now so much more widely employed. As a consequence, many hospitals and health systems insist that a nutrition support team take responsibility for those rarer patients who require TPN.

In general, patients with critical illness should undergo whatever initial hemodynamic resuscitation they require before initiation of nutritional support (either EN or PN). Absorption, distribution, and metabolism of nutrients require tissue blood flow, oxygen, and carbon dioxide removal. Adequate tissue blood flow requires an adequately resuscitated patient. Patients with critical illness who require EN will usually require placement of a feeding tube. Feeding tubes may be placed into the stomach in patients with adequate gastric emptying and low risk of aspiration. In patients with delayed gastric emptying or those at high risk of aspiration, feeding tubes are best placed into the small intestine. Ideally, the tip of such tubes will be sited within the small intestine, either by transpyloric placement of a nasoenteral tube or directly into the jejunum (via a percutaneous route) during abdominal surgery, reducing the likelihood of gastric distention and regurgitation. Patients who are unable to eat, but require EN over long periods of time, will often undergo percutaneous endoscopic placement of gastrostomy (PEG) tubes (the tips of such tubes can be sited distal to the pylorus). One should confirm that the tips of all feeding tubes are appropriately located before initiating feeds to reduce the likelihood that EN solutions will be accidentally infused, say, into the tracheobronchial tree or abdominal cavity.

TPN will generally require that a venous access line be placed with the catheter tip in the superior vena cava. PN can be given through a peripheral intravenous catheter but will require larger volumes of fluid (to accommodate the requirement for reduced osmolarity) and will carry an increased risk of phlebitis. The catheter or port through which the TPN solution will be infused should be dedicated to this purpose, if at all possible, and strict aseptic techniques should be employed for insertion and care of the catheter.

**COMPLICATIONS OF NUTRITIONAL SUPPORT**

Diarrhea is a common problem with EN and may be related to either hyperosmolarity of the solution or lactose intolerance. Gastric distention is another complication that increases the risk of regurgitation and pulmonary aspiration; the use of duodenal or jejunostomy tubes should decrease the likelihood of gastric distention. Complications of TPN are either metabolic or related to central venous access (Table 53–1). Bloodstream infections associated
with central and peripheral venous lines remain a major concern, particularly in patients with critical illness and immunocompromised states.

Overfeeding with excess amounts of glucose can increase energy
requirements and production of carbon dioxide; the respiratory quotient can be greater than 1 because of lipogenesis. Overfeeding can lead to reversible cholestatic jaundice. Mild elevations of serum transaminases and alkaline phosphatase may reflect fatty infiltration of the liver as a result of overfeeding.

SPECIFIC NUTRIENTS

Certain nutrients have been associated with improved outcomes. Surgery and anesthesia are well-recognized inducers of inflammation, producing changes in local (near the wound) and plasma concentrations of neurohormones, cytokines, and other mediators. Many investigators have hypothesized that adverse neurohormonal and inflammatory responses to surgery and anesthesia can be ameliorated through specific diets. Several clinical trials (and a recent meta-analysis) suggest that the addition of “immunomodulating” nutrients (specifically arginine and “fish” oil) to EN may reduce the risk of infection and reduce the length of hospital stay in high-risk surgical patients. Similarly, current guidelines for perioperative PN also advocate the inclusion of n-3 fatty acids. There is some evidence that inclusion of long-chain n-3 polyunsaturated fatty acids (n-3 PUFAs), long-chain monounsaturated fatty acids (found in olive oil), or medium-chain fatty acids may be preferable to the use of solutions (such as soybean-derived lipids) that are rich in longer chain n-6 PUFA. However, such solutions (although widely available outside of the United States) are not approved for use in the United States.

In the past, it was customary to individualize TPN solutions for each patient. Currently, there is little evidence that this is necessary, except in patients who cannot handle a sodium load (eg, those with severe heart failure). Adjustments may also be made in patients requiring renal replacement therapy; however, in most cases this is not necessary. Similarly, except in patients who are already suffering from hepatic encephalopathy, most patients with liver disease can safely receive standard amino acid solutions. Thus, most patients receiving EN and PN can be safely managed with standardized, “off-the-shelf” nutritional formulations. Both EN and PN standardized formulations are available in ready-to-use formats that decrease preparation times, reduce contamination risks during formulation, and are associated with lower costs and similar outcomes to compounded solutions.

ENTERAL NUTRITION & NIL PER OS RULES PRIOR TO ELECTIVE SURGERY
Long before the recognition by Mendelsohn of the problem posed by aspiration pneumonitis, anesthesiologists were reluctant to anesthetize patients scheduled for elective surgery if they had not been fasted overnight. Over time, the duration of obligatory time of no solid food *per os* has steadily declined, particularly in infants and young children. In the patient with critical illness, discontinuing an EN infusion may require multiple potentially dangerous adjustments in insulin infusions and maintenance of intravenous fluid rates. Meanwhile, the evidence is sparse that EN infusions delivered through an appropriately sited gastrointestinal feeding tube increases the risk of aspiration pneumonitis. It is also relatively easy to empty the stomach immediately prior to anesthesia and surgery using 5 to 10 minutes of intermittent suction through a nasogastric tube. Therefore, current guidelines and current published evidence support continuing EN infusions (particularly when they are delivered distal to the pylorus) perioperatively and intraoperatively. Similarly, allowing preoperative patients to consume clear liquids, as desired, up to the time of surgery seems to have no influence on the risk of adverse outcomes from aspiration pneumonitis. Moreover, there is abundant evidence that administering a preoperative carbohydrate “load” to nondiabetic patients shortly before surgery will have the salutary metabolic effect of increasing plasma insulin concentrations, decreasing postoperative insulin resistance, reducing the likelihood of hemodynamic instability, and reducing the likelihood of postoperative nausea or vomiting. Such preoperative carbohydrate loading is not nearly as commonplace as we believe it should be.

**TPN & SURGERY**

Patients who receive TPN often require surgical procedures. Metabolic abnormalities are relatively common and, ideally, should be corrected preoperatively. For example, hypophosphatemia is a serious and often unrecognized complication that can contribute to postoperative muscle weakness and respiratory failure.

When TPN infusions are suddenly stopped or decreased perioperatively, hypoglycemia may develop. Frequent measurements of blood glucose concentration are therefore required in such instances during general anesthesia. Conversely, if the TPN solution is continued unchanged, excessive hyperglycemia resulting in hyperosmolar nonketotic coma or ketoacidosis (in patients with diabetes) is also possible. The neuroendocrine stress response to surgery frequently aggravates glucose intolerance. Regardless of whether the TPN infusion is continued, reduced, replaced with 10% dextrose, or stopped,
blood glucose monitoring will be needed during all but short, minor surgical procedures.

GUIDELINES

SUGGESTED READINGS

Anesthetic Complications

KEY CONCEPTS

1. The likelihood of anesthetic complications will never be zero. All anesthesia practitioners, irrespective of their experience, abilities, diligence, and best intentions, will participate in anesthetics that are associated with patient injury.

2. Malpractice occurs when four requirements have been met: (1) the practitioner must have a duty to the patient; (2) there must have been a breach of duty (deviation from the standard of care); (3) the patient (plaintiff) must have suffered an injury; and (4) the proximate cause of the injury must have been the practitioner’s deviation from the standard of care.

3. Anesthetic mishaps can be categorized as preventable or unpreventable. Of the preventable incidents, most involve human error, as opposed to equipment malfunctions.

4. The relative decrease in death attributed to respiratory rather than cardiovascular damaging events has been attributed to the increased use of pulse oximetry and capnometry.

5. Many anesthetic fatalities occur only after a series of coincidental circumstances, misjudgments, and technical errors combine (mishap chain).

6. Despite differing mechanisms, anaphylactic and anaphylactoid reactions are typically clinically indistinguishable and equally life threatening.

7. True anaphylaxis due to anesthetic agents is rare; anaphylactoid reactions are much more common.

8. Patients with spina bifida, spinal cord injury, and congenital abnormalities of the genitourinary tract have a markedly increased incidence of latex allergy. The incidence of latex anaphylaxis in children is estimated to be 1 in 10,000.
There is no clear evidence that exposure to trace amounts of anesthetic agents presents a health hazard to operating room personnel; however, the U.S. Occupational Health and Safety Administration continues to set maximum acceptable trace concentrations of less than 25 ppm for nitrous oxide and 0.5 ppm for halogenated anesthetics (2 ppm if the halogenated agent is used alone).

Hollow (hypodermic) needles pose a greater risk than do solid (surgical) needles because of the potentially larger inoculum. The use of gloves, needleless systems, or protected needle devices may decrease the incidence of some (but not all) types of injury.

Anesthesiology is a high-risk medical specialty for substance abuse.

The three most important methods of minimizing radiation doses are limiting total exposure time during procedures, using proper barriers, and maximizing one’s distance from the source of radiation.

The likelihood of anesthetic complications will never be zero. All anesthesia practitioners, irrespective of their experience, abilities, diligence, and best intentions, will participate in anesthetics that are associated with patient injury. Moreover, unexpected adverse perioperative outcomes can lead to litigation, even if those outcomes did not directly arise from anesthetic mismanagement. This chapter reviews management approaches to complications secondary to anesthesia and discusses medical malpractice and legal issues from an American (U.S.) perspective. Readers based in other countries may not find this section to be as relevant to their practices.

**LITIGATION & ANESTHETIC COMPlications**

All anesthesia practitioners will have patients with adverse outcomes, and in the United States most anesthesiologists will at some point in their career be involved to one degree or another in malpractice litigation. Consequently, anesthesia staff should expect litigation to be a part of their professional lives and maintain adequate medical malpractice liability insurance with coverage appropriate for the community in which they practice.

When unexpected events occur, anesthesia staff must generate an appropriate differential diagnosis, seek any necessary consultation, and execute a treatment plan to mitigate (to the greatest degree possible) any patient injury. Appropriate documentation in the patient record is helpful, as adverse outcomes may be reviewed by quality assurance and performance improvement authorities.
Deviations from acceptable practice will likely be noted in the practitioner’s quality assurance file. Should an adverse outcome lead to litigation, the medical record documents the practitioner’s actions at the time of the incident. Years may pass before litigation proceeds to the point where the anesthesia provider is asked about the case in question. Although memories fade, a clear and complete anesthesia record can provide evidence that a complication was recognized and appropriately treated.

It is often difficult to predict which cases will be pursued by plaintiffs! Litigation may ensue when it is clear (at least to the defense team) that the anesthesia care conformed to standards, and, conversely, a suit may not be filed when there is obvious anesthesia culpability. That said, anesthetics that are followed by unexpected death, paralysis, or brain injury of young, economically productive individuals are particularly attractive to plaintiff’s lawyers. When a patient has an unexpectedly poor outcome, one should expect litigation irrespective of one’s “positive” relationship with the patient or the injured patient’s family or guardians.

Malpractice occurs when four requirements are met: (1) the practitioner must have a duty to the patient; (2) there must have been a breach of duty (deviation from the standard of care); (3) the patient (plaintiff) must have suffered an injury; and (4) the proximate cause of the injury must have been the practitioner’s deviation from the standard of care. A duty is established when the practitioner has an obligation to provide care (physician–patient relationship). The practitioner’s failure to execute that duty constitutes a breach of duty. Injuries can be physical, emotional, or financial. Causation is established if but for the breach of duty, the patient would not have experienced the injury. When a claim is meritorious, the tort system attempts to compensate the injured patient or family members, or both, by awarding them monetary damages.

Being sued is stressful, regardless of the perceived “merits” of the claim. Preparation for defense begins before an injury has occurred. The patient grants informed consent following a discussion of the risks and benefits of the anesthesia options that are available and reasonable. Informed consent does not consist of handing the patient a form to sign. Informed consent requires that the patient understand the choices being presented. As previously noted, appropriate documentation of patient care activities, differential diagnoses, and therapeutic interventions helps to provide a defensible record of the care that was provided, resistant to the passage of time and the stress of the litigation experience.

When an adverse outcome occurs, the hospital or practice risk management group, or both, should be immediately notified. Likewise, one’s liability
insurance carrier should be notified of the possibility of a claim for damages. Some policies have a clause that disallows the practitioner from admitting errors to patients and families. Consequently, it is important to know and obey the institution’s and insurer’s approach to adverse outcomes. Nevertheless, most risk managers advocate a frank and honest disclosure of adverse events to patients or approved family members. It is possible to express sorrow about an adverse outcome without admitting “guilt.” It may be helpful to have such discussions while accompanied by risk management personnel or a departmental leader.

It must never be forgotten that the tort system is designed to be adversarial. Unfortunately, this makes every patient a potential courtroom adversary. Malpractice insurers will hire a defense firm to represent the anesthesia staff involved. Typically, multiple practitioners and the hospitals in which they work will be named to involve the maximal number of insurance policies that might pay in the event of a plaintiff’s victory, and to ensure that the defendants cannot choose to attribute “blame” for the adverse event to whichever person or entity was not named in the suit. In some systems (usually when everyone in a health system is insured by the same carrier), all of the named entities are represented by one defense team. More commonly, various insurers and attorneys represent specific practitioners and institutional providers. In this instance, those involved may deflect and diffuse blame from themselves and focus blame on others also named in the action. Discovery is the process by which the plaintiff’s attorneys access the medical records and depose witnesses under oath to establish the elements of the case: duty, breach, injury, and causation. False testimony can lead to criminal charges of perjury. One should not discuss elements of any case with anyone other than a risk manager, insurer, or attorney, as other conversations are not protected from discovery.

Oftentimes, expediency and financial risk exposure will argue for settlement of the case. The practitioner may or may not be able to participate in this decision depending upon the insurance policy. Settled cases are reported to the National Practitioner Data Bank and become a part of the physician’s record. Moreover, malpractice suits, settlements, and judgments must be reported to hospital authorities as part of the credentialing process. When applying for licensure or hospital appointment, all such actions must be reported. Failure to do so can lead to adverse consequences.

For a medical defendant, the litigation process begins with the delivery of a summons indicating that an action is pending. Once delivered, the anesthesia defendant must contact his or her malpractice insurer/risk management department, who will appoint legal counsel. Counsel for both the plaintiff and
defense will identify “independent experts” to review the cases. These “experts” are paid for their time and expenses and can arrive at dramatically different assessments of the case materials. Following review by expert consultants, the plaintiff’s counsel may depose the principal actors involved in the case. Providing testimony can be stressful. Generally, one should follow the advice of one’s attorney. Oftentimes, plaintiff’s attorneys will attempt to anger or confuse the deponent, hoping to provoke a response favorable to the claim. Most defense attorneys will advise their clients to answer questions as literally and simply as possible, without offering extraneous commentary. Should the plaintiff’s attorney become abusive, the defense attorney will object for the record. However, depositions, also known as “examinations before trial,” are not held in front of a judge (only the attorneys, the deponent, the court reporter[s], and sometimes the videographer are present).

Following discovery, the insurers, plaintiffs, and defense attorneys will “value” the case and attempt to monetize the damages. Items, such as pain and suffering, loss of consortium with spouses, lost wages, and many other factors, are included in determining what the injury is worth. Also during this period, the defense attorney may petition the court to grant defendants a “summary judgment,” dismissing the defendant from the case if there is no evidence of malpractice elicited during the discovery process. At times, the plaintiff’s attorneys will dismiss the suit against certain named individuals after they have testified, particularly when their testimony implicates other named defendants.

Settlement negotiations will occur in nearly every action. Juries are unpredictable, and both parties are often hesitant to take a case to trial. There are expenses associated with litigation, and both plaintiff and defense attorneys will try to avoid uncertainties. Many anesthesia providers will not want to settle a case because the settlement must be reported. Nonetheless, an award in excess of the insurance policy maximum may (depending on the jurisdiction) place the personal assets of the defendant providers at risk. One should remember that an adverse judgment may arise from a case in which most anesthesiologists would find the care to meet acceptable standards!

When a case proceeds to trial, the first step is jury selection in the process of *voir dire*—from the French—“to see, to say.” In this process, attorneys for the plaintiff and defendant will use various profiling techniques to attempt to identify (and remove) jurors who are less likely to be sympathetic to their case, while keeping the jurors deemed most likely to favor their side. Each attorney is able to strike a certain number of jurors from the pool because they perceive an inherent bias. The jurors will be questioned about such matters as their
educational level, history of litigation themselves, professions, and so forth.

Following empanelment, the case is presented to the jury. Each attorney attempts to educate the jurors—who usually have limited knowledge of healthcare (physicians and nurses will usually be struck from the jury)—as to the standard of care for this or that procedure and how the defendants did or did not breach their duty to the patient to uphold those standards. Expert witnesses will attempt to define what the standard of care is for the community, and the plaintiff and defendant will present experts with views that are favorable to their respective cause. The attorneys will attempt to discredit the opponent’s experts and challenge their opinions. Exhibits are often used to explain to the jury what should or should not have happened and why the injuries for which damages are being sought were caused by the practitioner’s negligence.

After the attorneys conclude their closing remarks, the judge will “charge” the jurors with their duty and will delineate what they can consider in making their judgment. Once a case is in the hands of a jury, anything can happen. Many cases will settle during the course of the trial, as neither party wishes to be subject to the arbitrary decisions of an unpredictable jury. Should the case not settle, the jurors will reach a verdict. When a jury determines that the defendants were negligent and negligence was the cause of the plaintiff’s injuries, the jury will determine an appropriate award. If the award is so egregiously large that it is inconsistent with awards for similar injuries, the judge may reduce its amount. Of course, following any verdict, there are numerous appeals that may be filed. It is important to note that appeals typically do not relate to the medical aspects of the case, but are filed because the trial process itself was somehow flawed.

Unfortunately, a malpractice action can take years to reach a conclusion. Consultation with a mental health professional may be appropriate for the defendant when the litigation process results in unmanageable stress and depression.

Determining what constitutes the “standard of care” is increasingly complicated. In the United States, the definition of “standard of care” is made separately by each state. The standard of care is not necessarily “best practices” or even the care that another physician would prefer. Generally, the standard of care is met when a patient receives care that other reasonable physicians in similar circumstances would regard as adequate. The American Society of Anesthesiologists (ASA) has published standards, and these provide a basic framework for routine anesthetic practice (eg, monitoring). Increasingly, a number of “guidelines” have been developed by the multiple specialty societies to identify best practices in accordance with assessments of the evidence in the
literature. The increasing number of guidelines proffered by the numerous anesthesia and other societies and their frequent updating can make it difficult for clinicians to stay abreast of the changing nature of practice. This is a particular problem when two societies produce conflicting guidelines on the same topic using the same data. Likewise, the information upon which guidelines are based can range from randomized clinical trials to the opinion of “experts” in the field. Consequently, guidelines do not hold the same weight as standards. Guidelines produced by reputable societies will generally include an appropriate disclaimer based on the level of evidence used to generate the guideline. Nonetheless, plaintiff’s attorneys will attempt to use guidelines to establish a “standard of care,” when, in fact, clinical guidelines are prepared to assist in guiding the delivery of therapy. However, if deviation from guidelines is required for good patient care, the rationale for such actions should be documented on the anesthesia record, as plaintiff’s attorneys may attempt to use the guideline as a *de facto* standard of care.

**ADVERSE ANESTHETIC OUTCOMES**

**Incidence**

There are several reasons why it is difficult to accurately measure the incidence of adverse anesthesia-related outcomes. First, it is often difficult to determine whether a poor outcome arises from the patient’s underlying disease, the surgical procedure, or the anesthetic management. In some cases, all three factors contribute to a poor outcome. Clinically important measurable outcomes are relatively rare after elective anesthetics. For example, death is a clear endpoint, and perioperative deaths do occur with some regularity. But, because deaths attributable to anesthesia are much rarer, a very large series of patients must be studied to assemble conclusions that have statistical significance. Nonetheless, many studies have attempted to determine the incidence of complications due to anesthesia. Unfortunately, studies vary in criteria for defining an anesthesia-related adverse outcome and are limited by retrospective analysis.

Perioperative mortality is usually defined as death within 48 h of surgery. It is clear that most perioperative fatalities are due to the patient’s preoperative disease or the surgical procedure. In a study conducted between 1948 and 1952, anesthesia mortality in the United States was approximately 5100 deaths per year or 3.3 deaths per 100,000 population. A review of cause of death files in the United States showed that the rate of anesthesia-related deaths was 1.1/1,000,000 population or 1 anesthetic death per 100,000 procedures between
1999 and 2005 (Figure 54–1). These results suggest a 97% decrease in anesthesia mortality since the 1940s. However, a 2002 study reported an estimated rate of 1 death per 13,000 anesthetics. Due to differences in methodology, there are discrepancies in the literature as to how well anesthesiology is doing in achieving safe practice. In a 2008 study of 815,077 patients (ASA class 1, 2, or 3) who underwent elective surgery at U.S. Department of Veterans Affairs hospitals, the mortality rate was 0.08% on the day of surgery. The strongest association with perioperative death was the type of surgery (Figure 54–2). Other factors associated with increased risk of death included dyspnea, reduced albumin concentrations, increased bilirubin, and increased creatinine concentrations. A subsequent review of the 88 deaths that occurred on the surgical day noted that 13 of the patients might have benefitted from better anesthesia care, and estimates suggest that death might have been prevented by better anesthesia practice in 1 of 13,900 cases. Additionally, this study reported that the immediate postsurgical period tended to be the time of unexpected mortality. Indeed, often missed opportunities for improved anesthetic care occur following complications when “failure to rescue” contributes to patient demise.

American Society of Anesthesiologists Closed Claims Project

The goal of the ASA Closed Claims Project is to identify common events leading to claims in anesthesia, patterns of injury, and strategies for injury prevention. It is a collection of closed malpractice claims that provides a “snapshot” of anesthesia liability rather than a study of the incidence of anesthetic complications, as only events that lead to the filing of a malpractice claim are considered. The Closed Claims Project consists of trained physicians who review claims against physician anesthesiologists represented by some U.S. malpractice insurers. The number of claims in the database continues to rise each year as new claims are closed and reported. The claims are grouped according to specific damaging events and complication type. Closed Claims Project analyses have been reported for airway injury, nerve injury, awareness, and so forth. These analyses provide insights into the circumstances that result in claims; however, the incidence of a complication cannot be determined from closed claim data, because we know neither the actual incidence of the complication (some with the complication may not file suit), nor how many anesthetics were performed for which the particular complication might possibly develop. Other similar analyses have been performed in the United Kingdom, where National Health Service (NHS) Litigation Authority claims are reviewed.
Causes

Anesthetic mishaps can be categorized as preventable or unpreventable. Examples of the latter include fatal idiosyncratic drug reactions or any poor outcome that occurs despite proper management. However, studies of anesthetic-related deaths or near misses suggest that many accidents are preventable. Of these preventable incidents, most involve human error (Table 54–1), as opposed to equipment malfunctions (Table 54–2). Unfortunately, some rate of human error is inevitable. During the 1990s, the top three causes for claims in the ASA Closed Claims Project were death (22%), nerve injury (18%), and brain damage (9%). In a 2009 report based on an analysis of NHS litigation records, anesthesia-related claims accounted for 2.5% of total claims filed and 2.4% of the value of all NHS claims. Moreover, regional and obstetrical anesthesia were responsible for 44% and 29%, respectively, of anesthesia-related claims filed. The authors of the latter study noted that there are two ways to examine data related to patient harm: critical incident and closed claim analyses. Clinical (or critical) incident data consider events that either cause harm or result in a “near-miss.” Comparison between clinical incident datasets and closed claims analyses demonstrates that not all critical events generate claims and that claims may be filed in the absence of negligent care. Consequently, closed claims reports must always be considered in this context.

MORTALITY & BRAIN INJURY

Trends in anesthesia-related death and brain damage have been tracked for many years. In a Closed Claims Project report examining claims in the period between 1975 and 2000, there were 6750 claims (Figure 54–3A and B), 2613 of which were for brain injury or death. The proportion of claims for brain injury or death was 56% in 1975, but had decreased to 27% by 2000. The primary pathological mechanisms by which these outcomes occurred were related to cardiovascular or respiratory problems. Early in the study period, respiratory-related damaging events were responsible for more than 50% of brain injury/death claims, whereas cardiovascular-related damaging events were responsible for 27% of such claims; however, by the late 1980s, the percentage of damaging events related to respiratory issues had decreased, with both respiratory and cardiovascular events being equally likely to contribute to severe brain injury or death. Respiratory damaging events included difficult airway, esophageal intubation, and unexpected extubation. Cardiovascular damaging events were usually multifactorial. Close claims reviewers found that anesthesia care was substandard in 64% of claims in which respiratory complications contributed to brain injury or death, but in only 28% of cases in which the primary mechanism of patient injury was cardiovascular in nature. Esophageal intubation, premature extubation, and inadequate ventilation were the primary mechanisms by which less than optimal anesthetic care was thought to have contributed to patient injury related to respiratory events. The relative decrease in causes of death being attributed to respiratory rather cardiovascular damaging events during the review period was attributed to the increased use of pulse oximetry and capnometry.
A 2010 study examining the NHS Litigation Authority dataset noted that airway-related claims led to higher awards and poorer outcomes than did non–airway-related claims. Indeed, airway manipulation and central venous catheterization claims in this database were most associated with patient death. Trauma to the airway also generates significant claims if esophageal or tracheal rupture occur. Postintubation mediastinitis should always be considered whenever there are repeated unsuccessful airway manipulations, as early intervention presents the best opportunity to mitigate any injuries incurred.

**VASCULAR CANNULATION**

Claims related to central venous access in the ASA database were associated with patient death 47% of the time and represented 1.7% of the 6449 claims reviewed. Complications secondary to guidewire or catheter embolism, tamponade, bloodstream infections, carotid artery puncture, hemothorax, and pneumothorax all contributed to patient injury. Although guidewire and catheter embolisms were associated with generally lower level patient injuries, these complications were generally attributed to substandard care. Tamponade
following line placement often led to a claim for patient death. The authors of a 2004 closed claims analysis recommended reviewing the chest radiograph following line placement and repositioning lines found in the heart or at an acute angle to reduce the likelihood of vascular perforation and tamponade. Brain damage and stroke are associated with claims secondary to carotid cannulation. Multiple confirmatory methods including ultrasound should be used to ensure that the internal jugular and not the carotid artery is cannulated.

Claims related to peripheral vascular cannulation in the ASA database accounted for 2% of 6849 claims, 91% of which were for complications secondary to the extravasation of fluids or drugs from peripheral intravenous catheters that resulted in extremity injury (Figure 54–4). Air embolisms, infections, and vascular insufficiency secondary to arterial spasm or thrombosis also resulted in claims. Of interest, intravenous catheter claims in patients who had undergone cardiac surgery formed the largest cohort of claims related to peripheral intravenous catheters, most likely due to the usual practice of tucking the arms alongside the patient during the procedure, placing them out of view of the anesthesia providers. Radial artery catheters seem to generate few closed claims; however, femoral artery catheters can lead to greater complications and potentially increased liability exposure.

OBSTETRIC ANESTHESIA

Both critical incident and closed claims analyses have been reported regarding complications and mortality related to obstetrical anesthesia.

In a study reviewing anesthesia-related maternal mortality in the United States using the Pregnancy Mortality Surveillance System, which collects data on all reported deaths causally related to pregnancy, 86 of the 5946 pregnancy-related deaths reported to the Centers for Disease Control and Prevention were thought to be anesthesia related or approximately 1.6% of total pregnancy related-deaths in the period 1991 to 2002. The anesthesia mortality rate in this period was 1.2 per million live births, compared with 2.9 per million live births in the period 1979 to 1990. The decline in anesthesia-related maternal mortality may be secondary to the decreased use of general anesthesia in parturients, reduced doses of bupivacaine in epidurals, improved airway management protocols and devices, and greater use of incremental (rather than bolus) dosing of epidural catheters.

In a 2009 study examining the epidemiology of anesthesia-related complications in labor and delivery in New York State during 2002 to 2005, an anesthesia-related complication was reported in 4438 of 957,471 deliveries (0.46%). The incidence of complications was increased in patients undergoing cesarean section, those living in rural areas, and those with other medical conditions. Complications of neuraxial anesthesia (eg, postdural puncture headache) were most common, followed by systemic complications, including aspiration or cardiac events. Other reported problems were related to anesthetic dose administration and unintended overdosages.

ASA Closed Claims Project analyses were reported in 2009 for the period 1990 to 2003. Four hundred twenty-six claims from this period were compared with 190 claims in the database prior to 1990. After 1990, the proportion of claims for maternal or fetal demise was lower than that recorded prior to 1990. After 1990, the number of claims for maternal nerve injury increased. In the review of claims in which anesthesia was thought to have contributed to the adverse outcome, anesthesia delay, poor communication, and substandard care were thought to have resulted in poor newborn outcomes. Prolonged attempts to secure neuraxial blockade in the setting of emergent cesarean section can contribute to adverse fetal outcome. Additionally, the closed claims review indicated that poor communication between the obstetrician and the anesthesiologist regarding the urgency of newborn delivery was likewise thought to have contributed to newborn demise and neonatal brain injury.

Maternal death claims were secondary to airway difficulty, maternal
hemorrhage, and high neuraxial blockade. The most common claim associated with obstetrical anesthesia was related to nerve injury following regional anesthesia. Nerve injury can be secondary to neuraxial anesthesia and analgesia, but also due to obstetrical causes. Early neurological consultation to identify the source of nerve injury is suggested to discern if injury could be secondary to obstetrical rather than anesthesia interventions.

**REGIONAL ANESTHESIA**

In a closed claims analysis, peripheral nerve blocks were involved in 159 of the 6894 claims analyzed. Peripheral nerve block claims were for death (8%), permanent injuries (36%), and temporary injuries (56%). The brachial plexus was the most common location for nerve injury. In addition to ocular injury, cardiac arrest following retrobulbar block contributed to anesthesiology claims. Cardiac arrest and epidural hematomas are two of the more common damaging events leading to severe injuries related to regional anesthesia. Neuraxial hematomas in both obstetrical and nonobstetrical patients were associated with coagulopathy (either intrinsic to the patient or secondary to medical interventions). In one study, cardiac arrest related to neuraxial anesthesia contributed to roughly one-third of the death or brain damage claims in both obstetrical and nonobstetrical patients. Accidental intravenous injection and local anesthesia toxicity also contributed to claims for brain injury or death.

Nerve injuries constitute the third most common source of anesthesia litigation. A retrospective review of patient records and a claims database showed that 112 of 380,680 patients (0.03%) experienced perioperative nerve injury. Patients with hypertension and diabetes and those who were smokers were at increased risk of developing perioperative nerve injury. Perioperative nerve injuries may result from compression, stretch, ischemia, other traumatic events, and unknown causes. Improper positioning can lead to nerve compression, ischemia, and injury; however, not every nerve injury is the result of improper positioning. The care received by patients with ulnar nerve injury was rarely judged to be inadequate in the ASA Closed Claims database. Even awake patients undergoing spinal anesthesia have been reported to experience upper extremity injury. Moreover, many peripheral nerve injuries do not become manifest until more than 48 h after anesthesia and surgery, suggesting that some nerve damage that occurs in surgical patients may arise from events taking place after the patient leaves the operating room setting.
PEDIATRIC ANESTHESIA

In a 2007 study reviewing 532 claims in pediatric patients younger than 16 years of age in the ASA Closed Claims database from 1973 to 2000 (Figure 54–5), a decrease in the proportion of claims for death and brain damage was noted over the three decades. Likewise, the percentage of claims related to respiratory events also was reduced. Compared with before 1990, the percentage of claims secondary to respiratory events decreased during the years 1990 to 2000, accounting for only 23% of claims in the latter study years compared with 51% of claims in the 1970s. Moreover, the percentage of claims that could be avoided by better monitoring decreased from 63% in the 1970s to 16% in the 1990s. Death and brain damage constitute the major complications for which claims are filed. In the 1990s, cardiovascular events joined respiratory complications in sharing the primary causes of pediatric anesthesia litigation. In the previously mentioned study, better monitoring and newer airway management techniques may have reduced the incidence of respiratory events leading to litigation-generating complications in the latter years of the review period. Additionally, the possibility of a claim being filed secondary to death or brain injury is greater in children who are in ASA classes 3, 4, or 5.

FIGURE 54–5  Trends over time. Outcome, type of event, and prevention by

In a review of the Pediatric Perioperative Cardiac Arrest Registry, which collects information from about 80 North American institutions that provide pediatric anesthesia, 193 arrests were reported in children between 1998 and 2004. During the study period, 18% of the arrests were “drug related,” compared with 37% of all arrests during the years 1994 to 1997. Cardiovascular arrests occurred most often (41%), with hypovolemia and hyperkalemia being the most common causes. Respiratory arrests (27%) were most commonly associated with laryngospasm. Central venous catheter placement with resultant vascular injury also contributed to some perioperative arrests. Arrests from cardiovascular causes occurred most frequently during surgery, whereas arrests from respiratory causes tended to occur after surgery.

A review of data from the Pediatric Perioperative Cardiac Arrest Registry with a focus on children with congenital heart disease found that such children were more likely to arrest perioperatively secondary to a cardiovascular cause. In particular, children with a single ventricle were at increased risk of perioperative arrest. Children with aortic stenosis and cardiomyopathy were similarly found to be at increased risk of cardiac arrest perioperatively.

Increasingly, obese children present for anesthesia and surgery. These children are at particular risk for obstructive sleep apnea, increased sensitivity to opioids, and respiratory arrest. In particular, death and neurological injury have been reported following tonsillectomy in children at risk for sleep apnea. At-risk children require an extended period of postoperative monitoring to prevent death from perioperative apnea.

OUT OF THE OPERATING ROOM ANESTHESIA & MONITORED ANESTHESIA CARE

Review of the ASA Closed Claims Project database indicates that anesthesia at remote (non–operating room) locations poses a risk to patients secondary to hypoventilation and excessive sedation. Remote location anesthesia care was more likely than operating room anesthesia care to involve a claim for death (54% vs 29%, respectively). The endoscopy suite and cardiac catheterization laboratory were the most frequent locations from which claims were generated. Monitored anesthesia care (MAC) was the most common technique employed in these claims. Overwhelmingly, adverse respiratory events were most frequently
responsible for the injury.

An analysis of the ASA Closed Claims Project database focusing on MAC likewise revealed that oversedation and respiratory arrest frequently led to claims. Claims for burn injuries suffered in operating room fires were also found in the database. Supplemental oxygen, draping, pooling of flammable antiseptic preparatory solutions, and surgical cautery combine to produce the potential for operating room fires (see Chapter 2).

EQUIPMENT PROBLEMS

“Equipment problems” is probably a misnomer; the ASA Closed Claims Project review of 72 claims involving gas delivery systems found that equipment misuse was three times more common than equipment malfunction. Anesthesia gas delivery claims have decreased in recent years, accounting for just 1% of claims in the new millennium. Provider equipment misuse was associated with severe patient injuries.

Errors in drug administration also typically involve human error. It has been suggested that as many as 20% of the drug doses given to hospitalized patients are incorrect. Errors in drug administration account for 4% of cases in the ASA Closed Claims Project. Errors resulting in claims were most frequently due to either incorrect dosage or unintentional administration of the wrong drug (syringe swap). In the latter category, accidental administration of epinephrine proved particularly dangerous.

Another type of human error occurs when the most critical problem is ignored because the anesthesia provider’s attention is inappropriately focused on a less important problem or an incorrect solution (fixation error). Serious anesthetic mishaps are often associated with distractions and other factors (Table 54–3). The harmful impact of most equipment failures can be decreased or avoided when the problem is identified during the mandatory preoperative anesthesia workstation inspection and checkout. Many anesthetic fatalities occur only after a series of coincidental circumstances, misjudgments, and technical errors combine (mishap chain).

TABLE 54–3 Factors associated with human errors and equipment misuse.
Prevention

To minimize errors in drug administration, drug syringes and ampules in the workspace should be restricted to those needed for the current specific case. Drugs should be consistently diluted to the same concentration in the same way for each use, and they should be clearly labeled. Computer systems for scanning bar-coded drug labels are available that may help to reduce medication errors. The conduct of all anesthetics should follow a predictable pattern by which the anesthetist actively surveys the monitors, the surgical field, and the patient on a recurrent basis. In particular, patient positioning should be frequently reassessed to avoid the possibility of compression or stretch injuries. Increasingly, protocols or algorithms, or both, are provided in anesthetizing locations to ensure compliance with preprocedural checklists, to standardize responses to adverse events, and to minimize errors related to transfer of patient care between clinicians.

AIRWAY INJURY

The daily insertion of endotracheal tubes (particularly with stylets), laryngeal mask airways, oral/nasal airways, gastric tubes, transesophageal echocardiogram (TEE) probes, esophageal (bougie) dilators, and emergency airways all involve the risk of airway damage. Common complaints, such as sore throat and
dysphagia, are usually self-limiting, but they may also be nonspecific symptoms of more ominous complications.

The most common persisting airway injury is dental trauma. In a retrospective study of 600,000 surgical cases, the incidence of injury requiring dental intervention and repair was approximately 1 in 4500. In most cases, laryngoscopy and endotracheal intubation were involved, and the upper incisors were the most frequently injured. Major risk factors for dental trauma included tracheal intubation, preexisting poor dentition, and patient characteristics associated with difficult airway management (including limited neck motion, previous head and neck surgery, craniofacial abnormalities, and a history of difficult intubation).

Laryngeal injuries included vocal cord paralysis, granuloma, and arynetenoid dislocation. Most tracheal injuries were associated with emergency surgical tracheotomy, but a few were related to endotracheal intubation. Some injuries occurred during seemingly easy, routine intubations. Proposed mechanisms include excessive tube movement in the trachea and excessive cuff inflation, leading to pressure necrosis. Esophageal perforations contributed to death in 5 of 13 patients reviewed. Esophageal perforation often presents with delayed-onset subcutaneous emphysema or pneumothorax, unexpected febrile state, and sepsis. Pharyngoesophageal perforation is associated with difficult intubation, age over 60 years, and female gender. As in tracheal perforation, signs and symptoms are often delayed in onset. Initial sore throat, cervical pain, and cough progress to fever, dysphagia, and dyspnea, as mediastinitis, abscess, or pneumonia develop. Mortality rates of up to 50% have been reported after esophageal perforation, with better outcomes attributable to rapid detection and treatment.

Minimizing the risk of airway injury begins with the preoperative assessment. Documentation of current dentition (including dental work) should be included. The ASA algorithm for difficult airway management is a useful guide to have immediately available in every anesthetizing location.

**PERIPHERAL NERVE INJURY**

The most commonly injured peripheral nerve is the ulnar nerve (Figure 54–6). In a retrospective study of over 1 million patients, ulnar neuropathy (persisting for more than 3 months) occurred in approximately 1 in 2700 patients. Of interest, initial symptoms were most frequently noted more than 24 h after a surgical procedure. Risk factors included male gender, hospital stay greater than 14 days, and very thin or obese body habitus. More than 50% of these patients
regained full sensory and motor function within 1 year. Anesthetic technique was not implicated as a risk factor; 25% of patients with ulnar neuropathy underwent monitored care or lower extremity regional technique. Many ulnar neuropathies occurred despite notation of extra padding over the elbow area.

**FIGURE 54–6**  
A: Pronation of the forearm can cause external compression of the ulnar nerve in the cubital tunnel. B: Forearm supination avoids this problem.  
(Modified with permission from Wadsworth TG. The cubital tunnel and the external compression syndrome. *Anesth Analg.* 1974 Mar-April;53(2):303-308.)

**The Role of Positioning**

External pressure on a nerve may compromise its perfusion and disrupt its cellular integrity, resulting in edema, ischemia, and necrosis. Pressure injuries are particularly likely when nerves pass through closed compartments or take a superficial course (eg, the peroneal nerve around the fibula). Postoperative lower extremity neuropathies, particularly those involving the peroneal nerve, have been associated with such factors as extreme degrees (high) and prolonged (greater than 2 h) durations of the lithotomy position. Other risk factors for postoperative lower extremity neuropathy include hypotension, thin body habitus, older age, vascular disease, diabetes, and cigarette smoking. An axillary (chest) “roll” is commonly used to reduce pressure on the inferior shoulder of patients in the lateral decubitus position. This roll should be located caudad to
the axilla to prevent direct pressure on the brachial plexus and should be large enough to relieve any pressure from the mattress on the lower shoulder.

The data are convincing that some postoperative peripheral nerve injuries are not preventable. The risk of peripheral neuropathy should be included in discussions leading to informed consent. When reasonable, patients with contractures (or other causes of limited flexibility) can be positioned before induction of anesthesia to check for feasibility and discomfort. Final positioning should be evaluated prior to draping. In most circumstances, the head and neck should be kept in a neutral position. Shoulder braces to support patients maintained in a steep Trendelenburg position should be avoided if possible, and shoulder abduction and lateral rotation should be minimized. The upper extremities should not be extended greater than 90°. (There should be no continuous external compression on the knee, ankle, or heel.) Although injuries may still occur, additional padding may be helpful in vulnerable areas. Documentation should include information on positioning, including the presence of padding. Finally, patients who complain of sensory or motor dysfunction in the postoperative period should be reassured that this is usually a temporary condition. Motor and sensory function should be documented. When symptoms persist for more than 24 h, the patient should be referred to a neurologist, physiatrist, or hand surgeon who is knowledgeable about perioperative nerve damage for evaluation. Physiological testing, such as nerve conduction and electromyographic studies, can be useful to document whether nerve damage is a new or chronic condition. In the latter case, fibrillations will be observed in chronically denervated muscles. Fibrillations should not be present in the first few days after an acute nerve injury.

Complications Related to Positioning

Changes of body position have physiological consequences that can be exaggerated in disease states. General and regional anesthesia may limit the cardiovascular response to such a change. Even positions that are safe for short periods may eventually lead to complications in persons who are not able to move in response to pain. Regional and general anesthesia abolish protective reflexes and predispose patients to injury.

Many complications, including air embolism, blindness from sustained pressure on the globe, and finger amputation following a crush injury, can be caused by improper patient positioning (Table 54–4). These complications are best prevented by evaluating the patient’s postural limitations during the preanesthetic visit; padding pressure points, susceptible nerves, and any area of
the body that will *possibly* be in contact with the operating table or its attachments; avoiding flexion or extension of a joint to its limit; having an awake patient assume the position to ensure comfort; and understanding the potential complications of each position. Monitors must often be disconnected during patient repositioning, making this a time of greater risk for unrecognized hemodynamic derangement or hypoventilation.

Compartment syndromes can result from hemorrhage into a closed space following a vascular puncture or prolonged venous outflow obstruction, particularly when associated with hypotension. In severe cases, this may lead to muscle necrosis, myoglobinuria, and renal damage, unless the pressure within the extremity compartment is relieved by surgical decompression (fasciotomy) or in the abdominal compartment by laparotomy.

**AWARENESS UNDER GENERAL ANESTHESIA**

A continuing series of media reports have imprinted the fear of awareness under general anesthesia into the psyche of the general population. Accounts of recall and helplessness while paralyzed have made unconsciousness a primary concern of patients undergoing general anesthesia. When unintended intraoperative awareness does occur, patients may exhibit symptoms ranging from mild anxiety to posttraumatic stress disorder (eg, sleep disturbances, nightmares, and social difficulties).

Although the incidence is difficult to measure, approximately 2% of the closed claims in the ASA Closed Claims Project database relate to awareness
under anesthesia. Analysis of the NHS Litigation Authority database from 1995 to 2007 revealed that 19 of 93 relevant claims were for “awake paralysis.” Clearly, awareness is of great concern to patients and may lead to litigation. Certain types of surgeries are most frequently associated with awareness, including those for major trauma, obstetrics, and major cardiac procedures. In some instances, awareness may result from the reduced depth of anesthesia that can be tolerated by the patient. In early studies, recall rates for intraoperative events during major trauma surgery have been reported to be as frequent as 43%; the incidence of awareness during cardiac surgery and cesarean sections is 1.5% and 0.4%, respectively. As of 1999, the ASA Closed Claims Project reported 79 awareness claims; approximately 20% of the claims were for awake paralysis, and the remainder of the claims were for recall under general anesthesia. Most claims for awake paralysis were thought to be due to errors in drug labeling and administration, such as administering paralytics before inducing anesthesia. Since the 1999 review, another 71 cases have appeared in the database. Claims for recall were more likely in women undergoing general anesthesia without a volatile agent. Patients with long-term substance abuse may have increased anesthesia requirements that if not met can lead to awareness.

Other specific causes of awareness include inadequate inhalational anesthetic delivery (eg, from vaporizer malfunction) and medication errors. Some patients may complain of awareness, when, in fact, they received monitored anesthesia care or regional anesthesia with moderate sedation; thus, anesthetists should make sure that patients have reasonable expectations when regional or local techniques are employed. Likewise, patients requesting regional or local anesthesia because they want to “see it all” or “stay in control” often can become irate when sedation dulls their memory of the perioperative experience. In all cases, frank discussion between anesthesia staff and the patient is necessary to avoid unrealistic expectations.

Some clinicians routinely discuss the possibility of intraoperative recall and the steps that will be taken to minimize it as part of the informed consent for general anesthesia. This makes particular sense for those procedures in which recall is more likely. It is advisable to also remind patients who are undergoing monitored anesthesia care with sedation that awareness is expected. Volatile anesthetics should be administered at a level consistent with amnesia. If this is not possible, benzodiazepines (or scopolamine, or both) can be used. Movement of a patient may indicate inadequate anesthetic depth. Documentation should include end-tidal concentrations of anesthetic gases (when available) and dosages of amnesic drugs. Use of a bispectral index scale (BIS) monitor or
similar monitors may be helpful, although randomized clinical trials have failed to demonstrate a reduced incidence of awareness with use of BIS when compared with appropriate concentrations of volatile agents. Finally, if there is evidence of intraoperative awareness during postoperative rounds, the practitioner should obtain a detailed account of the experience, answer patient questions, be very empathetic, and refer the patient for psychological counseling if appropriate.

**EYE INJURY**

A wide range of conditions from simple corneal abrasion to blindness have been reported. Corneal abrasion is by far the most common and transient eye injury. The ASA Closed Claims Project identified a small number of claims for abrasion, in which the cause was rarely identified (20%) and the incidence of permanent injury was low (16%). It also identified a subset of claims for blindness that resulted from patient movement during ophthalmological surgery. These cases occurred in patients receiving either general anesthesia or monitored anesthesia care.

Although the cause of corneal abrasion may not be obvious, securely closing the eye lids with tape after loss of consciousness (but prior to intubation) and avoiding direct contact between eyes and oxygen masks, drapes, lines, and pillows (particularly during monitored anesthesia care, in transport, and in nonsupine positions) can help to minimize the possibility of injury. Adequate anesthetic depth (and, in most cases, paralysis) should be maintained to prevent movement during ophthalmological surgery under general anesthesia. In patients scheduled for MAC, the patient must understand that movement under monitored care is hazardous and, thus, that only minimal sedation may be administered to ensure that he or she can cooperate. Vigilance must be maintained regarding patients’ propensity to want to rub their eyes following emergence from anesthesia, especially in response to blurred vision secondary to residual eye lubrication ointment.

Ischemic optic neuropathy (ION) is a devastating perioperative complication. ION is now the most common cause of postoperative vision loss. Postoperative vision loss is most commonly reported after cardiopulmonary bypass, radical neck dissection, and spinal surgeries in the prone position. Both preoperative and intraoperative factors may be contributory. Many of the case reports implicate preexisting hypertension, diabetes, coronary artery disease, and smoking, suggesting that preoperative vascular abnormalities may play a role. Intraoperative deliberate hypotension and anemia have also been implicated (in
spine surgery), perhaps because of their potential to reduce oxygen delivery. Finally, prolonged surgical time in positions that compromise venous outflow (prone, head down, compressed abdomen) have also been found to be factors in spine surgery. Symptoms are usually present immediately upon awakening from anesthesia, but have been reported up to 12 days postoperatively. Such symptoms range from decreased visual acuity to complete blindness. Analysis of case records submitted to the ASA Postoperative Vision Loss Registry revealed that vision loss was secondary to ION in 83 of 93 cases. Instrumentation of the spine was associated with ION when surgery lasted more than 6 h and blood loss was more than 1 L. ION can occur in patients whose eyes are free of pressure secondary to the use of pin fixation, indicating that direct pressure on the eye is not required to produce ION. Cortical blindness can likewise occur perioperatively in association with profound hypoperfusion or embolic loads. Recovery from cortical blindness is more likely than from other causes of perioperative vision loss. Increased venous pressure in patients in the Trendelenburg position may reduce blood flow to the optic nerve.

It is difficult to formulate recommendations to prevent this complication because risk factors for ION are often unavoidable. Steps that might be taken include (1) limiting the degree and duration of hypotension during controlled (deliberate) hypotension, (2) administering a transfusion to severely anemic patients who seem to be at risk of ION, and (3) discussing with the surgeon the possibility of staged operations in high-risk patients to limit prolonged procedures.

Of note, postoperative vision loss can be caused by other mechanisms as well, including angle closure glaucoma or embolic phenomenon to the cortex or retina. Immediate evaluation is advised.

**CARDIOPULMONARY ARREST DURING SPINAL ANESTHESIA**

Sudden cardiac arrest during an otherwise routine administration of spinal anesthetics is an uncommon complication. The initial published report was a closed claims analysis of 14 patients who experienced cardiac arrest during spinal anesthesia. The cases primarily involved young (average age 36 years), relatively healthy (ASA physical status I–II) patients who were given appropriate doses of local anesthetic that produced a high dermatomal level of block prior to arrest (T4 level). Respiratory insufficiency with hypercarbia due to sedatives was thought to be a potential contributing factor. The average time from induction of
spinal anesthesia to arrest was 36 min, and, in all cases, arrest was preceded by a gradual decline in heart rate and blood pressure. Just prior to arrest, the most common signs were bradycardia, hypotension, and cyanosis. Treatment consisted of ventilatory support, ephedrine, atropine, cardiopulmonary resuscitation (average duration 10.9 min), and epinephrine. Despite these interventions, 10 patients remained comatose and 4 patients regained consciousness with significant neurological deficits. A subsequent study concluded that such arrests had little relationship to sedation, but were related to extensive degrees of sympathetic blockade, with unopposed vagal tone and profound bradycardia. Rapid appropriate treatment of bradycardia and hypotension is essential to minimize the risk of profound bradycardia, complete heart block, or cardiac arrest. Early treatment of bradycardia with atropine or glycopyrrolate may prevent a downward spiral. Stepwise doses of ephedrine, epinephrine, and other vasoactive drugs should be given to treat hypotension. If cardiopulmonary arrest occurs, ventilatory support, cardiopulmonary resuscitation, and full resuscitation doses of atropine and epinephrine should be administered without delay.

HEARING LOSS
Perioperative hearing loss is usually transient and often goes unrecognized. The incidence of low-frequency hearing loss following dural puncture may be as high as 50%. It seems to be due to cerebrospinal fluid leak and, if persistent, can be relieved with an epidural blood patch. Hearing loss following general anesthesia can be due to a variety of causes and is much less predictable. Mechanisms include middle ear barotrauma, vascular injury, and ototoxicity of drugs (aminoglycosides, loop diuretics, nonsteroidal antiinflammatory drugs, and antineoplastic agents).

ALLERGIC REACTIONS
Hypersensitivity (or allergic) reactions are exaggerated immunological responses to antigenic stimulation in previously sensitized persons. The antigen, or allergen, may be a protein, polypeptide, or smaller molecule. Moreover, the allergen may be the substance itself, a metabolite, or a breakdown product. Patients may be exposed to antigens through the respiratory tract, gastrointestinal tract, eyes, skin and from previous intravenous, intramuscular, or peritoneal exposure. 

Anaphylaxis occurs when inflammatory agents are released from basophils
and mast cells as a result of an antigen interacting with immunoglobulin (Ig) E. 

*Anaphylactoid reactions* manifest themselves in the same manner as anaphylactic reactions, but are not the result of an interaction with IgE. Direct activation of complement and IgG-mediated complement activation can result in similar inflammatory mediator release and activity.

Depending on the antigen and the immune system components involved, hypersensitivity reactions are classically divided into four types (*Table 54–5*). In many cases, an allergen (e.g., latex) may cause more than one type of hypersensitivity reaction. Type I reactions involve antigens that cross-link IgE antibodies, triggering the release of inflammatory mediators from mast cells. In type II reactions, complement-fixing (C1-binding) IgG antibodies bind to antigens on cell surfaces, activating the classic complement pathway and lysing the cells. Examples of type II reactions include hemolytic transfusion reactions and heparin-induced thrombocytopenia. Type III reactions occur when antigen–antibody (IgG or IgM) immune complexes are deposited in tissues, activating complement and generating chemotactic factors that attract neutrophils to the area. The activated neutrophils cause tissue injury by releasing lysosomal enzymes and toxic products. Type III reactions include serum sickness reactions and acute hypersensitivity pneumonitis. Type IV reactions, often referred to as delayed hypersensitivity reactions, are mediated by CD4+ T lymphocytes that have been sensitized to a specific antigen by prior exposure. Examples of type IV reactions are those associated with tuberculosis, histoplasmosis, schistosomiasis, hypersensitivity pneumonitis, and some autoimmune disorders.

*TABLE 54–5  Hypersensitivty reactions.*
1. Immediate Hypersensitivity Reactions

Initial exposure of a susceptible person to an antigen induces CD4\(^+\) T cells to lymphokines that activate and transform specific B lymphocytes into plasma cells, producing allergen-specific IgE antibodies (Figure 54–7). The Fc portion of these antibodies then associates with high affinity receptors on the cell surface of tissue mast cells and circulating basophils. During subsequent reexposure to the antigen, it binds the Fab portion of adjacent IgE antibodies on the mast cell surface, inducing degranulation and release of inflammatory lipid mediators and additional cytokines from the mast cell. The end result is the release of histamine, tryptase, proteoglycans (heparin and chondroitin sulfate), and carboxypeptidases. An elevated tryptase concentration in the setting of clinical signs of hypersensitivity signals mast cell activation and is the diagnostic test of choice for anaphylactic reactions. The combined effects of these mediators can produce arteriolar vasodilation, increased vascular permeability, increased mucus secretion, smooth muscle contraction, and other clinical manifestations of type I reactions.
Type I hypersensitivity reactions are classified as atopic or nonatopic. Atopic disorders typically affect the skin or respiratory tract and include allergic rhinitis, atopic dermatitis, and allergic asthma. Nonatopic hypersensitivity disorders include urticaria, angioedema, and anaphylaxis; when these reactions are mild, they are confined to the skin (urticaria) or subcutaneous tissue (angioedema), but when they are severe, they become generalized and a life-threatening medical emergency (anaphylaxis). Urticarial lesions are characteristically well-circumscribed skin wheals with raised erythematous borders and blanched centers; they are intensely pruritic. Angioedema presents as deep, nonpitting cutaneous edema from marked vasodilation and increased permeability of
subcutaneous blood vessels. When angioedema is extensive, it can be associated with large fluid shifts; when it involves the pharyngeal or laryngeal mucosa, it can rapidly compromise the airway.

Angioedema can lead to airway compromise and is frequently the cause for anesthesiology airway management consultation in the emergency department. Angioedema is secondary to increased capillary permeability secondary either to activation of mast cells or through kinin mediation. Patients taking angiotensin-converting enzyme (ACE) inhibitors may experience kinin-mediated angioedema. Bradykinin is inactivated by ACE and consequently it may accumulate when ACE is inhibited. Hereditary angioedema can occur in patients with ineffective amounts of complement inhibitor (C1-INH). Treatment for angioedema first focuses upon airway management as needed. Fresh frozen plasma can be given to increase ACE if ACE inhibition is thought to be contributing to angioedema. The bradykinin receptor antagonist icatibant can likewise be administered if available. C1-INH replacement protein is also available to inhibit kinin synthesis. The kallikrein inhibitor ecallantide can also be used to decrease bradykinin production (Figure 54–8).

**FIGURE 54–8** Treatment of acute attacks of angioedema based on underlying etiology. 2. Anaphylactic Reactions

Anaphylaxis is an exaggerated response to an allergen (eg, antibiotic) that is mediated by a type I hypersensitivity reaction. The syndrome appears within minutes of exposure to a specific antigen in a sensitized person and characteristically presents as acute respiratory distress, circulatory shock, or both. Death may occur from asphyxiation or irreversible circulatory shock. The incidence of anaphylactic reactions during anesthesia has been estimated at a rate of 1:3500 to 1:20,000 anesthetics. A study of 789 anaphylactic and anaphylactoid reactions reported that the most common source antigens were neuromuscular blockers (58%), latex (17%), and antibiotics (15%).

The most important mediators of anaphylaxis are histamine, leukotrienes, basophil kallikrein (BK-A), and platelet-activating factor. They increase vascular permeability and contract smooth muscle. $H_1$-receptor activation contracts bronchial smooth muscle, whereas $H_2$-receptor activation causes vasodilation, mucus secretion, tachycardia, and increased myocardial contractility. BK-A cleaves bradykinin from kininogen; bradykinin increases vascular permeability and vasodilation and contracts smooth muscle. Activation of Hageman factor can initiate intravascular coagulation. Eosinophil chemotactic factor of anaphylaxis, neutrophil chemotactic factor, and leukotriene B$_4$ attract inflammatory cells that mediate additional tissue injury. Angioedema of the pharynx, larynx, and trachea produce upper airway obstruction, whereas bronchospasm and mucosal edema result in lower airway obstruction. Transudation of fluid into the skin (angioedema) and viscera produces hypovolemia, whereas arteriolar vasodilation decreases systemic vascular resistance. Coronary hypoperfusion and arterial hypoxemia promote arrhythmias and myocardial ischemia. Leukotriene and prostaglandin mediators may also cause coronary vasospasm. Prolonged circulatory shock leads to progressive lactic acidosis and ischemic damage to vital organs. Table 54–6 summarizes important manifestations of anaphylactic reactions.

**TABLE 54–6  Clinical manifestations of anaphylaxis.**
Anaphylactoid reactions resemble anaphylaxis but do not depend on IgE antibody interaction with antigen. A drug can directly release histamine from mast cells (eg, urticaria following high-dose morphine sulfate) or activate complement. Despite differing mechanisms, anaphylactic and anaphylactoid reactions typically are clinically indistinguishable and equally life threatening. Table 54–7 lists common causes of anaphylactic and anaphylactoid reactions.

Serum tryptase measurement is helpful in confirming the diagnosis of an anaphylactic reaction. Treatment must be immediate and tailored to the severity of the reaction (Table 54–8).
3. **Allergic Reactions to Anesthetic Agents**

True anaphylaxis due to anesthetic agents is rare; anaphylactoid reactions are much more common. Risk factors associated with hypersensitivity to anesthetics include female gender, atopic history, preexisting allergies, and previous anesthetic exposures. An estimated 1 in 6500 patients has an allergic reaction to a muscle relaxant. In many instances, the patient had no previous exposure to the agent. Investigators suggest that over-the-counter drugs, cosmetics, and food products, many of which contain tertiary or quaternary ammonium ions, can sensitize susceptible individuals.

The incidence of anaphylaxis for thiopental and propofol is 1 in 30,000 and 1 in 60,000, respectively. Allergic reactions to etomidate, ketamine, and benzodiazepines are exceedingly rare. True anaphylactic reactions due to opioids are far less common than nonimmune histamine release. Similarly, anaphylactic reactions to local anesthetics are much less common than vasovagal reactions, toxic reactions to accidental intravenous injections, and side effects from absorbed or intravenously injected epinephrine. IgE-mediated reactions to certain ester-type local anesthetics (eg, procaine and benzocaine), however, are well described secondary to reaction to the metabolite, para-aminobenzoic acid. In contrast, true anaphylaxis due to amide-type local anesthetics is very rare; in some instances, the preservative (paraben or methylparaben) was believed to be responsible for an apparent anaphylactoid reaction to a local anesthetic. Moreover, the cross-reactivity between amide-type local anesthetics seems to be low. Volatile anesthetics are not likely to initiate anaphylaxis.

4. **Latex Allergy**
The severity of allergic reactions to latex-containing products ranges from mild contact dermatitis to life-threatening anaphylaxis. Latex allergy associated with anaphylaxis during anesthesia is now much rarer due to removal of latex-containing products from the medical environment. Most serious reactions seem to involve a direct IgE-mediated immune response to polypeptides in natural latex, although some cases of contact dermatitis may be due to a type IV sensitivity reaction to chemicals introduced in the manufacturing process. Nonetheless, a relationship between the occurrence of contact dermatitis and the probability of future anaphylaxis has been suggested. Chronic exposure to latex and a history of atopy increases the risk of sensitization. Healthcare workers and patients undergoing frequent procedures with latex items (eg, repeated urinary bladder catheterization, barium enema examinations) should therefore be considered at increased risk.

Patients with spina bifida, spinal cord injury, and congenital abnormalities of the genitourinary tract have a markedly increased incidence of latex allergy. The incidence of latex anaphylaxis in children is estimated to be 1 in 10,000. A history of allergic symptoms to latex should be sought in all patients during the preanesthetic interview. Foods that cross-react with latex include mango, kiwi, chestnut, avocado, passion fruit, and banana. Interleukin (IL)-18 and IL-13 single nucleotide polymorphisms may affect the sensitivity of individuals to latex and promote allergic responses.

Anaphylactic reactions to latex may be confused with reactions to other substances (eg, drugs, blood products) because the onset of symptoms can be delayed for more than 1 h after initial exposure. Treatment is the same as for other forms of anaphylactic reactions. Preventing a reaction in sensitized patients includes pharmacological prophylaxis and absolute avoidance of latex. Preoperative administration of H₁ and H₂ histamine antagonists and steroids may provide some protection, although their use is controversial. Although most pieces of anesthetic equipment are now latex-free, some may still contain latex. Manufacturers of latex-containing medical products must label their products accordingly. Only devices specifically known not to contain latex (eg, polyvinyl or neoprene gloves, silicone endotracheal tubes or laryngeal masks, plastic face masks) can be used in latex-allergic patients.

5. Allergies to Antibiotics

Many true drug allergies in surgical patients are due to antibiotics, mainly β-lactam antibiotics, such as penicillins and cephalosporins. Although 1% to 4% of β-lactam administrations result in allergic reactions, only 0.004% to 0.015% of these reactions result in anaphylaxis. Up to 2% of the general population is
allergic to penicillin, but only 0.01% of penicillin administrations result in anaphylaxis. Cephalosporin cross-sensitivity in patients with penicillin allergy is estimated to be 2% to 7%, but a history of an anaphylactic reaction to penicillin increases the cross-reactivity rate up to 50%. Patients with a prior history of an anaphylactic reaction to penicillin should therefore not receive a cephalosporin. Although imipenem exhibits similar cross-sensitivity, aztreonam seems to be antigenically distinct and reportedly does not cross-react with other β-lactams. Sulfonamide allergy is also relatively common in surgical patients. Sulfa drugs include sulfonamide antibiotics, furosemide, hydrochlorothiazide, and captopril. Fortunately, the frequency of cross-reactivity among these agents is low.

Like cephalosporins, vancomycin is commonly used for antibiotic prophylaxis in surgical patients. Vancomycin is associated with a reaction (the “red man” or “red neck” syndrome) that consists of intense pruritus, flushing, and erythema of the head and upper torso in addition to arterial hypotension. Isolated systemic hypotension seems to be primarily mediated by histamine release, because pretreatment with H₁ and H₂ antihistamines can prevent hypotension, even with rapid rates of vancomycin administration. Vancomycin can also produce true anaphylactic or anaphylactoid reactions. Protamine commonly causes vasodilatory hypotension and less commonly presents as an anaphylactoid reaction with pulmonary hypertension and systemic hypotension.

Immunological mechanisms are associated with other perioperative pathologies. Transfusion-related lung injury may be secondary to the activity of antibodies in the donor plasma, producing a hypersensitivity reaction that leads to lung infiltrates and hypoxemia (see Chapter 51). IgG antibody formation directed at heparin–PF4 complexes results in platelet activation, thrombosis, and heparin-induced thrombocytopenia.

QUALITY MANAGEMENT
Risk management and continuous quality improvement programs at the departmental level may reduce anesthetic morbidity and mortality rates, and decrease perioperative costs, by addressing monitoring standards, equipment, practice guidelines, continuing education, care variation and quality of care, and staffing and “system” issues. Specific responsibilities of peer review committees include identifying (and, ideally, preventing) potential problems, formulating and periodically revising departmental policies, ensuring the availability of properly functioning anesthetic equipment, enforcing standards required for clinical privileges, and evaluating the appropriateness and quality of patient care. A
quality improvement system impartially and continuously reviews complications, compliance with standards, and quality indicators (see Chapter 59).

Health care purchasers seek maximal health care value.

\[
\text{Value} = \frac{\text{Quality}}{\text{Cost}}
\]

Consequently, anesthesia providers must consistently deliver high-quality results while minimizing expenses. To achieve value, hospitals and providers alike have looked to adopt principles of continuous improvement borrowed from industry. Adapting the work of W. Edwards Deming, health care organizations often employ the PDSA (Plan-Do-Study-Act) cycle to promote ongoing improvement, to standardize results, and to reduce waste (see Figure 54–9). So-called lean management strategies are used to achieve maximal health care value by continually attempting to improve processes to minimize variability so to ensure optimal results with minimal waste.

OCCUPATIONAL HAZARDS IN ANESTHESIOLOGY

Anesthesia providers spend much of their workday exposed to anesthetic gases, low-dose ionizing radiation, electromagnetic fields, blood products, and
workplace stress. Each of these can contribute to negative health effects. A 2000 paper compared the mortality risks of anesthesiologists and internists. Death from heart disease or cancer did not differ between the groups; however, anesthesiologists had an increased rate of suicide and illicit drug-related death (Table 54–9). Anesthesiologists also had a greater chance of death from external causes, such as boating, bicycling, and aeronautical accidents compared with internists. Nevertheless, both anesthesiologists and internists had lower mortality than the general population, likely due to their higher socioeconomic status. Anesthesiologists’ access to parenteral opioids possibly contributes to a 2.21 relative risk for drug-related deaths compared with that of internists.

### 1. Chronic Exposure to Anesthetic Gases

There is no clear evidence that exposure to trace amounts of anesthetics presents a health hazard to operating room personnel. However, because previous studies examining this issue have yielded flawed but conflicting results, the U.S. Occupational Health and Safety Administration (OSHA) continues to set maximum acceptable trace concentrations of less than 25 ppm for nitrous oxide and 0.5 ppm for halogenated anesthetics (2 ppm if the halogenated agent is used alone). Achieving these low levels depends on efficient scavenging equipment, adequate operating room ventilation, and conscientious anesthetic technique. Most people cannot detect the odor of volatile agents at a concentration of less than 30 ppm. If there is no functioning scavenging system, operating room anesthetic gas concentrations reach 3000 ppm for nitrous oxide and 50 ppm for volatile agents.
2. Infectious Diseases

Hospital workers are exposed to many infectious diseases prevalent in the community (eg, respiratory viral infections, rubella, and tuberculosis). Herpetic whitlow is an infection of the finger with herpes simplex virus type 1 or 2 and usually involves direct contact of previously traumatized skin with contaminated oral secretions. Prevention involves wearing gloves when contacting oral secretions.

Viral DNA has been identified in the smoke plume generated during laser treatment of condylomata. The theoretical possibility of viral transmission from this source can be minimized by using smoke evacuators, gloves, and appropriate OSHA-approved masks.

More disturbing is the potential of acquiring serious blood-borne infections, such as hepatitis B, hepatitis C, or HIV. Although parenteral transmission of these diseases can occur following mucous membrane, cutaneous, or percutaneous exposure to infected body fluids, accidental injury with a needle contaminated with infected blood represents the most common occupational mechanism. The risk of transmission can be estimated if three factors are known: the prevalence of the infection within the patient population, the incidence of exposure (eg, frequency of needlestick), and the rate of seroconversion after a single exposure. The seroconversion rate after a specific exposure depends on several factors, including the infectivity of the organism, the stage of the patient’s disease (extent of viremia), the size of the inoculum, and the immune status of the health care provider. Rates of seroconversion following a single needlestick are estimated to range between 0.3% and 30%. Hollow (hypodermic) needles pose a greater risk than do solid (surgical) needles because of the potentially larger inoculum. The use of gloves, needleless systems, or protected needle devices may decrease the incidence of some (but not all) types of injury.

The initial management of needlesticks involves cleaning the wound and notifying the appropriate authority within the health care facility. After an exposure, anesthesia workers should report to their institution’s emergency or employee health department for appropriate counseling on postexposure prophylaxis options. All operating room staff should be made aware of the institution’s employee health notification pathway for needlestick and other injuries.

Fulminant hepatitis B (1% of acute infections) carries a 60% mortality rate. Chronic active hepatitis (<5% of all cases) is associated with an increased incidence of hepatic cirrhosis and hepatocellular carcinoma. Transmission of the
virus is primarily through contact with blood products or body fluids. The diagnosis is confirmed by detection of hepatitis B surface antigen (HBsAg). Uncomplicated recovery is signaled by the disappearance of HBsAg and the appearance of antibody to the surface antigen (anti-HBs). A hepatitis B vaccine is available and is strongly recommended prophylactically for anesthesia personnel. The appearance of anti-HBs after a three-dose regimen indicates successful immunization.

Hepatitis C is another important occupational hazard in anesthesiology. Many of these infections lead to chronic hepatitis, which, although often asymptomatic, can progress to liver failure and death. It is now possible to cure hepatitis C with antiviral drug regimens.

Anesthesia personnel seem to be at low risk for the occupational contraction of HIV. Universal contact precautions should be routinely employed to mitigate the risk of transmission of infectious diseases to anesthesia workers.

3. Substance Abuse

Anesthesiology is a high-risk medical specialty for substance abuse. Probable reasons for this include the stress of anesthetic practice and the easy availability of drugs with addiction potential (potentially attracting people at risk of addiction to the field). The likelihood of developing substance abuse is increased by coexisting personal problems.

The voluntary use of nonprescribed mood-altering pharmaceuticals is a disease. Untreated, substance abuse often leads to death from drug overdose—intentional or unintentional. One of the greatest challenges in treating drug abuse is identifying the afflicted individual, as denial is a consistent feature. Unfortunately, changes evident to an outside observer are often both vague and late: reduced involvement in social activities, subtle changes in appearance, extreme mood swings, and altered work habits. Options related to routine and for-cause workplace drug testing can be explored with a certified medical review officer (MRO). Treatment begins with a careful, well-planned intervention. Those inexperienced in this area would be well advised to consult with an addictionologist or their employee health department, local medical society, or licensing authority about how to proceed. The goal is to enroll the individual in a formal rehabilitation program. The possibility that one may lose one’s medical license and be unable to return to practice provides powerful motivation. Some diversion programs report a success rate of approximately 70%; however, most rehabilitation programs report a recurrence rate of at least 25%. Long-term compliance often involves continued participation in support groups (eg,
Narcotics Anonymous), random urine testing, and oral naltrexone therapy (a long-acting opioid antagonist). Effective prevention strategies are difficult to formulate; “better” control of drug availability is unlikely to deter a determined individual. It is unlikely that education about the severe consequences of substance abuse will bring new information to the potential drug-abusing physician. There remains controversy regarding the rate at which anesthesia staff will experience recidivism. Many experts argue for a “one strike and you’re out” policy for anesthesiology residents who abuse injectable drugs. The decision as to whether a fully trained and certified physician who has been discovered to abuse injectable drugs should return to anesthetic practice after completing a rehabilitation program varies and depends on the rules and traditions of the practice group, the medical center, the relevant medical licensing board, and the perceived likelihood of recidivism. Physicians returning to practice following successful completion of a program must be carefully monitored over the long term, as relapses can occur years after apparent successful rehabilitation.

Alcohol abuse is a common problem among physicians and nurses, and anesthesia personnel are no exception. Interventions for alcohol abuse, as is true for injectable drug abuse, must be carefully orchestrated. Guidance from the employee health program, local medical society, or licensing authority is highly recommended.

4. Ionizing Radiation Exposure

The use of imaging equipment (eg, fluoroscopy) during surgery and interventional radiological procedures exposes the anesthesiologist to the potential risks of ionizing radiation. The three most important methods of minimizing radiation doses are limiting total exposure time during procedures, using proper barriers, and maximizing one’s distance from the source of radiation. Anesthesiologists who routinely perform fluoroscopic image-guided invasive procedures should consider wearing protective eyewear incorporating radiation shielding. Lead glass partitions or lead aprons with thyroid shields are mandatory for all personnel who are exposed to ionizing radiation. The inverse square law states that the dosage of radiation varies inversely with the square of the distance. Thus, the exposure at 4 m will be one-sixteenth that at 1 m. The maximum recommended occupational whole-body exposure to radiation is 5 rem/y. This can be monitored with an exposure badge. The health impact of exposure to electromagnetic radiation remains unclear.
CASE DISCUSSION

Unexplained Intraoperative Tachycardia & Hypertension

A 73-year-old man is scheduled for emergency relief of an intestinal obstruction from a sigmoid volvulus. The patient had a myocardial infarction 1 month earlier that was complicated by congestive heart failure. His blood pressure is 160/90 mm Hg, pulse 110 beats/min, respiratory rate 22 breaths/min, and temperature 38.8°C.

Why is this case an emergency?

Strangulation of the bowel begins with venous obstruction, but can quickly progress to arterial occlusion, ischemia, infarction, and perforation. Acute peritonitis could lead to severe dehydration, sepsis, shock, and multiorgan failure.

What special monitoring is appropriate for this patient?

Because of the history of recent myocardial infarction and congestive heart failure, an arterial line would be useful. TEE and pulse contour analysis monitors of cardiac output could be used. Pulmonary arterial flotation catheters have often been used in the past, but they are associated with significant complications and their use does not improve patient outcomes. Large fluid shifts should be anticipated. Furthermore, information regarding myocardial oxygen supply (diastolic blood pressure) and demand (systolic blood pressure, left ventricular wall stress, and heart rate) should be continuously available.

What cardiovascular medications might be useful during general anesthesia?

Severe tachycardia or extremes in arterial blood pressure should be avoided. During the laparotomy, gradual increases in heart rate and blood pressure are noted. ST-segment elevations appear on the electrocardiogram. A nitroglycerin infusion is started. The heart rate is now 130 beats/min, and the blood pressure is 220/140 mm Hg. The concentration of volatile anesthetic is increased, and metoprolol is administered intravenously in 1-mg increments. This results in a decline in heart rate to 115 beats/min, with no change in blood pressure. Suddenly, the rhythm converts to ventricular
tachycardia, with a profound drop in blood pressure. As amiodarone is being administered and the defibrillation unit prepared, the rhythm degenerates into ventricular fibrillation.

**What can explain this series of events?**

A differential diagnosis of pronounced tachycardia and hypertension might include pheochromocytoma, malignant hyperthermia, or thyroid storm. In this case, further inspection of the nitroglycerin infusion reveals a labeling error: although the tubing was labeled “nitroglycerin,” the infusion bag was labeled “epinephrine.”

**How does this explain the paradoxical response to metoprolol?**

Metoprolol is a β₁-adrenergic antagonist. It inhibits epinephrine’s β₁-stimulation of heart rate, but does not antagonize α-induced vasoconstriction. The net result is a decrease in heart rate, but a sustained increase in blood pressure.

**What is the cause of the ventricular tachycardia?**

An overdose of epinephrine can cause life-threatening ventricular arrhythmias. In addition, if a central venous catheter was malpositioned, with its tip in the right ventricle, the catheter tip could have stimulated ventricular arrhythmias.

**What other factors may have contributed to this anesthetic mishap?**

Multiple factors will often combine to create an anesthetic misadventure. Incorrect drug labels are but one example of errors that can result in patient injury. Inadequate preparation, technical failures, knowledge deficits, and practitioner fatigue or distraction can all contribute to adverse outcomes. Careful adherence to hospital policies, checklists, patient identification procedures, and surgical and regional block timeouts can all help to prevent iatrogenic complications.

### Cardiopulmonary Resuscitation

*N. Martin Giesecke, MD and George W. Williams, MD, FASA, FCCP*

---

#### KEY CONCEPTS

1. Cardiopulmonary resuscitation and emergency cardiac care (CPR-ECC) should be considered any time an individual cannot adequately oxygenate or perfuse vital organs—not only following cardiac or respiratory arrest.

2. Regardless of which transtracheal jet ventilation system is chosen, it must be readily available, use low-compliance tubing, and have secure connections.

3. Chest compressions should not be delayed; intubation may take place during CPR or the pulse check.

4. Attempts at intubation should not interrupt ventilation for more than 10 s.

5. Chest compressions should begin prior to the delivery of breaths in the pulseless patient.

6. Whether adult resuscitation is performed by a single rescuer or by two rescuers, two breaths are administered every 30 compressions (30:2), allowing 3 to 4 s for each two breaths. The cardiac compression rate should be 100/min regardless of the number of rescuers.

7. Health care personnel working in hospitals and ambulatory care facilities must be able to provide early defibrillation to patients with ventricular fibrillation as soon as possible. Shock should be delivered within 3 to 4 min of arrest.

8. If intravenous cannulation is difficult, an intraosseous infusion can provide emergency vascular access in children and adults.

9. Lidocaine, epinephrine, atropine, naloxone, and vasopressin (but not sodium bicarbonate) can be delivered via a catheter whose tip extends
past the endotracheal tube. Dosages 2 to $2\frac{1}{2}$ times higher than recommended for intravenous use, diluted in 10 mL of normal saline or distilled water, are recommended for adult patients.

Because carbon dioxide, but not bicarbonate, readily crosses cell membranes and the blood–brain barrier, arterial hypercapnia causes intracellular tissue acidosis.

A wide QRS complex following a pacing spike signals electrical capture, but mechanical (ventricular) capture must be confirmed by an improving pulse or blood pressure.

Cardiopulmonary resuscitation and emergency cardiac care (CPR-ECC) should be considered any time an individual cannot adequately oxygenate or perfuse vital organs—not only following cardiac or respiratory arrest.

This chapter presents an overview of the 2015 American Heart Association (AHA) Guidelines Update for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, which provides revised recommendations for establishing and maintaining the “CABDs” of cardiopulmonary resuscitation: Circulation, Airway, Breathing, and Defibrillation (Table 55–1, Figures 55–1 and 55–2). The 2015 CPR-ECC guidelines have been updated with new evidence-based recommendations. Points of particular importance for the layperson are that the pulse should not be checked, and chest compression without ventilation may be as effective as compression with ventilation for the first several minutes. If a second lay rescuer is unavailable to perform mouth-to-mask ventilation, chest compressions alone are preferred to the primary rescuer attempting to do both. For the health care provider, defibrillation using biphasic electrical current works best and endotracheal tube (ETT) placement should be confirmed with a quantitative capnographic waveform analysis. More importantly, in the new guidelines, emphasis has been placed on the quality and adequacy of compressions, minimizing interruption time of compressions and preshock pause (the time taken from the last compression to the delivery of shock).

**TABLE 55–1** Emergency cardiac care (ECC).

**FIGURE 55–2** Comprehensive emergency cardiac care algorithm. BLS, basic life support; CPR, cardiopulmonary resuscitation; IO, intraosseous; IV, intravenous; PEA, pulseless electrical activity; VF/VT, ventricular fibrillation and pulseless ventricular tachycardia.

The sequence of steps in resuscitation has been changed since the 2010 guidelines from ABC (airway and breathing first, before compression) to CAB (compression first, with airway and breathing treated later). Based on the 2015 guidelines, titrating resuscitative efforts to physiological parameters
does not improve outcome. Nonetheless, physiological monitoring methods to optimize CPR quality and return of spontaneous circulation (ROSC) are still useful. The rule of tens and multiples can be applied: less than 10 s to check for pulse, less than 10 s to place and secure the airway, target chest compression adequacy to maintain end-tidal pressure of carbon dioxide (Petco2) greater than 10 mm Hg, and target chest compression to maintain arterial diastolic blood pressure greater than 20 mm Hg and central venous oxygen saturation (Scvo2) greater than 30%. The 2015 guidelines suggest that a lack of a PetCO2 greater than 10 mm Hg after 20 min in an intubated patient may be considered as a marker to end resuscitative efforts. An exception to this determination applies to nonintubated patients, in whom a specific PetCO2 cutoff should not be used to aid in the decision to end resuscitative efforts.

Changes in drug recommendations are notable for the exclusion of routine administration of high-dose epinephrine (0.1–0.2 mg/kg) during cardiac arrest. Additionally, vasopressin alone or in combination with epinephrine, according to the guidelines, offers no advantage over normal-dose epinephrine (1 mg every 3–5 min) in adult resuscitation following cardiac arrest. Amiodarone may be considered for ventricular fibrillation that is unresponsive to resuscitative efforts. Lidocaine is no longer recommended for routine use after cardiac arrest; however, it may be administered as an infusion following ROSC if the arrest occurred because of ventricular fibrillation or pulseless ventricular tachycardia. Additionally, β-blockers should not be used routinely in cardiac arrest (until after the CPR period has passed).

While the use of extracorporeal membrane oxygenation (ECMO, also referred to as extracorporeal cardiopulmonary resuscitation, ECPR) has been a topic of great interest and is increasingly available, the routine use of ECPR for cardiac arrest is not yet recommended. However, the guidelines suggest that when the etiology of the cardiac arrest is potentially reversible, the use of ECPR may be considered. The new guidelines also allow for the use of point-of-care ultrasound, but do not require it. Ultrasound techniques should only be performed by qualified personnel, and ultrasound interventions should not disrupt normal resuscitative practices and protocols.

This chapter is not intended as a substitute for a formal course in either life support without the use of special equipment (Basic Life Support [BLS]) or with the use of special equipment and drugs (Advanced Cardiac Life Support [ACLS]). Neonatal resuscitation is described in Chapter 41.
AIRWAY

Before CPR is initiated, unresponsiveness is established and the emergency response system is activated. During low blood flow states such as cardiac arrest, oxygen delivery to the heart and brain is limited by blood flow rather than by arterial oxygen content; thus, current guidelines place greater emphasis on immediate initiation of chest compressions than on rescuer breaths.

The patient is positioned supine on a firm surface. After initiation of chest compressions, the airway is evaluated. The airway is most commonly obstructed by posterior displacement of the tongue or epiglottis. If there is no evidence of cervical spine instability, a head-tilt chin-lift should be tried first (Figure 55–3). One hand (palm) is placed on the patient’s forehead applying pressure to tilt the head back while lifting the chin with the forefinger and index finger of the opposite hand. The jaw-thrust may be more effective in opening the airway and is executed by placing both hands on either side of the patient’s head, grasping the angles of the jaw, and lifting. Basic airway management is discussed in detail in Chapter 19, and the trauma patient is considered in Chapter 39.
FIGURE 55–3 Loss of consciousness is often accompanied by loss of submandibular muscle tone (A). Occlusion of the airway by the tongue can be relieved by a head-tilt chin-lift (B) or a jaw-thrust (C). In patients with possible cervical spine injury, the angles of the jaw should be lifted anteriorly without hyperextending the neck.

Any vomitus or foreign body visible in the mouth of an unconscious patient should be removed. If the patient is conscious or if the foreign body cannot be removed by a finger sweep, the *Heimlich maneuver* is recommended. This subdiaphragmatic abdominal thrust elevates the diaphragm, expelling a blast of air from the lungs that displaces the foreign body (Figure 55–4). Complications of the Heimlich maneuver include rib fracture, trauma to internal viscera, and regurgitation with aspiration. A combination of back blows and chest thrusts is recommended to clear foreign body obstruction in infants (Table 55–2).

FIGURE 55–4 The Heimlich maneuver can be performed with the victim standing (A) or lying down (B). The hands are positioned slightly above the navel and well below the xiphoid process and then pressed into the abdomen with a quick upward thrust. The maneuver may need to be repeated.

TABLE 55–2 Summary of recommended basic life support techniques.
If after opening the airway there is no evidence of adequate breathing, the rescuer should initiate assisted ventilation by inflating the victim’s lungs with each breath using a bag-mask device (see Chapter 19). Breaths are delivered slowly (inspiratory time of $\frac{1}{2}$–1 s) at a rate of about 10 breaths/min, with smaller tidal volumes [$V_T$] so as to minimize adverse effect on cardiac preload. **Compressions (100–120/min) should not be suspended during two-person CPR to permit ventilation unless ventilation is not possible during compressions.**

With positive-pressure ventilation, even with a small $V_T$, gastric inflation with subsequent regurgitation and aspiration is possible. Therefore, as soon as feasible, the airway should be secured with an ETT, or, if that is not possible, an alternative airway should be inserted. There is inadequate evidence to support the optimal timing of the placement of an advanced airway (supraglottic device, ETT); however, chest compressions should not be more than minimally interrupted to place any advanced airway device. The benefit of an advanced airway must be considered in light of the risk of potential interruption in compressions. Advanced airways include the esophageal–tracheal Combitube (ETC), laryngeal mask airway (LMA), pharyngotracheal lumen airway, King laryngeal tube, and cuffed oropharyngeal airway. The ETC and LMA, along with oral and nasopharyngeal airways, face masks, laryngoscopes, and ETTs, are discussed in Chapter 19. Of these, the LMA is increasingly preferred for in-hospital arrests. The choice of bag-mask ventilation versus placement of an advanced airway is dependent upon the skills of the providers. Studies conflict as to optimal use of advanced airway management techniques in comparison to bag-mask ventilation.

Independent of which airway adjunct is used, the guidelines state that rescuers must confirm ETT placement with a $\text{PETCO}_2$ detector—an indicator, a capnograph, or a capnometric device. The preferred choice for confirmation of ETT placement is continuous capnographic waveform analysis. All confirmation devices are considered adjuncts to clinical conformation techniques (eg,
auscultation). Once an artificial airway is successfully placed, it must be carefully secured with a tie or tape (25% of airways are displaced during transportation).

Some causes of airway obstruction may not be relieved by conventional methods. Furthermore, endotracheal intubation may be technically impossible to perform (eg, severe facial trauma), or repeated attempts may be unwise (eg, cervical spine trauma). In these circumstances, cricothyrotomy or tracheotomy may be necessary. Cricothyrotomy involves placing a large intravenous catheter or a commercially available cannula into the trachea through the midline of the cricothyroid membrane (Figure 55–5). Proper location is confirmed by aspiration of air. A 12- or 14-gauge catheter requires a driving pressure of 50 psi to generate sufficient gas flow for transtracheal jet ventilation. The catheter must be adequately secured to the skin, as the jet ventilation pressure can otherwise easily propel the catheter out of the trachea and, if the tip remains beneath the skin, lead to massive subcutaneous emphysema.
FIGURE 55–5 Percutaneous cricothyrotomy with a 14-gauge over-the-needle intravenous catheter. **A:** Locate the cricothyroid membrane. **B:** Puncture the membrane at the midline while stabilizing the trachea with the other hand. Proper location is confirmed by easy aspiration of air. **C:** Advance the catheter and withdraw the needle. Attach syringe to catheter and aspirate again after the catheter is advanced in order to confirm that the catheter remains in the tracheal lumen.
Various systems are available that connect a high-pressure source of oxygen (eg, central wall oxygen, tank oxygen, or the anesthesia machine fresh gas outlet) to the catheter (Figure 55–6). A hand-operated jet injector or the oxygen flush valve of an anesthesia machine controls ventilation. The addition of a pressure regulator minimizes the risk of barotrauma.

**FIGURE 55–6** A, B: Two systems for transtracheal jet ventilation after cricothyrotomy (see Figure 55–5). A jet ventilator and pressure regulator (as shown in A) provide better control of the inspiratory cycle. Both systems use low-compliance tubing and a high-pressure source of oxygen. C: The hub from a 7.0 ETT may be adapted to connect with a 14-gauge catheter and 3 mL syringe in order to provide jet ventilation with oxygen when outside the operating room or when jet ventilation is not available.

Regardless of which transtracheal jet ventilation system is chosen, it must be readily available, use low-compliance tubing, and have secure connections. Direct connection of a 12- or 14-gauge intravenous catheter to the anesthesia circle system does not allow adequate ventilation because of the high compliance of the corrugated breathing tubing and breathing bag. Similarly, one
cannot reliably deliver acceptable ventilation through a 12- or 14-gauge catheter with a self-inflating resuscitation bag.

Adequacy of ventilation—particularly expiration—is judged by observation of chest wall movement and auscultation of breath sounds. Acute complications include pneumothorax, subcutaneous emphysema, mediastinal emphysema, bleeding, esophageal puncture, aspiration, and respiratory acidosis. Long-term complications include tracheomalacia, subglottic stenosis, and vocal cord changes. Cricothyrotomy is not generally recommended in children younger than 10 years of age.

Tracheotomy can be performed in a more controlled fashion after oxygenation has been restored by cricothyrotomy (see Chapter 19).

**BREATHING**

Assessment of spontaneous breathing should immediately follow the opening or the establishment of the airway. Chest compressions and ventilation should not be delayed for intubation if a patent airway is established by a jaw-thrust maneuver; intubation may take place during CPR or the pulse check. Apnea is confirmed by lack of chest movement, absence of breath sounds, and lack of airflow. Regardless of the airway and breathing methods employed, a specific regimen of ventilation has been proposed for the apneic patient and described earlier in this chapter. Initially, two breaths are slowly administered (2 s per breath in adults, 1–1½ s in infants and children). If these breaths cannot be delivered, either the airway is still obstructed and the head and neck need repositioning or a foreign body is present that must be removed.

Bag-mask rescue breathing should be instituted in the apneic patient when these devices are immediately available. Supplemental oxygen, preferably 100%, should always be used if available. Successful rescue breathing, **400–700 mL Vt, 8–10 times per minute in an adult with a secured airway and a ratio of 30 compressions to 2 ventilations if the airway is unsecured**, is confirmed by observing the chest rising and falling with each breath and hearing and feeling the escape of air during expiration.

Devices that avoid use of the provider’s mouth should be immediately available everywhere in the hospital. Ventilation with a mask may be performed in most patients by adjusting the airway or making the airtight seal more effective (see Chapter 19). Use of cricoid pressure to prevent regurgitation during cardiac arrest resuscitation may be considered; however, there are no data to support its efficacy in this (or any other) circumstance and its routine use is
not recommended.

Endotracheal intubation by competent personnel should be attempted as soon as practical. Attempts at endotracheal intubation should not interrupt ventilation for more than 10 s. After intubation, the patient can be ventilated with high oxygen concentrations. A rate of 8 to 10 breaths/min should be maintained, as higher ventilatory rates may impede cardiac output during CPR in a cardiac arrest situation.

The ratio of physiological dead space to tidal volume ($V_d/V_T$) reflects the efficiency of CO$_2$ elimination. $V_d/V_T$ increases during CPR as a result of low pulmonary blood flow and high alveolar pressures. Thus, minute ventilation may need to be increased by 50% to 100% once circulation is restored as CO$_2$ from the periphery is brought back to the lungs.

**Circulation**

Circulation takes precedence over airway interventions and breathing in the cardiac arrest patient. As previously noted, chest compressions should begin prior to the delivery of breaths. Subsequent actions to assess circulation may then vary depending on whether the responder is a lay person or health care provider. Although lay rescuers should assume that an unresponsive patient is in cardiac arrest and need not check the pulse, health care providers should assess for presence or absence of a pulse.

If the patient has an adequate pulse (carotid artery in an adult or child, brachial or femoral artery in an infant) or blood pressure, breathing is continued at 10 to 12 breaths/min for an adult or a child older than 8 years, and 20 breaths/min for an infant or a child younger than 8 years of age (Table 55–2). If the patient is pulseless or severely hypotensive, the circulatory system must be supported by a combination of external chest compressions, intravenous drug administration, and defibrillation when appropriate. Initiation of chest compressions is mandated by the inadequacy of peripheral perfusion, and drug choices and defibrillation energy levels often depend on electrocardiographic diagnosis of arrhythmias.

**External Chest Compression**

Chest compressions force blood to flow either by increasing intrathoracic pressure (thoracic pump) or by directly compressing the heart (cardiac pump). During CPR of short duration, the blood flow is created more by the cardiac
pump mechanism; as CPR continues, the heart becomes less compliant and the thoracic pump mechanism becomes more important. As important as the rate and force of compression are for maintaining blood flow, effective perfusion of the heart and brain is best achieved when chest compression consumes 50% of the duty cycle, with the remaining 50% devoted to the relaxation phase (allowing blood return into the chest and heart).

To perform chest compressions in the unresponsive or pulseless patient, the xiphoid process is located and the heel of the rescuer’s hand is placed over the lower half of the sternum. The other hand is placed over the hand on the sternum with the fingers either interlaced or extended, but off the chest. The rescuer’s shoulders should be positioned directly over the hands with the elbows locked into position and arms extended, so that the weight of the upper body is used for compressions. With a straight downward thrust, the sternum is depressed approximately 2 in. (5 cm) in adults, 1 to 1½ in. (2–4 cm) in children, and then allowed to return to its normal position. For an infant, compressions ½ to 1 in. (1½–2½ cm) in depth are made with the middle and ring fingers on the sternum one finger-breadth below the nipple line. Compression and release times should be equal.

Whether adult resuscitation is performed by a single rescuer or by two rescuers, **two breaths are administered every 30 compressions (30:2)**, allowing 3 to 4 s for the two breaths. **The cardiac compression rate should be 100/min** regardless of the number of rescuers. A slightly higher compression rate of more than 100/min is suggested for infants, with two breaths delivered every 30 compressions.

**Assessing the Adequacy of Chest Compressions**

Adequacy of cardiac output can be estimated by monitoring $P_{ETCO_2}$ (>10 mm Hg), $ScVO_2$ (>30%), or arterial pulsations (with arterial diastolic relaxation pressure >20 mm Hg). Arterial pulsations during chest compressions are not a good measure of adequate chest compression; however, spontaneous arterial pulsations are an indicator of ROSC. Physiological parameters, such as $P_{ETCO_2}$, $ScVO_2$, and diastolic arterial pressure, may aid in assessing the adequacy of chest compressions but cannot be used exclusively to determine if CPR should be discontinued.

1. **Petco2**—In an intubated patient, a $P_{ETCO_2}$ greater than 10 mm Hg indicates good-quality chest compressions; a $P_{ETCO_2}$ less than 10 mm Hg has been shown
to be a predictor of poor outcomes of CPR (decreased chance of ROSC) in CPR of more than 20 min duration. A transient increase in PETCO₂ may be seen with administration of sodium bicarbonate; however, an abrupt and sustained rise of PETCO₂ is an indicator of ROSC.

2. **Coronary perfusion pressure (CPP)**—This is the difference between the aortic diastolic pressure and the right atrial diastolic pressure. Arterial diastolic pressure in the radial, brachial, or femoral artery is a good indicator of CPP. Arterial diastolic pressure greater than 20 mm Hg is an indicator of adequate chest compressions.

3. **Scvo₂**—An Scvo₂ less than 30% in the jugular vein is associated with poor outcomes. If the Scvo₂ is less than 30%, attempts to improve the quality of CPR, either by improving the quality of compressions or through administration of medications, should be considered.

**DEFIBRILLATION**

Ventricular fibrillation is found most commonly in adults who experience nontraumatic cardiac arrest. The **time from collapse to defibrillation is the most important determinant of survival**. The chances for survival decline 7% to 10% for every minute without defibrillation (Figure 55–7). Therefore, patients who have cardiac arrest should be defibrillated as soon as possible. Health care personnel working in hospitals and ambulatory care facilities must be able to provide early defibrillation to collapsed patients with ventricular fibrillation as soon as possible. Shock should be delivered within 3 to 4 min of arrest.
Success of defibrillation versus time. The chance of successful defibrillation of a patient in ventricular fibrillation decreases 7% to 10% per minute.

There is no definite relationship between the energy requirement for successful defibrillation and body size. A shock with too low an energy level will not successfully defibrillate; conversely, too high an energy level may result in myocardial injury. Defibrillators deliver energy in either monophasic or biphasic waveforms. Biphasic waveforms are recommended for cardioversion as they achieve the same degree of success but with less energy and theoretically less myocardial damage; newly manufactured defibrillators use biphasic waveforms.

In many institutions, automated external defibrillators (AEDs) are available. Such devices are increasingly being used throughout communities by police, firefighters, security personnel, sports marshals, ski patrol members, and airline flight attendants, among others. They are placed in any public location where 20,000 or more people pass by every day. AEDs are technologically advanced, microprocessor-based devices that are capable of electrocardiographic analysis with very high specificity and sensitivity in differentiating shockable from nonshockable rhythms. All AEDs manufactured today deliver some type of biphasic waveform shock. Compared with monophasic shocks, biphasic shocks deliver energy in two directions with equivalent efficacy at lower energy levels and possibly with less myocardial injury. These devices deliver impedance-compensating shocks employing either biphasic truncated exponential (BTE) or
rectilinear (RBW) morphology. Biphasic shocks delivering low energy for defibrillation (120–200 joule [JJ]) have been found to be as or more effective than 200 to 360 J monophasic damped sine (MDS) waveform shocks. When using AEDs, one electrode pad is placed beside the upper right sternal border, just below the clavicle, and the other pad is placed just lateral to the left nipple, with the top of the pad a few inches below the axilla.

A decrease in time delay between the last compression and the delivery of a shock (the preshock pause) has received special emphasis in the new guidelines. Stacking shocks (delivering two or more shocks in immediate succession without intervening compressions) increases the time to next compression, and it has been noted that the first shock is usually associated with a 90% efficacy. Thus, stacked shocks have been replaced by a recommendation for a single shock, followed by immediate resumption of chest compressions.

For cardioversion of atrial fibrillation (Table 55–3), 120–200 J can be used initially with escalation if needed. For atrial flutter or paroxysmal supraventricular tachycardia (PSVT), an initial energy level of 50 to 100 J is often adequate. All monophasic shocks should start with 200 J. Manufacturer instructions typically provide the recommended starting shock energy level specific to the device.

**TABLE 55–3** Energy requirements for cardioversion using biphasic truncated exponential (BTE) or rectilinear morphology.¹

<td>120–200</td>
</tr>
</tbody>
</table>

Ventricular tachycardia, particularly monomorphic ventricular tachycardia, responds well to shocks at initial energy levels of 100 J. For polymorphic ventricular tachycardia or for ventricular fibrillation, initial energy can be set at 120 to 200 J, depending upon the type of biphasic waveform being used.
Stepwise increases in energy levels can be used if the first shock fails, although some AEDs operate with a fixed-energy protocol of 150 J with very high success in terminating ventricular fibrillation (Table 55–3).

Cardioversion should be synchronized with the QRS complex and is recommended for hemodynamically stable, wide-complex tachycardia requiring cardioversion, PSVT, atrial fibrillation, and atrial flutter. Polymorphic ventricular tachycardia should be treated as ventricular fibrillation with unsynchronized shocks.

**Invasive Cardiopulmonary Resuscitation**

Thoracotomy and open-chest cardiac massage are not part of routine CPR because of the frequent incidence of complications. Nonetheless, these invasive techniques can be helpful in specific life-threatening circumstances that preclude effective closed-chest massage. Possible indications include cardiac arrest associated with penetrating or blunt chest trauma, penetrating abdominal trauma, severe chest deformity, pericardial tamponade, or pulmonary embolism. Extracorporeal membrane oxygenation is increasing employed when the cause of arrest (eg, local anesthetic systemic toxicity) is reversible.

**Intravenous Access**

*Even though establishing reliable intravenous access is a high priority, it should not take precedence over initial chest compressions, airway management, or defibrillation.* A preexisting internal jugular or subclavian catheter is ideal for venous access during resuscitation. If there is no central line access, an attempt should be made to establish peripheral intravenous access in either the antecubital or the external jugular vein. Peripheral intravenous sites are associated with a significant delay of 1 to 2 min between drug administration and delivery to the heart, as peripheral blood flow is drastically reduced during CPR. Administration of drugs given through a peripheral intravenous line should be followed by an intravenous flush (eg, a 20-mL fluid bolus in adults) or elevation of the extremity for 10 to 20 s, or both. Establishing central vein access can potentially cause interruption of CPR but should be considered if an inadequate response is seen to peripherally-administered drugs.

If intravenous cannulation is difficult, an *intraosseous infusion* can provide emergency vascular access in children and adults. A rigid 18-gauge spinal needle with a stylet or a small bone marrow trephine needle can be inserted into the distal femur or proximal tibia. If the tibia is chosen, a needle is inserted 2 to 3
cm below the tibial tuberosity at a 45° angle away from the epiphyseal plate (Figure 55–8). Once the needle is advanced through the cortex, it should stand upright without support. Correct placement is confirmed by the ability to aspirate marrow through the needle and deliver a smooth infusion of fluid. A network of venous sinusoids within the medullary cavity of long bones drains into the systemic circulation by way of nutrient or emissary veins. This route is very effective for administration of drugs, crystalloids, colloids, and blood and can achieve flow rates exceeding 100 mL/h under gravity. Much higher flow rates are possible if the fluid is placed under pressure (eg, 300 mm Hg) with an infusion bag. The onset of drug action may be slightly delayed compared with intravenous or tracheal administration. The intraosseous route may require a higher dose of some drugs (eg, epinephrine) than recommended for intravenous administration. The use of intraosseous infusion for induction and maintenance of general anesthesia, antibiotic therapy, seizure control, and inotropic support has been described. (Note that most studies have evaluated the placement of intraosseous access in patients with intact hemodynamics or hypovolemic states, not in cardiac arrest situations.) Because of the risks of osteomyelitis and compartment syndrome, however, intraosseous infusions should be replaced by a conventional intravenous route as soon as possible. In addition, because of the theoretical risk of bone marrow or fat emboli, intraosseous infusions should be avoided if possible in patients with right-to-left shunts, pulmonary hypertension, or severe pulmonary insufficiency. Some resuscitation drugs are fairly well absorbed following administration through an ETT. Lidocaine, epinephrine, atropine, naloxone, and vasopressin (but not sodium bicarbonate) can be delivered via a catheter whose tip extends past the ETT. Notably, the American Heart Association recommends endotracheal dosing only when IV and intraosseous dosing cannot be accomplished. Dosages 2 to 2½ times higher than recommended for intravenous use, diluted in 10 mL of normal saline or distilled water, are recommended for adult patients.
FIGURE 55–8 Intraosseous infusions provide emergency access to the venous circulation in pediatric patients by way of the large medullary venous channels. The needle is directed away from the epiphyseal plate to minimize the risk of injury.

**Arrhythmia Recognition**

Successful pharmacological and electrical treatment of cardiac arrest (Figure 55–9) depends on definitive identification of the underlying arrhythmia. Interpreting rhythm strips in the midst of a resuscitation situation is frequently complicated by artifacts and variations in monitoring techniques (eg, lead systems, equipment).
FIGURE 55–9 Adult cardiac arrest algorithm—2015 update. Algorithm for treating ventricular fibrillation and pulseless ventricular tachycardia (VF/VT). Pulseless ventricular tachycardia should be treated in the same way as ventricular fibrillation. Note: This figure and Figures 55–1 and 55–2 emphasize the concept that rescuers and health care providers must assume that all unmonitored adult cardiac arrests are due to VF/VT. In each figure, the flow of the algorithm assumes that the arrhythmia is continuing. CPR, cardiopulmonary resuscitation; IV/IO, intravenous or intraosseous; PEA, pulseless electrical activity. (Reprinted with permission from Advanced Cardiovascular Life Support Provider Manual)
Drug Administration

Many of the drugs administered during CPR have been described elsewhere in this text. Table 55–4 summarizes the cardiovascular actions, indications, and dosages of drugs commonly used during resuscitation.

### TABLE 55–4 Cardiovascular effects, indications, and dosages of resuscitation drugs.\(^1,2\)

</tbody>
</table>
Atropine is not included as a drug for pulseless electrical activity/asystole in the new CPR-ECC guidelines; however, its use is retained for symptomatic bradycardia. Infusions of chronotropic drugs (eg, dopamine, epinephrine, isoproterenol) can be considered as an alternative to pacing if atropine is ineffective in the setting of symptomatic bradycardia. Calcium chloride, sodium bicarbonate, and bretylium are conspicuously absent from this table. Calcium (2–4 mg/kg of the chloride salt) is helpful in the treatment of documented hypocalcemia, hyperkalemia, hypermagnesemia, or a calcium channel blocker overdose. When used, 10% calcium chloride can be given at 2 to 4 mg/kg every 10 min. Sodium bicarbonate (0.5–1 mEq/kg) is not recommended in the guidelines and should be considered only in specific situations such as preexisting metabolic acidosis or hyperkalemia, or in the treatment of tricyclic antidepressant or barbiturate overdose. Sodium bicarbonate elevates plasma pH by combining with hydrogen ions to form carbonic acid, which readily dissociates into carbon dioxide and water. Because carbon dioxide, but not bicarbonate, readily crosses cell membranes and the blood–brain barrier, arterial hypercapnia causes intracellular tissue acidosis. Although successful defibrillation is not related to arterial pH, increased intramyocardial carbon dioxide may reduce the possibility of successful cardiac resuscitation. Furthermore, bicarbonate administration can lead to detrimental alterations in osmolality and the oxygen–hemoglobin dissociation curve. Therefore, effective alveolar hyperventilation and adequate tissue perfusion are the treatments of choice for the respiratory and metabolic acidosis that accompany resuscitation.
Intravenous fluid therapy with either colloid or balanced salt solutions is indicated in patients with intravascular volume depletion (eg, acute blood loss, diabetic ketoacidosis, thermal burns). Dextrose-containing solutions may lead to a hyperosmotic diuresis and may worsen neurological outcome. They should be avoided unless hypoglycemia is suspected. Likewise, administration of free water (eg, D$_5$W) may lead to cerebral edema.

**Emergency Pacemaker Therapy**

*Transcutaneous cardiac pacing (TCP)* is a noninvasive method of rapidly treating arrhythmias caused by conduction disorders or abnormal impulse. TCP is not routinely recommended in cardiac arrest. TCP use may be considered to treat asystole, bradycardia caused by heart block, or tachycardia from a reentrant mechanism. If there is concern about the use of atropine in high-grade block, TCP is always appropriate. If the patient is unstable with marked bradycardia, TCP should be implemented immediately while awaiting treatment response to drugs. A pacemaker unit has become a built-in feature of some defibrillator models. Disposable pacing electrodes are usually positioned on the patient in an anterior–posterior manner. The placement of the negative electrode corresponds to a V$_2$ electrocardiograph position, whereas the positive electrode is placed on the left posterior chest beneath the scapula and lateral to the spine. Note that this positioning does not interfere with paddle placement during defibrillation. Failure to capture may be due to electrode misplacement, poor electrode-to-skin contact, or increased transthoracic impedance (eg, barrel-shaped chest, pericardial effusion). Current output is slowly increased until the pacing stimuli obtain electrical and mechanical capture. A wide QRS complex following a pacing spike signals *electrical* capture, but *mechanical* (ventricular) capture must be confirmed by an improving pulse or blood pressure. Conscious patients may require sedation to tolerate the discomfort of skeletal muscle contractions. Transcutaneous pacing can provide effective temporizing therapy until transvenous pacing or other definitive treatment can be initiated. TCP has many advantages over transvenous pacing because it can be used by almost all acute care providers and can be initiated quickly at the bedside.

**Precordial Thump**

The precordial thump is to be considered only in witnessed, monitored, pulseless ventricular tachycardia when a defibrillator is not immediately available. It provides only 5 to 10 joules of mechanical energy to the heart. Recent studies
suggest the precordial thump rarely results in ROSC and usually results in either no change in rhythm or deterioration into ventricular fibrillation or asystole. The latter situation may represent the phenomenon known as *commotio cordis*, where blunt impact to the chest without structural trauma results in ventricular arrhythmias or asystole.

**RECOMMENDED RESUSCITATION PROTOCOLS**

A resuscitation team leader integrates the assessment of the patient, including electrocardiographic diagnosis, with the electrical and pharmacological therapy (*Table 55–5*). This person must have a firm grasp of the guidelines for cardiac arrest presented in the CPR-ECC algorithms (*Figures 55–9* to *55–13*).

CASE DISCUSSION

Intraoperative Hypotension & Cardiac Arrest

A 16-year-old boy is rushed to the operating room for emergency laparotomy and thoracotomy after suffering multiple abdominal and thoracic stab wounds. In the field, paramedics intubated the patient, started two large-bore intravenous lines, began fluid resuscitation, and inflated a pneumatic antishock garment. Upon arrival in the operating room, the patient’s blood pressure is unobtainable, heart rate is 128 beats/min (sinus tachycardia), and respirations are being controlled by a bag-valve device.
What should be done immediately?

Cardiopulmonary resuscitation must be initiated immediately: external chest compressions should be started as soon as the arterial blood pressure is found to be inadequate for vital organ perfusion. Because the patient is already intubated, the location of the endotracheal tube should be confirmed with chest auscultation and quantitative waveform capnography (if available, to assist in both confirmation of tube placement as well as to assess the adequacy of CPR) and 100% oxygen should be delivered.

Which CPR sequence best fits this situation?

Pulselessness in the presence of sinus rhythm suggests severe hypovolemia, cardiac tamponade, ventricular rupture, dissecting aortic aneurysm, tension pneumothorax, profound hypoxemia and acidosis, or pulmonary embolism. Epinephrine, 1 mg, should be administered intravenously.

What is the most likely cause of this patient’s profound hypotension?

The presence of multiple stab wounds strongly suggests hypovolemia. Point-of-care abdominal ultrasonography can rapidly identify a collapsed vena cava, which is pathognomonic of hypovolemia. Warmed fluids should be rapidly administered. Additional venous access can be sought as other members of the operating room team administer fluid through blood pumps or other rapid infusion devices. Five percent albumin or lactated Ringer’s solution is acceptable until blood products are available. Activation of a massive transfusion protocol is indicated.

What are the signs of tension pneumothorax and pericardial tamponade?

The signs of tension pneumothorax—the presence of air under pressure in the pleural space—include increasing peak inspiratory pressures, tachycardia and hypotension (decreased venous return), hypoxia (atelectasis), distended neck veins, unequal breath sounds, tracheal deviation, and mediastinal shift away from the pneumothorax. Point-of-care ultrasonography can also be used for identification of tension pneumothorax (and for diagnosis of pericardial tamponade), but should not interrupt chest compressions.
Pericardial tamponade—cardiac compression from pericardial contents—should be suspected in any patient with narrow pulse pressure, pulsus paradoxus (>10 mm Hg drop in systolic blood pressure with inspiration), elevated central venous pressure with neck vein distention, distant heart sounds, tachycardia, hypotension, and equalization of central venous, atrial, and ventricular end-diastolic pressures. Many of these signs may be masked by concurrent hypovolemic shock.

Fluid administration and properly performed external cardiac compressions do not result in satisfactory carotid or femoral pulsations. What else should be done?

Because external chest compressions are often ineffective in trauma patients, an emergency thoracotomy should be performed as soon as possible to clamp the thoracic aorta, relieve a tension pneumothorax or pericardial tamponade, identify possible intrathoracic hemorrhage, and perform open-chest cardiac compressions. Cross-clamping of the thoracic aorta increases brain and heart perfusion and decreases subdiaphragmatic hemorrhage. Lack of response to cross-clamping is a good predictor of demise.

What is the function of the pneumatic antishock garment, and how should it be removed?

Inflation of the bladders within a pneumatic antishock garment increases arterial blood pressure by elevating peripheral vascular resistance. Functionally, the suit has the same effect as thoracic aorta cross-clamping by decreasing blood flow and hemorrhage in the lower half of the body. Complications of inflating the abdominal section of the pneumatic antishock garment include kidney dysfunction, altered lung volumes, and visceral injury during external chest compressions. The suit should be deflated only after restoration of hemodynamic parameters. Even then, deflation should be gradual, as it may be accompanied by marked hypotension and by metabolic acidosis caused by reperfusion of ischemic tissues.

GUIDELINES

SUGGESTED READINGS

Postanesthesia Care

KEY CONCEPTS

1. Patients emerging from anesthesia should not leave the operating room until they have a patent airway, have adequate ventilation and oxygenation, and are hemodynamically stable; qualified anesthesia personnel must attend the transfer to the postanesthesia care unit (PACU).

2. Before the recovering patient is fully responsive, pain is often manifested as postoperative restlessness or agitation. Significant systemic disturbances (eg, hypoxemia, respiratory or metabolic acidosis, hypotension), bladder distention, or a surgical complication (eg, occult intraabdominal hemorrhage) must also be considered in the differential diagnosis of postoperative restlessness or agitation.

3. Postoperative nausea and vomiting (PONV; see Chapter 17) is the most common significant complication following general anesthesia, occurring in approximately 30% or more of all patients.

4. Intense shivering causes precipitous rises in oxygen consumption, CO₂ production, and cardiac output. These physiological effects may be poorly tolerated by patients with cardiac or pulmonary impairment.

5. Respiratory problems are the most frequently encountered serious complications in the PACU. The overwhelming majority are related to airway obstruction, hypoventilation, hypoxemia, or a combination of these problems.

6. Hypoventilation in the PACU is most commonly due to the residual depressant effects of anesthetic agents on respiratory drive, often made worse by preexisting obstructive sleep apnea.

7. Hypoventilation with obtundation, circulatory depression, and severe acidosis (arterial blood pH < 7.15) is an indication for immediate and
decisive ventilatory and hemodynamic intervention, including airway and inotropic support as needed.

Following naloxone administration, patients should be observed closely for recurrence of opioid-induced respiratory depression (“renarcotization”), as naloxone has a shorter duration of action than many opioids.

Increased intrapulmonary shunting from a decreased functional residual capacity relative to closing capacity is the most common cause of hypoxemia following general anesthesia.

The possibility of a postoperative pneumothorax should always be considered following central line placement, supraclavicular or intercostal blocks, abdominal or chest trauma (including rib fractures), neck dissection, thyroidectomy (especially if thyroid dissection extends into the thorax), tracheostomy, nephrectomy, or other retroperitoneal or intraabdominal procedures (including laparoscopy), especially if the diaphragm may have been penetrated or disrupted.

Hypovolemia is the most common cause of hypotension in the PACU and can result from inadequate fluid replacement, wound draining, or hemorrhage.

Noxious stimulation from incisional pain, endotracheal intubation, bladder distention, or preoperative discontinuation of antihypertensive medication is usually responsible for postoperative hypertension.

Historically, emphasis on specialized nursing care during the immediate postoperative period was prompted by the realization that many preventable early postoperative deaths occurred immediately after anesthesia and surgery. The World War II experience of providing surgical care to large numbers of battle casualties contributed to the postwar trend of centralization of immediate postoperative care in recovery rooms, where skilled nurses could pay close attention to several acute postoperative patients simultaneously. Recently, the practice of caring for selected postoperative patients overnight in a postanesthesia care unit (PACU), or the equivalent, has been a response to increasingly complex surgical procedures performed on higher-acuity patients, when there is a shortage of surgical intensive care beds.

Another recent transformation in postanesthesia care is related to the shift from inpatient to outpatient surgery. Now, more than 70% of surgical procedures in the United States are performed on an outpatient basis. Two phases of
recovery may be recognized for outpatient surgery. Phase 1 is the immediate care for patients during emergence and awakening from anesthesia that continues until standard PACU discharge criteria are met (see Discharge Criteria, later in the chapter). Phase 2 is a lower-level care that continues until the patient is ready to go home. “Fast-tracking” of appropriately managed outpatients may allow them to safely bypass phase 1 recovery and go directly to the phase 2 level of care.

In many institutions, the PACU also functions as a more intensely monitored location for perioperative and chronic pain patients undergoing procedures such as single-shot nerve blocks and placement of epidural and peripheral nerve catheters, and for patients undergoing other invasive procedures such as central line placement, electroconvulsive therapy, thoracentesis, paracentesis, or cardioversion. The PACU must be appropriately staffed and equipped to manage such patients and their potential complications. For example, in areas where regional and epidural blocks are administered, Intralipid should be stocked in anticipation of treating systemic local anesthetic toxicity.

This chapter reviews the essential components of a modern PACU, the general care of patients acutely recovering from anesthesia and surgery, and the respiratory and circulatory complications most commonly encountered in the PACU.

THE POSTANESTHESIA CARE UNIT

At the conclusion of any procedure requiring anesthesia, after anesthetic agents are discontinued, monitors are disconnected and the emerging patient is taken to the PACU by one or more qualified anesthesia providers, often assisted by other personnel. During transport, supplemental oxygen is given by nasal cannulae or mask and the patient is monitored with pulse oximetry. Following general anesthesia, if an endotracheal tube or laryngeal mask airway (LMA) was utilized, the endotracheal tube or LMA will usually be removed prior to transport. Patients are also routinely observed in the PACU following regional anesthesia and monitored anesthesia care (local anesthesia with sedation). Most facilities have protocols that require patients to be admitted to the PACU following any type of anesthesia, except by specific order of the attending anesthesiologist. After a brief “hand off” report to the PACU nurse, the patient will remain in the PACU until the major effects of anesthesia have worn off and any anesthesia- or surgery-related complications of significance have been adequately addressed. This period is characterized by a frequent incidence of potentially life-threatening respiratory and circulatory complications.
The delivery of anesthesia services in areas remote from the main operating room, such as gastrointestinal and pulmonary endoscopy, interventional radiology, and magnetic resonance imaging suites, is common. Patients recovering from anesthesia delivered in these areas must receive the same standard of care as surgical patients recovering from anesthesia. Some institutions have “satellite” PACUs to serve each of these remote areas individually and others send patients from their various procedural areas to one centralized PACU; however, the standard of postanesthesia care must be the same for all PACUs within a given institution.

Design

The PACU should be located near the operating rooms and remote procedure areas. A central location in the operating room area itself is desirable, as it ensures that the patient can be urgently transported back to surgery, if needed, or that members of the operating room team can quickly respond to urgent or emergent patient care issues in the PACU. Proximity to radiographic, laboratory, and other intensive care facilities on the same floor is also advantageous. Prolonged transfers subject critically ill patients to increased jeopardy from urgent problems that may arise along the way.

An open-ward design facilitates observation of multiple patients simultaneously. However, individually enclosed patient care spaces are required for patients needing isolation for infection control. Many institutions constructing new PACUs choose to fully enclose all the PACU patient beds for infection control and privacy. A ratio of 1.5 PACU beds per operating room is customary, although this ratio will vary depending on the respective operating room suite’s case type and volume, average case duration, and patient acuity. Each patient space should be well lit and large enough to allow easy access to patients for intravenous infusion pumps, ventilators, and radiographic equipment. Construction guidelines typically specify a minimum of 7 ft between beds and 120 sq ft per patient. Multiple electrical outlets, including at least one with backup emergency power, and at least one outlet each for oxygen and suction, should be present at each bed space.

Equipment

Inadequate monitoring in the PACU can lead to serious morbidity or mortality. Pulse oximetry ($SpO_2$), electrocardiogram (ECG), and automated noninvasive blood pressure (NIBP) monitors are mandatory for each patient. Although ECG,
\( \text{Spo}_2 \), and NIBP must be utilized for every patient in the initial phase of recovery from anesthesia (phase 1), decreased monitoring may be adequate thereafter. Appropriate equipment must be available for those patients with intraarterial, central venous, pulmonary artery, or intracranial pressure monitoring. Capnography is often useful for both intubated and extubated patients alike. Mercury or electronic thermometers must be used if an abnormality in temperature is suspected. A forced-air warming device, heating lamp, or a warming/cooling blanket should be available.

The PACU must have its own supplies of basic and emergency equipment, separate from that of the operating room, including airway equipment and supplies, such as oxygen cannulas, a selection of masks, oral and nasal airways, laryngoscopes, endotracheal tubes, LMAs, a cricothyrotomy kit, and self-inflating bags for ventilation. Respiratory therapy equipment for aerosol bronchodilator treatments, continuous positive airway pressure (CPAP), and ventilators should be in close proximity to the recovery room. A difficult airway equipment and supplies cart with a bronchoscope and a video laryngoscope must be immediately available.

A readily available supply of catheters for venous, arterial, and central venous cannulation is mandatory in an inpatient setting. A defibrillation device with transcutaneous pacing capabilities, and an emergency cart with drugs and supplies for advanced life support (see Chapter 55) and infusion pumps, must be present and periodically inspected according to accreditation standards. Transvenous pacing catheters; pulse generators; and tracheostomy, chest tube, and vascular cut-down trays are typically present, depending on the surgical patient population. Point-of-care ultrasonography equipment is increasingly available for central line and perineural catheter placement, assessment of hemodynamic status, endotracheal tube placement, gastric and bladder volume, and detection of pleural effusion, pneumothorax, and other pulmonary pathology.

**Staffing**

Inadequate staffing is often cited as a major contributing factor in PACU mishaps. The PACU should be staffed by nurses specifically trained in the care of patients emerging from anesthesia. They should have expertise in airway management and advanced cardiac life support, as well as in problems commonly encountered in surgical patients relating to wound care, drainage catheters, and postoperative hemorrhage.
Patients in the PACU should be under the medical direction of a physician, usually an anesthesiologist, who must be immediately available to respond to urgent or emergent patient care problems. High-volume tertiary care surgical institutions often have an anesthesiologist assigned full time to the PACU. The management of the patient in the PACU should reflect a coordinated effort involving qualified anesthesia providers, surgeons, nurses, respiratory therapists, and appropriate consultants. The anesthesia team emphasizes management of analgesia, airway, cardiac, pulmonary, and metabolic problems, whereas the surgical team generally manages any problems directly related to the surgical procedure itself. A ratio of one recovery nurse for two patients is generally satisfactory; however, staffing for nursing care should be tailored to the unique requirements of each patient and each facility. If the operating room schedule regularly includes pediatric patients or frequent short procedures, a ratio of one nurse to one patient is often needed. A charge nurse should be assigned to ensure optimal staffing resource management at all times, including the appropriate response to urgent or emergent patient care problems.

### Care of the Patient

**EMERGENCE FROM GENERAL ANESTHESIA**

Emergence from general anesthesia should ideally be characterized by a smooth and gradual awakening in a controlled environment. However, problems such as airway obstruction, shivering, agitation, delirium, pain, nausea and vomiting, hypothermia, and autonomic lability are frequently encountered. Patients receiving spinal or epidural anesthesia may experience decreases in blood pressure during transport or recovery; the sympatholytic effects of major conduction blocks may prevent compensatory reflex vasoconstriction when patients are moved or when they sit up.

Following an inhalational-based anesthetic, the speed of emergence is directly proportional to alveolar ventilation, but inversely proportional to the agent’s blood solubility (see Chapter 8). Hypoventilation delays emergence from inhalational anesthesia. As the duration of anesthesia increases, emergence also becomes increasingly dependent on total tissue uptake, which is a function of agent solubility, the average concentration used, and the duration of exposure to the anesthetic. Emergence from an intravenous anesthetic is a function of drug pharmacokinetics. Recovery from most intravenous agents is dependent primarily on redistribution rather than metabolism and elimination. As the total
administered dose increases, however, cumulative effects become clinically apparent in the form of prolonged emergence; the termination of action becomes increasingly dependent on the metabolism or elimination. This is the basis for the concept of a context-sensitive half-time (see Chapter 7). Advanced age or kidney or liver disease can prolong emergence (see Chapter 9). Short- and ultrashort-acting anesthetic agents, such as propofol and remifentanil, significantly shorten emergence and time to discharge. Use of a bispectral index (BIS) monitor (see Chapter 6) may reduce total drug dosage and shorten recovery and time to discharge. The speed of emergence can also be influenced by preoperative medications. Premedication with agents that outlast the procedure (eg, lorazepam) may be expected to prolong emergence. The short duration of action of midazolam makes it a suitable premedication agent for short procedures.

**Delayed Emergence**

The most frequent cause of delayed emergence (when the patient fails to regain consciousness within an expected period of time after general anesthesia) is residual drug effect. Delayed emergence may occur as a result of absolute or relative drug overdose. The effects of preoperative sleep deprivation or drug ingestion (alcohol, sedatives) can be additive to those of anesthetic agents in producing prolonged emergence. Intravenous naloxone (in 80 mcg increments in adults) and flumazenil (in 0.2 mg increments in adults) will readily reverse the effects of an opioid and benzodiazepine, respectively. Intravenous physostigmine (1–2 mg) may partially reverse the effect of other agents. A nerve stimulator can be used to exclude persisting neuromuscular blockade in poorly responsive patients on a mechanical ventilator who have inadequate spontaneous tidal volumes.

Less common causes of delayed emergence include hypothermia, marked metabolic disturbances, and perioperative stroke. A core temperature of less than 33°C has an anesthetic effect and greatly potentiates the actions of central nervous system depressants. Forced-air warming devices are most effective in raising body temperature. Hypoxemia and hypercarbia are readily excluded by pulse oximetry, capnography, and blood gas analysis. Hypercalcemia, hypermagnesemia, hyponatremia, and hypoglycemia and hyperglycemia are rare causes of delayed emergence that require laboratory measurements for diagnosis. Perioperative stroke is rare, except after neurological, cardiac, and cerebrovascular surgery (see Chapter 28); diagnosis is facilitated by neurological evaluation and radiological imaging.
TRANSPORT FROM THE OPERATING ROOM TO THE PACU

This seemingly short period may be complicated by the lack of adequate monitoring, medication access, or airway and resuscitative equipment. Patients emerging from anesthesia should not leave the operating room until they have a patent airway, have adequate ventilation and oxygenation, and are hemodynamically stable; qualified anesthesia personnel must attend the transfer. Transient hypoxemia (SpO₂ <90%) may develop in as many as 30% to 50% of otherwise “normal” patients during transport while breathing room air; supplemental oxygen may therefore be advisable for all transported patients, especially if the PACU is not in immediate proximity to the operating room. Unstable patients should remain intubated and should be transported with a portable monitor (ECG, SpO₂, and blood pressure) and a supply of emergency drugs. Since the transfer of intubated patients will always include the risk of inadvertent endotracheal tube dislodgement, appropriate airway equipment and supplies should be included in the transfer process, especially if the transfer travel distance is lengthy or includes an elevator ride.

All patients should be taken to the PACU on a bed or gurney that can be placed in either the head-down (Trendelenburg) or back-up position. The head-down position is useful for management of hypovolemic patients, whereas the back-up position is useful for patients with underlying pulmonary dysfunction (see Chapters 20 and 23). Patients at increased risk of vomiting or upper airway bleeding (eg, following tonsillectomy) should be transported in the lateral position, which also helps prevent airway obstruction and facilitates drainage of secretions.

ROUTINE RECOVERY

General Anesthesia

Airway patency, vital signs, oxygenation, and level of consciousness must be assessed immediately upon PACU arrival. Subsequent blood pressure, heart rate, and respiratory rate measurements are routinely made at least every 5 min for 15 min or until stable, and every 15 min thereafter. Pulse oximetry and ECG are monitored continuously in all patients. In awake PACU patients, neuromuscular function should be assessed clinically (eg, head-lift and grip strength). At least one temperature measurement must also be obtained. Additional monitoring
includes assessment of pain; the presence or absence of nausea or vomiting; and adequacy of hydration and output, including urine flow, drainage, and bleeding. After initial vital signs have been recorded, the anesthesia provider should give a report to the PACU nurse that includes (1) relevant preoperative history (including mental status and any communication problems, such as language barriers, deafness, blindness, or mental disability); (2) pertinent intraoperative events (type of anesthesia, the surgical procedure, blood loss, fluid replacement, antibiotic and other relevant medication administration, and any complications); (3) any expected postoperative problems; (4) any anticipated need for PACU medication administration, such as antibiotics; and (5) postanesthesia orders. Postoperative orders should address analgesia and nausea/vomiting therapy; epidural or perineural catheter care, including the need for acute pain service involvement; administration of fluids or blood products; postoperative ventilation; chest radiographs for follow-up of central venous catheterization, etc.

All patients recovering from general anesthesia must receive supplemental oxygen and pulse oximetry monitoring during emergence because transient hypoxemia can develop even in healthy patients. A decision regarding continuation of supplemental oxygen therapy at the time of PACU discharge can be made based on $\text{SpO}_2$ readings on room air. Arterial blood gas measurements may be obtained to confirm abnormal oximetry readings, but are usually not necessary. Oxygen therapy should be carefully controlled in patients with a history of, or potential for, $\text{CO}_2$ retention. Patients should generally be nursed in the back-up position to optimize oxygenation. However, elevating the head of the bed before the patient is responsive can lead to airway obstruction. In such cases, a preexisting oral or nasal airway should be left in place until the patient is awake and able to maintain airway. Deep breathing and coughing should be encouraged periodically.

**Regional Anesthesia**

Patients who are heavily sedated or hemodynamically unstable following regional anesthesia should also receive supplemental oxygen in the PACU. Sensory and motor levels should be periodically recorded following regional anesthesia to document regression of the block. Precautions in the form of padding or repeated warning may be necessary to prevent self-injury from uncoordinated arm movements following brachial plexus blocks. Blood pressure should be closely monitored following spinal and epidural anesthesia. Bladder
catheterization may be necessary in patients who have had spinal or epidural anesthesia.

**Pain Control**

Moderate to severe postoperative pain is most commonly treated with oral or parenteral opioids. However, perioperative opioid administration is associated with side effects (nausea and vomiting, respiratory depression, pruritus, ileus, and urinary retention) which may have significant adverse effects on postoperative convalescence. In response to this problem, a variety of *opioid-sparing* strategies have been embraced over the past two decades to decrease opioid requirements and opioid-related side effects, while maintaining satisfactory analgesia (see Chapter 47). Preoperative oral administration of nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, and gabapentin or pregabalin may significantly reduce postoperative opioid requirements, and these medications may be readministered postoperatively when the patient can resume oral medication. Additional analgesic modalities utilizing local anesthetics, such as intraoperative wound infiltration, field blocks, postoperative wound catheter infusions, single-shot and continuous catheter peripheral nerve blocks, and continuous epidural infusions, also reduce postoperative opioid analgesic requirements, and thus also reduce opioid-related side effects.

Mild to moderate postoperative pain can be treated orally with acetaminophen, ibuprofen, hydrocodone, or oxycodone. Alternatively, ketorolac (15–30 mg in adults), an equivalent dose of diclofenac or ibuprofen, or acetaminophen (paracetamol) (15 mg/kg, or 1 g if patient >50 kg) may be administered intravenously.

In situations where moderate to severe postoperative pain is present, or oral analgesia is not possible, parenteral or intraspinal opioids, single-shot or continuous nerve blocks, wound infiltration, field blocks, intravenous lidocaine infusion, and continuous epidural analgesia are used, often in combination techniques (see Section IV). Parenteral opioids are most safely administered by titration of small doses. Considerable variability in opioid requirements should be expected, and adequate analgesia must be balanced against the risk of excessive sedation and respiratory depression. Intravenous opioids of intermediate to long duration, such as hydromorphone, 0.25 to 0.5 mg (0.015–0.02 mg/kg in children), or morphine, 2 to 4 mg (0.025–0.05 mg/kg in children), are most commonly used. Intravenous meperidine is most often used in small doses to treat postoperative shivering. Opioid requirements are often markedly increased in patients with opioid tolerance, especially in patients with
psychological dependence. Consultation with a pain specialist is often extremely helpful in these situations. If liposomal bupivacaine (Exparel) wound infiltration is used, appropriate written and verbal communication must be employed to preempt use of additional local anesthetics that could lead to systemic local anesthetic toxicity.

Analgesic effects of intravenous opioids usually peak within minutes of administration, although maximal respiratory depression, particularly with morphine and hydromorphone, may not occur until 20 to 30 min later. Patient-controlled analgesia can be instituted for inpatients when they are fully awake. Intramuscular administration of opioids is discouraged because delayed and variable onset (10–20 min or longer) and delayed respiratory depression (up to 1 h).

When an epidural catheter is used, epidural bolus administration of fentanyl (50–100 mcg) or sufentanil (20–30 mcg) with 5 to 10 mL of 0.1% bupivacaine can provide excellent pain relief in adults. Epidural morphine (3–5 mg) may also be used, but delayed respiratory depression with epidural administration of this opioid mandates close monitoring for 24 h afterward (see Chapter 48).

**Agitation**

Before the recovering patient is fully responsive, pain is often manifested as postoperative restlessness or agitation. Significant systemic disturbances (eg, hypoxemia, respiratory or metabolic acidosis, hypotension), bladder distention, or a surgical complication (eg, occult intraabdominal hemorrhage) must also be considered in the differential diagnosis of postoperative restlessness or agitation. Marked agitation may necessitate arm and leg restraints to avoid self-injury, particularly in children. When serious physiological disturbances have been excluded in children, cuddling and kind words from a sympathetic attendant or, preferably, the parents, often calms the pediatric patient. Other contributory factors include marked preoperative anxiety and fear, as well as adverse drug effects (large doses of central anticholinergic agents, phenothiazines, or ketamine). Physostigmine, 1 to 2 mg intravenously (0.05 mg/kg in children), is most effective in treating delirium due to atropine and scopolamine. If serious systemic disturbances and pain are excluded, persistent agitation may require sedation with intermittent intravenous doses of midazolam, 0.5 to 1 mg (0.05 mg/kg in children).

**Nausea & Vomiting**
Postoperative nausea and vomiting (PONV; see Chapter 17) is the most common significant complication following general anesthesia, occurring in approximately 30% or more of all patients. Moreover, PONV occurs at home within 24 h of an uneventful discharge (postdischarge nausea and vomiting) in a significant number of ambulatory surgery patients. The etiology of PONV is usually multifactorial and associated with anesthetic and analgesic agents, the type of surgical procedure, and intrinsic patient factors, such as a history of motion sickness. It is also important to recognize that nausea is a common complaint reported at the onset of hypotension, particularly following spinal or epidural anesthesia.

Table 56–1 lists commonly recognized risk factors for PONV. An increased incidence of nausea and vomiting is reported following opioid administration and following intraperitoneal (especially laparoscopic), breast, or strabismus surgery. The greatest incidence seems to be in young women. Increased vagal tone manifested as sudden bradycardia commonly precedes, or coincides with, emesis. Propofol anesthesia decreases the incidence of PONV, and a preoperative history of smoking lessens the likelihood of PONV. Selective 5-hydroxytryptamine (serotonin) receptor 3 (5-HT₃) antagonists, such as ondansetron, 4 mg (0.1 mg/kg in children), granisetron, 0.01–0.04 mg/kg, and dolasetron, 12.5 mg (0.035 mg/kg in children), are effective in preventing PONV, and, to a lesser extent, in treating established PONV. It should be noted that unlike ondansetron, which is usually effective immediately, dolasetron requires 15 min for onset of action. An orally disintegrating tablet preparation of ondansetron (8 mg) may be useful for treatment of, and prophylaxis against, postdischarge nausea and vomiting. Metoclopramide, 0.15 mg/kg intravenously, is a less effective alternative to 5-HT₃ antagonists. 5-HT₃ antagonists are not associated with the acute extrapyramidal (dystonic) manifestations and dysphoric reactions that may be encountered with metoclopramide or phenothiazine-type antiemetics. Transdermal scopolamine is effective, but can be associated with side effects including sedation, dysphoria, blurred vision, dry mouth, urinary retention, or exacerbation of glaucoma, particularly in elderly patients. Intravenous dexamethasone, 4 to 10 mg (0.10 mg/kg in children), when utilized as an antiemetic, has the additional advantages of providing a varying degree of analgesia and a sense of patient well-being. Moreover, it seems to be effective for up to 24 h, and, thus, may be useful for postdischarge nausea and vomiting. Oral aprepitant (Emend), 40 mg, may be administered within 3 h prior to anesthesia induction. Intravenous droperidol, 0.625 to 1.25 mg (0.05–0.075 mg/kg in children), when given intraoperatively, significantly decreases the
likelihood of PONV. Unfortunately, droperidol carries a U.S. Food and Drug Administration “black box” warning, indicating that large (5–15 mg) doses can prolong the QT interval and have been associated with fatal cardiac arrhythmias. Nonpharmacological prophylaxis against PONV includes ensuring adequate hydration (20 mL/kg) after fasting, and stimulation of the P6 acupuncture point (wrist). The latter may include application of pressure, electrical current, or injections.

Controversy exists regarding routine PONV prophylaxis for all patients. Because of the cost of treatment of established PONV, it may be cost-effective to provide prophylaxis to all patients in certain populations (eg, outpatients). Clearly, patients with multiple risk factors should receive prophylaxis. In
addition, the use of two or three agents that act on differing receptors is more effective than single-agent prophylaxis.

**Shivering & Hypothermia**

Shivering can occur in the PACU as a result of intraoperative hypothermia or the effects of anesthetic agents, or both, and it is also common in the immediate postpartum period. The most important cause of hypothermia is a redistribution of heat from the body core to the peripheral compartments (see Chapter 52). A relatively cool ambient operating room temperature, prolonged exposure of a large wound, and use of large amounts of unwarmed intravenous fluids or high flows of unhumidified gases can also be contributory. Nearly all anesthetics, particularly volatile agents and spinal and epidural anesthesia, decrease the normal vasoconstrictive response to hypothermia by decreasing sympathetic tone. Although anesthetic agents also decrease the shivering threshold, shivering commonly observed during or after emergence from general anesthesia often represents the body’s effort to increase heat production and raise body temperature, and may be associated with intense vasoconstriction. Emergence from even brief general anesthesia is sometimes also associated with shivering, and although the shivering can be one of several nonspecific neurological signs (eg, posturing, clonus, or Babinski’s sign) that are sometimes observed during emergence, it is most often due to hypothermia. Regardless of the mechanism, its incidence seems to be related to the duration of surgery and the use of a volatile agent. Shivering may occasionally be sufficiently intense to cause hyperthermia (38–39°C) and significant metabolic acidosis, both of which promptly resolve when the shivering stops. Other causes of shivering should be excluded, such as bacteremia and sepsis, drug allergy, or transfusion reaction.

Hypothermia should be treated with a forced-air warming device, or (less satisfactorily) with warming lights or heating blankets, to raise body temperature to normal. Intense shivering causes precipitous rises in oxygen consumption, CO₂ production, and cardiac output. These physiological effects may be poorly tolerated by patients with cardiac or pulmonary impairment. Hypothermia has been associated with an increased incidence of myocardial ischemia, arrhythmias, coagulopathy with increased transfusion requirements, and prolonged muscle relaxant effects. Small intravenous doses of meperidine (10–25 mg) can dramatically reduce or even stop shivering. Intubated, mechanically ventilated, and sedated patients can be given a muscle relaxant until normothermia is reestablished by active rewarming.
Discharge Criteria

A. PACU
Standards for discharging patients from the PACU are established by the department of anesthesiology and the hospital medical staff. They may allow PACU nurses to determine when patients may be transferred without the presence of a qualified anesthesia provider if all PACU discharge criteria have been met. Criteria can vary according to whether the patient is going to be discharged to an intensive care unit, a regular ward, phase 2 recovery, or directly home.

Before PACU discharge, patients should have been observed for respiratory depression for at least 20 to 30 min after the last dose of parenteral opioid. Other minimum discharge criteria for patients recovering from general anesthesia usually include the following:

1. Easy arousability
2. Full orientation
3. The ability to maintain and protect the airway
4. Stable vital signs for at least 15 to 30 min
5. The ability to call for help, if necessary
6. No obvious surgical complications (such as active bleeding)

Postoperative pain and nausea and vomiting must be controlled, and normothermia should be reestablished prior to PACU discharge. PACU patient scoring systems are widely used. Most assess $\text{SpO}_2$ (or color), consciousness, circulation, respiration, and motor activity (Table 56–2). The majority of patients can meet discharge criteria within 60 min from the time of PACU arrival. Patients to be transferred to other intensive care areas need not meet all requirements.

**TABLE 56–2** Postanesthetic Aldrete recovery score$^{1,2}$
In addition to the preceding criteria, patients receiving regional anesthesia should also be assessed for regression of both sensory and motor blockade. Complete resolution of the block prior to PACU dismissal avoids inadvertent injuries due to motor weakness or sensory deficits; however, many institutions have protocols that allow earlier discharge to appropriately monitored areas, and patients may be discharged with peripheral nerve blocks from single-shot or continuous perineural catheter infusions for the purpose of regional analgesia. Documenting regression of a block is important. Failure of a spinal or epidural block to resolve 6 h after the last dose of local anesthetic raises the possibility of spinal subdural or epidural hematoma, which should be excluded by prompt radiological imaging and neurologic evaluation.

A major goal of most anesthetics should be rapid, comfortable emergence with minimal risk of PONV and postoperative pain in order to minimize the time needed in recovery and facilitate transfer to the next stage of recovery. Outpatients who meet the discharge criteria when they exit the operating room may be “fast-tracked,” bypassing the PACU and proceeding directly to the phase 2 recovery area. Similarly, inpatients who meet the same criteria may be transferred directly from the operating room to their ward, if appropriate staffing and monitoring are present.

### B. Outpatients

In addition to emergence and awakening, recovery from anesthesia following outpatient procedures includes two additional stages: home readiness (phase 2...
recovery) and complete psychomotor recovery. A scoring system has been developed to help assess home readiness discharge (Table 56–3). Recovery of proprioception, sympathetic tone, bladder function, and motor strength are additional criteria following regional anesthesia. For example, intact proprioception of the big toe, minimal orthostatic blood pressure or heart rate changes, and normal plantar flexion of the foot are important signals of recovery following spinal anesthesia. Urination and drinking or eating before discharge are usually no longer required; exceptions include patients with a history of urinary retention and those with diabetes.

**TABLE 56–3  Postanesthesia discharge scoring system (PADS).**¹,²
All outpatients must be discharged home in the company of a responsible adult who will stay with them overnight. Patients and their adult accompaniment must be provided with written postoperative instructions covering both routine follow-up care and urgent/emergent assistance. The assessment of home readiness is the responsibility of a qualified anesthesia provider who is preferably already familiar with the patient, although authority to discharge a patient home can be delegated to a nurse if approved discharge criteria are

applied.

Home readiness does not imply that the patient has the ability to make important decisions, to drive, or to return to work. These activities require complete psychomotor recovery, which is often not achieved until 24 to 72 h postoperatively. All outpatient centers must use some system of postoperative follow-up, preferably phone contact or smartphone/web app the day after discharge.

Management of Complications

RESPIRATORY COMPLICATIONS

Respiratory problems are the most frequently encountered serious complications in the PACU. The overwhelming majority are related to airway obstruction, hypoventilation, hypoxemia, or a combination of these problems. Because hypoxemia is the final common pathway to serious morbidity and mortality, routine monitoring of pulse oximetry in the PACU leads to earlier recognition of these complications and fewer adverse outcomes.

Airway Obstruction

Airway obstruction in unconscious patients is most commonly due to the tongue falling back against the posterior pharynx and is often seen in patients with obstructive sleep apnea (see Chapter 19). Other causes include laryngospasm, glottic edema, aspirated vomitus, a retained throat pack, secretions or blood in the airway, or external pressure on the trachea (eg, from a neck hematoma). Partial airway obstruction usually presents as sonorous respiration. Near-total or total obstruction causes cessation of airflow and an absence of breath sounds and may be accompanied by paradoxic (rocking) movement of the chest. The abdomen and chest should normally rise together during inspiration; however, with airway obstruction, the chest descends as the abdomen rises during each inspiration (paradoxic chest movement). Patients with airway obstruction should receive supplemental oxygen while corrective measures are undertaken. A combined jaw-thrust and head-tilt maneuver pulls the tongue forward and opens the airway, and insertion of an oral or nasal airway often alleviates the problem. Nasal airways may be better tolerated than oral airways by patients emerging from anesthesia, especially when lidocaine-containing lubricant is used, and may decrease the likelihood of
trauma to the teeth if the patient bites down. Nasal airways may be easier to insert, with less risk of significant nasal bleeding, if a nasal spray vasoconstrictor, such as phenylephrine, is first administered. They should be inserted with caution, if at all, in patients with coagulopathy.

Laryngospasm should be considered if the aforementioned maneuvers fail to reestablish a patent airway. Laryngospasm is usually characterized by high-pitched crowing noises during ventilation, but may be silent with complete glottic closure. Spasm of the vocal cords is more apt to occur following airway trauma, repeated instrumentation, or stimulation from secretions, blood, or other foreign material in the airway. The jaw-thrust maneuver, particularly when combined with gentle positive airway pressure via a tight-fitting face mask, usually breaks laryngospasm. Insertion of an oral or nasal airway is also helpful in ensuring a patent airway down to the level of the vocal cords. Secretions, blood, or other foreign material in the hypopharynx should be suctioned to prevent recurrence. Refractory laryngospasm should be treated with a small dose of intravenous succinylcholine (10–20 mg in adults) and positive-pressure ventilation with 100% oxygen. Endotracheal intubation may occasionally be necessary to reestablish ventilation; emergent cricothyrotomy or transtracheal jet ventilation is indicated if intubation is unsuccessful in such instances.

Glottic edema following airway instrumentation is an important cause of airway obstruction in infants and young children because of the relatively small airway lumen. Significant pharyngeal and glottic edema and irritability, with friable, oozing oropharyngeal mucosa, is common in patients undergoing head and neck radiation therapy. Intravenous corticosteroids (dexamethasone, 0.5 mg/kg, 10-mg dose maximum) or aerosolized racemic epinephrine (0.5 mL of a 2.25% solution with 3 mL of normal saline) may be useful in such cases. Postoperative wound hematomas following thyroid, carotid artery, and other neck procedures can quickly compromise the airway, and opening the wound immediately relieves tracheal compression in most cases. Rarely, a gauze “throat pack” may be unintentionally left in the hypopharynx following oral surgery and can cause immediate or delayed complete airway obstruction.

Decannulation of a fresh tracheostomy is hazardous because recannulation may be very difficult or impossible when the wound has not yet healed into a well-formed track. When a tracheostomy has been performed within the previous 4 weeks, intentional replacement of a tracheostomy cannula should only be performed with a surgeon at the bedside and with a tracheostomy instrument set, along with other appropriate difficult airway equipment, immediately available.
**Hypoventilation**

Hypoventilation, which is generally defined as a PaCO₂ greater than 45 mm Hg, is common following general anesthesia. In most instances, such hypoventilation is mild and not recognized. Significant hypoventilation may present clinical signs when the PaCO₂ is greater than 60 mm Hg or arterial blood pH is less than 7.25, including excessive somnolence, airway obstruction, slow respiratory rate, tachypnea with shallow breathing, or labored breathing. Mild to moderate respiratory acidosis may cause tachycardia, hypertension, and cardiac irritability via sympathetic stimulation, but more severe acidosis produces circulatory depression (see Chapter 50). If significant hypoventilation is suspected, assessment and management is facilitated by capnography or arterial blood gas measurement, or both.

**Hypoventilation in the PACU is most commonly due to the residual depressant effects of anesthetics on respiratory drive, often made worse by preexisting obstructive sleep apnea.** Opioid-induced respiratory depression characteristically produces a slow respiratory rate, often with large tidal volumes. The patient is somnolent, but often responsive to verbal and physical stimulus and able to breathe on command. Delayed occurrence of respiratory depression has been reported with all opioids. Proposed mechanisms include variations in the intensity of stimulation during recovery and delayed release of the opioid from peripheral tissue compartments as the patient rewarms or begins to move.

Causes of residual muscle weakness in the PACU include inadequate muscle relaxant reversal, drug interactions that potentiate muscle relaxants, altered muscle relaxant pharmacokinetics (due to hypothermia, altered volumes of distribution, and renal or hepatic dysfunction), and metabolic factors such as hypokalemia, hyper- or hypomagnesemia, or respiratory acidosis. Regardless of the cause, generalized weakness, uncoordinated movements (“fish out of water”), shallow tidal volumes, and tachypnea are usually apparent. The diagnosis of inadequate neuromuscular blockade reversal can be made with a nerve stimulator in unconscious patients; head lift and grip strength can be assessed in awake and cooperative patients. Splinting due to incisional pain, diaphragmatic dysfunction following upper abdominal or thoracic surgery, abdominal distention, and tight abdominal dressings are other factors that can contribute to hypoventilation. Increased CO₂ production from shivering, hyperthermia, or sepsis can also increase PaCO₂, even in normal patients recovering from general anesthesia. Marked hypoventilation and respiratory
acidosis can result when these factors are superimposed on an impaired ventilatory reserve due to preexisting pulmonary, neuromuscular, or neurological disease.

**Treatment of Hypoventilation**

Treatment should generally be directed at the underlying cause, but marked hypoventilation always requires assisted or controlled ventilation until causal factors are identified and corrected. **Hypoventilation with obtundation, circulatory depression, and severe acidosis (arterial blood pH <7.15) is an indication for immediate and decisive ventilatory and hemodynamic intervention, including airway and inotropic support as needed.** If intravenous naloxone is used to reverse opioid-induced respiratory depression, titration in small increments (80 mcg in adults) usually avoids complications and minimizes reversal of analgesia. Antagonism of opioid-induced depression with large doses of naloxone often results in sudden pain and marked increase in sympathetic tone. The latter can precipitate a hypertensive crisis, pulmonary edema, and myocardial ischemia or infarction. Following naloxone administration, patients should be observed closely for recurrence of opioid-induced respiratory depression (“renarcotization”), as naloxone has a shorter duration of action than many opioids. If residual muscle paralysis is present, sugammadex (if rocuronium or vecuronium has been administered) or an additional cholinesterase inhibitor may be administered. Inadequate reversal in spite of a full dose of sugammadex or a cholinesterase inhibitor necessitates controlled ventilation under close observation until adequate recovery of muscle strength occurs. Hypoventilation due to pain and splinting following upper abdominal or thoracic procedures should be treated with multimodal analgesia, including intravenous or intraspinal opioid administration, intravenous acetaminophen, or NSAIDs, or with regional anesthesia techniques.

**Hypoxemia**

Mild hypoxemia is common in patients recovering from anesthesia when supplemental oxygen is not given. Mild to moderate hypoxemia (Pao₂ 50–60 mm Hg) in young healthy patients may be well tolerated initially, but with increasing duration or severity, the initial sympathetic stimulation often seen is replaced with progressive acidosis and circulatory depression. Cyanosis may not be detected if the hemoglobin concentration is reduced. Hypoxemia may also be suspected from restlessness, agitation, tachycardia, or atrial or ventricular
dysrhythmias. Obtundation, bradycardia, hypotension, and cardiac arrest are late signs. Pulse oximetry facilitates early detection of hypoxemia and must be routinely utilized in the PACU. Arterial blood gas measurements may be performed to confirm the diagnosis and guide therapy.

**Hypoxemia in the PACU is usually caused by hypoventilation with or without obstruction, increased right-to-left intrapulmonary shunting, or both.** A decrease in cardiac output or an increase in oxygen consumption (as with shivering) will accentuate hypoxemia. Diffusion hypoxia (see Chapter 8) is an uncommon cause of hypoxemia when recovering patients are given supplemental oxygen. Hypoxemia due exclusively to hypoventilation without obstruction is also unusual in patients receiving supplemental oxygen, unless marked hypercapnia or a concomitant increase in intrapulmonary shunting is present. Increased intrapulmonary shunting from a decreased functional residual capacity (FRC) relative to closing capacity is the most common cause of hypoxemia following general anesthesia. The greatest reductions in FRC occur following upper abdominal and thoracic surgery. The loss of lung volume is often attributed to microatelectasis, as atelectasis is often not identified on a chest radiograph. A semi-upright position helps maintain FRC.

Marked right-to-left intrapulmonary shunting ($Q_s/Q_T > 15\%$) is usually caused by atelectasis from prolonged intraoperative hypoventilation with low tidal volumes, unintentional endobronchial intubation, lobar collapse from bronchial obstruction by secretions or blood, pulmonary aspiration, pulmonary edema, large pleural effusion, or pneumothorax. Postoperative pulmonary edema may present with wheezing or less commonly with pink frothy fluid in the airway. Pulmonary edema may be due to left ventricular failure (cardiogenic), acute respiratory distress syndrome, or relief of prolonged airway obstruction (negative-pressure pulmonary edema). In contrast to wheezing associated with pulmonary edema, wheezing due to primary obstructive lung disease, which also often results in large increases in intrapulmonary shunting, is not associated with edema fluid in the airway or infiltrates on the chest radiograph. The possibility of a postoperative pneumothorax should always be considered following central line placement, supraclavicular or intercostal blocks, abdominal or chest trauma (including rib fractures), neck dissection, thyroidectomy (especially if the thyroid dissection extends into the thorax), tracheostomy, nephrectomy, or other retroperitoneal or intraabdominal procedures (including laparoscopy), especially if the diaphragm may have been penetrated or disrupted. Patients with subpleural blebs or large bullae can also develop pneumothorax during positive-pressure ventilation.
Treatment of Hypoxemia

Oxygen therapy, with or without positive airway pressure, and relief of any existing airway obstruction with airway maneuvers, an oral or nasal airway, or oropharyngeal suctioning, provide the cornerstones of treatment for hypoxemia. Routine administration of 30% to 60% oxygen is usually enough to prevent hypoxemia with even moderate hypoventilation and hypercapnia. Importantly, clinical signs of hypoventilation and hypercapnia may be masked by routine oxygen administration. Patients with underlying pulmonary or cardiac disease may require higher concentrations of oxygen; oxygen therapy should be guided by \( \text{SpO}_2 \) or arterial blood gas measurements. Oxygen concentration must be closely controlled in patients with chronic CO\(_2\) retention to avoid precipitating acute respiratory failure. Patients with severe or persistent hypoxemia should be given 100% oxygen via a nonrebreathing mask, LMA, or endotracheal tube until the cause is established and appropriate therapy is instituted; controlled or assisted mechanical ventilation may also be necessary. The chest radiograph (preferably with the patient positioned sitting upright) is valuable in assessing lung volume and heart size and in demonstrating pneumothorax, atelectasis, pulmonary infiltrates. However, in cases of pulmonary aspiration, infiltrates are usually initially absent. If pneumothorax is suspected, a chest radiograph taken at end-expiration helps highlight the pneumothorax by providing the greatest contrast between lung tissue and adjacent air in the pleural space. In the intubated patient with hypoxemia, a chest radiograph should be used to verify proper endotracheal tube position. Transthoracic ultrasonography is also a valuable tool for rapid, accurate assessment of endotracheal tube placement and diagnosis of lobar consolidation, pleural effusion, and pneumothorax.

Additional treatment of hypoxemia should be directed at the underlying cause. A chest tube or Heimlich valve should be inserted for any symptomatic pneumothorax or one that is greater than 15% to 20%. An asymptomatic pneumothorax may be aspirated or followed by observation. Bronchospasm should be treated with aerosolized bronchodilator therapy and potential or partial obstruction secondary to glottic or pharyngeal edema can be treated with racemic epinephrine or corticosteroids, or both. Diuretics should be given for fluid overload. Persistent hypoxemia in spite of 50% oxygen generally is an indication for positive end-expiratory pressure ventilation or continuous positive airway pressure. Therapeutic bronchoscopy is often useful in reexpanding lobar atelectasis caused by bronchial plugs or particulate aspiration. In the setting of an intubated patient, secretions or debris must be removed by suction and also by lavage, if necessary, and a malpositioned endotracheal tube must be
appropriately repositioned.

**CIRCULATORY COMPLICATIONS**

The most common circulatory disturbances in the PACU are hypotension, hypertension, and arrhythmias. The possibility that the circulatory abnormality is secondary to an underlying respiratory disturbance should always be considered before any other intervention, especially in children.

**Hypotension**

Hypotension is usually due to hypovolemia, left ventricular dysfunction, or excessive arterial vasodilatation. Hypovolemia is the most common cause of hypotension in the PACU, and can result from inadequate fluid replacement, wound drainage, or hemorrhage. Vasoconstriction from hypothermia may mask hypovolemia until the patient’s temperature begins to rise again; subsequent peripheral vasodilation during rewarming unmasks the hypovolemia and results in hypotension. Spinal and epidural anesthesia produce hypotension from a combination of arterial vasodilation and venous pooling of blood. Venodilators such as nitroglycerine (or spinal anesthesia) produce venous pooling and reduce the effective circulating blood volume, despite an otherwise normal intravascular volume (see Chapter 45). Hypotension associated with sepsis and allergic reactions is usually the result of both hypovolemia and vasodilation. Hypotension from a tension pneumothorax or cardiac tamponade is the result of impaired venous return to the right atrium. Removal of more than 500 to 1000 mL of ascites fluid during surgical procedure or paracentesis may result in subsequent hypotension as additional fluid migrates from the intravascular space into the abdomen.

Left ventricular dysfunction in previously healthy persons is unusual unless associated with severe metabolic disturbances (hypoxemia, acidosis, or sepsis). Hypotension due to ventricular dysfunction is primarily encountered in patients with underlying coronary artery or valvular heart disease or congestive heart failure and is usually precipitated by fluid overload, myocardial ischemia, acute increases in afterload, or arrhythmias.

**Treatment of Hypotension**

Mild hypotension during recovery from anesthesia is common and typically does not require intensive treatment. Significant hypotension is often defined as a
20% to 30% reduction in blood pressure below the patient’s baseline level and usually requires correction. Treatment depends on the ability to assess intravascular volume. An increase in blood pressure following a fluid bolus (250–500 mL crystalloid or 100–250 mL colloid) generally confirms hypovolemia. With severe hypotension, a vasopressor or inotrope (dopamine or epinephrine) may be necessary to increase arterial blood pressure until the intravascular volume deficit can be at least partially corrected. Signs of cardiac dysfunction should be sought in patients with known heart disease or cardiac risk factors. Failure of a patient with severe hypotension to promptly respond to initial treatment mandates echocardiographic examination or invasive hemodynamic monitoring (see Chapter 5). Manipulations of cardiac preload, contractility, and afterload are at times all required to restore the blood pressure to acceptable levels. The presence of a tension pneumothorax, as suggested by hypotension with unilaterally decreased breath sounds, hyperresonance, and tracheal deviation, is an indication for immediate pleural aspiration, even before ultrasound or radiographic confirmation. Similarly, hypotension due to cardiac tamponade, usually following chest trauma or thoracic surgery, often necessitates immediate pericardiocentesis or surgical exploration.

**Hypertension**

Postoperative hypertension is common in the PACU and typically occurs within the first 30 min after admission. Noxious stimulation from incisional pain, endotracheal intubation, bladder distention, or preoperative discontinuation of antihypertensive medication, is usually responsible. Postoperative hypertension may also reflect the neuroendocrine stress response to surgery or increased sympathetic tone secondary to hypoxemia, hypercapnia, or metabolic acidosis. Patients with a history of hypertension are more likely to develop hypertension in the PACU. Fluid overload or intracranial hypertension may also occasionally present as postoperative hypertension.

**Treatment of Hypertension**

Mild hypertension generally does not require treatment, but a reversible cause should be sought. Marked hypertension can precipitate postoperative bleeding, myocardial ischemia, heart failure, or intracranial hemorrhage. Although decisions to treat postoperative hypertension should be individualized, in general, elevations in blood pressure greater than 20% to 30% of the patient’s baseline, or those associated with adverse effects such as myocardial ischemia,
heart failure, or bleeding, should be treated. After pain and potential bladder distention have been addressed, mild to moderate elevations can be treated with intravenous labetalol; an angiotensin-converting enzyme inhibitor, such as enalapril; or a calcium channel blocker, such as nicardipine. Hydralazine and sublingual nifedipine (when administered to patients not receiving β-blockers) may cause tachycardia and myocardial ischemia and infarction. Marked hypertension in patients with limited cardiac reserve requires direct intraarterial pressure monitoring and should be treated with an intravenous infusion of nitroprusside, nitroglycerin, nicardipine, clevidipine, or fenoldopam. The endpoint for treatment should be consistent with the patient’s own normal blood pressure.

### Arrhythmias

Respiratory disturbances, particularly hypoxemia, hypercarbia, and acidosis, will commonly be associated with cardiac arrhythmias. Residual effects from anesthetic agents, increased sympathetic nervous system activity, other metabolic abnormalities, and preexisting cardiac or pulmonary disease also predispose patients to arrhythmias in the PACU.

Bradycardia often represents the residual effects of cholinesterase inhibitors, opioids, or β-adrenergic blockers. Tachycardia in the PACU is most commonly caused by pain, hypovolemia, or fever, but may also be due to the effects of an anticholinergic agent, a β-agonist such as albuterol, or reflex tachycardia from hydralazine. Anesthetic-induced depression of baroreceptor function makes heart rate an unreliable monitor of intravascular volume in the PACU.

Premature atrial and ventricular beats may be the result of hypokalemia, hypomagnesemia, increased sympathetic tone, or, less commonly, myocardial ischemia. The latter can be diagnosed with a 12-lead ECG. Premature atrial or ventricular beats noted in the PACU without discernable cause will often also be found on the patient’s preoperative ECG, if one is available. Supraventricular tachyarrhythmias, including paroxysmal supraventricular tachycardia, atrial flutter, and atrial fibrillation, are typically encountered in patients with a history of these arrhythmias and are more commonly encountered following thoracic surgery. The management of arrhythmias is discussed in [Chapters 21](#) and 55.
Fever & Tachycardia in a Young Adult Male

A 19-year-old man sustained a closed fracture of the femur in a motor vehicle accident. He was placed in traction for 3 days prior to surgery. During that time, a persistent low-grade fever (37.5–38.7°C orally), mild hypertension (150–170/70–90 mm Hg), and tachycardia (100–126 beats/min) were noted. His hematocrit remained at 30%. Broad-spectrum antibiotic coverage was initiated.

He is scheduled for open reduction and internal fixation of the fracture. When the patient is brought into the operating room, vital signs are as follows: blood pressure 160/95 mm Hg, pulse 150 beats/min, respirations 20 breaths/min, and oral temperature 38.1°C. He is sweating and is anxious. On close examination, he is noted to have a slightly enlarged thyroid gland.

Should the surgical team proceed with the operation?

The proposed operation is elective; therefore, significant abnormalities should be diagnosed and properly treated preoperatively, if possible, to prepare the patient optimally for surgery. If the patient had an open fracture, the risk of infection would clearly mandate immediate operation. Even with a closed femoral fracture, cancellations or delays should be avoided because nonoperative treatment potentiates the risks associated with bed rest, including atelectasis, pneumonia, deep venous thrombosis, and potentially lethal pulmonary thromboembolism. In deciding whether to proceed with the surgery, the anesthesia provider must ask the following questions:

1. What are the most likely causes of the abnormalities based on the clinical presentation?
2. What, if any, additional investigations or consultations might be helpful?
3. How would these or other commonly associated abnormalities affect anesthetic management?
4. Are the potential anesthetic interactions serious enough to delay surgery until a suspected cause is conclusively excluded? The tachycardia of 150 beats/min and the low-grade fever therefore require further evaluation prior to surgery.
What are the likely causes of the tachycardia and fever in this patient?

These two abnormalities may reflect one process or separate entities (Tables 56–4 and 56–5). Moreover, although multiple factors can often be simultaneously identified, their relative contribution is often not readily apparent. Fever commonly follows major trauma; contributory factors can include the inflammatory reaction to the tissue trauma, superimposed infection (most commonly wound, pulmonary, or urinary), antibiotic therapy (drug reaction), or thrombophlebitis. Infection must be seriously considered in this patient because of the risk of bacteria seeding and infecting the metal fixation device placed during surgery. Although tachycardia is commonly associated with a low-grade fever, it is usually not of this magnitude in a 19-year-old patient. Moderate to severe pain, anxiety, hypovolemia, or anemia may be other contributory factors. Pulmonary embolism should also be considered in any patient with long bone fracture, particularly when hypoxemia, tachypnea, or mental status changes are present. Lastly, the possibly enlarged thyroid gland, sweating, and anxious appearance, together with both fever and tachycardia, suggest thyrotoxicosis.

</table>
What (if any) additional measures may be helpful in evaluating the fever and tachycardia?

Arterial blood gas measurements, echocardiography and a chest radiograph would be helpful in the identification of pulmonary embolism. A repeat hematocrit or hemoglobin concentration measurement would exclude worsening anemia; significant tachycardia may be expected when the hematocrit is below 25% to 27% (hemoglobin <8 g/dL) in most patients. The response to an intravenous fluid challenge with 250 to 500 mL of a colloid or crystalloid solution may be helpful; a decrease in heart rate after the fluid bolus would be strongly suggestive of hypovolemia. Similarly, response of the heart rate to sedation and additional opioid analgesia would be helpful in excluding anxiety and pain, respectively, as causes. Although a tentative diagnosis of hyperthyroidism can be made based on clinical grounds, confirmation requires measurement of serum thyroid hormones. Signs of infection—such as increased inflammation or purulence in a wound, purulent sputum, an infiltrate on the chest film, pyuria, or leukocytosis with premature white cells on a blood smear ("shift to the
left”)—should prompt cultures and a delay of surgery until the results are obtained and correct antibiotic coverage is confirmed.

The patient is transferred to the PACU for further evaluation. A 12-lead ECG confirms sinus tachycardia of 150 beats/min. A chest film is normal. Arterial blood gas measurements on room air are normal (pH 7.44, \( \text{Paco}_2 \) 41 mm Hg, \( \text{Pao}_2 \) 87 mm Hg, and \( \text{HCO}_3^- \) 27 mEq/L). The hemoglobin concentration is found to be 11 g/dL. Blood for thyroid function tests is sent to the laboratory. The patient is sedated intravenously with midazolam (2 mg) and fentanyl (50 mcg) and is given 500 mL of 5% albumin. He seems to be relaxed and pain free, but the heart rate decreases only to 144 beats/min. The decision is made to proceed with surgery using continuous lumbar epidural anesthesia with 2% lidocaine. Esmolol is administered slowly until his pulse decreases to 120 beats/min, and a continuous esmolol infusion is administered at a rate of 300 mcg/kg/min.

The procedure is completed in 3 h. Although the patient did not complain of any pain during the procedure and was given only minimal additional sedation (midazolam, 2 mg), he is delirious upon admission to the PACU. The esmolol infusion is continuing at a rate of 500 mcg/kg/min. Estimated blood loss was 500 mL, and fluid replacement consisted of 2 units of packed red blood cell, 500 mL of 5% albumin solution, and 2000 mL of lactated Ringer’s injection. Vital signs are as follows: blood pressure 105/40 mm Hg, pulse 124 beats/min, respirations 30 breaths/min, and rectal temperature 38.8°C. Arterial blood gas measurements are reported as follows: pH 7.37, \( \text{Paco}_2 \) 37 mm Hg, \( \text{Pao}_2 \) 91 mm Hg, and \( \text{HCO}_3^- \) 22 mEq/L.

**What is the most likely diagnosis?**

The patient appears to be in a hypermetabolic state manifested by excessive adrenergic activity, fever, and a worsening mental status. The absence of major metabolic acidosis and lack of exposure to a known triggering agent exclude malignant hyperthermia (see Chapter 52). Other possibilities include a transfusion reaction, sepsis, or an undiagnosed pheochromocytoma. The sequence of events makes the first two unlikely, and the decreasing prominence of hypertension (now replaced with relative hypotension) and increasing fever also make the latter unlikely. The clinical presentation now suggests thyroid storm. He has also received a very large dose of esmolol for several hours and this may be contributing to the relatively low blood pressure despite aggressive fluid administration.
Emergency consultation is obtained with an endocrinologist, who concurs with the diagnosis of thyroid storm and assists with its management. How is thyroid storm managed?

Thyroid storm (crisis) is a medical emergency that carries a 10% to 50% mortality rate. It is usually encountered in patients with poorly controlled or undiagnosed Graves disease. Precipitating factors include (1) the stress of surgery and anesthesia, (2) labor and delivery, (3) severe infection, and, rarely, (4) thyroiditis 1 to 2 weeks following administration of radioactive iodine. Manifestations usually include mental status changes (irritability, delirium, or coma), fever, tachycardia, and hypotension. Both atrial and ventricular arrhythmias are common, particularly atrial fibrillation. Congestive heart failure develops in 25% of patients. Hypertension that often precedes hypotension, heat intolerance with profuse sweating, nausea and vomiting, and diarrhea may be prominent initially. Hypokalemia is present in up to 50% of patients. Levels of thyroid hormones are high in plasma, but correlate poorly with the severity of the crisis. The sudden exacerbation of thyrotoxicosis may represent a rapid shift of the hormone from the protein-bound to the free state or increased responsiveness to thyroid hormones at the cellular level.

Treatment is directed toward reversing the crisis and its complications. Large doses of corticosteroids inhibit the synthesis, release, and peripheral conversion of thyroxine (T₄) to the more active triiodothyronine (T₃). Corticosteroids also prevent relative adrenal insufficiency secondary to the hypermetabolic state. Propylthiouracil is administered to inhibit synthesis of thyroid hormone, and iodide is given to inhibit release of thyroid hormones from the gland. Propranolol not only antagonizes the peripheral effects of the thyrotoxicosis, but may also inhibit the peripheral conversion of T₄. Combined β₁- and β₂-blockade is preferable to selective β₁-antagonism (esmolol or metoprolol) because excessive β₂-receptor activity is responsible for the metabolic effects. β₂-Receptor blockade also reduces muscle blood flow and may decrease heat production. Supportive measures include surface cooling (cooling blanket), acetaminophen (aspirin is not recommended because it may displace thyroid hormone from plasma carrier proteins), and generous intravenous fluid replacement. Vasopressors are often necessary to support arterial blood pressure.

Ventricular rate control is indicated in patients with atrial fibrillation. Transthoracic echocardiography, transesophageal echocardiography, and
hemodynamic monitoring may facilitate management of patients with signs of congestive heart failure or persistent hypotension. β-Adrenergic blockade is contraindicated in patients with congestive heart failure.

Propranolol, dexamethasone, propylthiouracil, and sodium iodide are given; the patient is admitted to the intensive care unit, where treatment is continued. Over the next 3 days, his mental status markedly improves. The T₃ and total T₄ levels on the day of surgery were both elevated to 250 ng/dL and 18.5 ng/dL, respectively. He was discharged home 6 days later on a regimen of propranolol and propylthiouracil, with a blood pressure of 124/80 mm Hg, a pulse of 92 beats/min, and an oral temperature of 37.3°C.

SUGGESTED READINGS

CHAPTER 57

Common Clinical Concerns in Critical Care Medicine

KEY CONCEPTS

1. Pulmonary edema usually results from either an increase in the net hydrostatic pressure across the capillaries (hemodynamic or cardiogenic pulmonary edema) or an increase in the permeability of the alveolar–capillary membrane (increased permeability edema or noncardiogenic pulmonary edema).

2. Reduced tidal volumes are associated with the greatest improvement in outcome after ARDS of any intervention subjected to a randomized clinical trial to date.

3. Early elective tracheal intubation is advisable when there are obvious signs of heat injury to the airway. Patients with hoarseness and stridor require immediate tracheal intubation or a surgical airway.

4. The criteria developed by the Acute Kidney Injury Network are now most often used to stage acute kidney injury (AKI). AKI is diagnosed by documenting an increase in serum creatinine of more than 50%, or an absolute increase of 0.3 mg/dL, and a reduction in urine output to less than 0.5 mL/kg/h for 6 h or longer, with all findings developing over 48 h or less.

5. Septic shock is defined as acute circulatory failure in a patient with sepsis or, more specifically, systolic blood pressure less than 90 mm Hg that is not responsive to volume resuscitation and requiring vaspressors for life support.

6. Critically ill patients frequently have abnormal host defenses from advanced age, malnutrition, drug therapy, loss of integrity of mucosal and skin barriers, and underlying diseases. Thus, age greater than 70 years, corticosteroid therapy, chemotherapy of malignancy, prolonged...
use of invasive devices, respiratory failure, kidney failure, head trauma, and burns are established risk factors for nosocomial infections.

Systemic pooling of blood and transudation of fluid into tissues result in relative hypovolemia in patients with sepsis.

Scope

The range of conditions that specialists in critical care medicine must address is extraordinarily broad. Many frequent concerns of the intensivist are covered in other chapters and will not be discussed here, to avoid duplication. Therefore, for an overview of critical care medicine, the reader will need to refer to chapters where airway management (Chapter 19), inhalation therapy and ventilator management (Chapter 58), adrenergic agonists (Chapter 14), vasodilators (Chapter 15), fluids and electrolytes (Chapters 49–51), burn injury (Chapter 39), arrhythmias (Chapter 21), acute hypertension (Chapter 21), asthma and chronic obstructive pulmonary disease (Chapter 24), liver failure (Chapter 34), kidney disease (Chapter 31), resuscitation (Chapter 55), traumatic brain injury (Chapter 39), spinal cord injury (Chapter 39), diabetes (Chapter 35), nutrition (Chapter 53), and delirium (Chapters 28 and 54) are discussed.

Poisoning and drug overdosage commonly result in patient admissions to the critical care unit and, indeed, this chapter contains such a case description. Initial treatment of such patients is most often initiated in the emergency department. The possible drugs (and drug combinations) are so great that we must refer interested readers to other sources. Specifics regarding overdosage with anesthetic drugs are discussed in Chapters 7 and 10. Hypothermia and malignant hyperthermia are discussed in Chapter 52. There is increasing interest in preventing post-traumatic stress disorder (PTSD) after critical illness. Studies have shown that this may occur in as many as 25% of patients surviving a stay in the intensive care unit (ICU). Finally, there is also increasing interest in preventing PTSD and “burnout” in the physicians, nurses, and therapists who care for patients with critical illness. Thus, the scope of critical care is enormous, and not all of the important topics can be covered here.

Respiratory Failure

Respiratory failure may be defined as a disorder of gas exchange severe enough
to require acute therapeutic intervention. Definitions based on arterial blood gas measurements may not apply to patients with chronic pulmonary diseases. For example, dyspnea and progressive respiratory acidosis may be present in patients with chronic CO₂ retention. Arterial blood gases typically follow one of several patterns in patients with respiratory failure (Figure 57–1). At one extreme, the derangement primarily affects oxygen transfer from the alveoli into blood, giving rise to hypoxemia (hypoxic respiratory failure); in these patients CO₂ elimination is typically normal or even enhanced unless severe ventilation/perfusion mismatching is present. At the other extreme, pure ventilatory failure primarily affects CO₂ elimination, resulting in hypercapnia; mismatching of ventilation to perfusion is typically absent or minimal. Hypoxemia, however, can occur with pure ventilatory failure when arterial CO₂ tension reaches 75 to 80 mm Hg in patients breathing room air (see the alveolar gas equation in Chapter 23). Few patients with respiratory failure display a pattern as “pure” as these extreme examples.

**FIGURE 57–1** Arterial gas tension (room air) patterns during acute respiratory failure.
Treatment

Regardless of the disorder, the treatment of respiratory failure is primarily supportive while the reversible components of underlying disease(s) are treated. Hypoxemia is treated with oxygen therapy and positive airway pressure (if functional residual capacity is decreased), whereas hypercarbia (ventilatory failure) is treated with mechanical ventilation when there is no effective pharmacological countermeasure (eg, naloxone for milder degrees of opioid overdosage). Other general measures may include using aerosolized bronchodilators, intravenous antibiotics, and diuretics for fluid overload, therapy to improve cardiac function, and nutritional support.

PULMONARY EDEMA

Pathophysiology

Pulmonary edema results from transudation of fluid, first from pulmonary capillaries into interstitial spaces and then from the interstitial spaces into alveoli. Fluid within the interstitial space and alveoli is collectively referred to as extravascular lung water. The movement of water across the pulmonary capillaries is similar to what occurs in other capillary beds and can be expressed by the Starling equation:

$$ Q = K \times [(Pc' - Pi) - \sigma(\pi c' - \pi i)] $$

in which $Q$ is net flow across the capillary; $Pc'$ and $Pi$ are capillary and interstitial hydrostatic pressures, respectively; $\pi c'$ and $\pi i$ are capillary and interstitial oncotic pressures, respectively; $K$ is a filtration coefficient related to effective capillary surface area per mass of tissue; and $\sigma$ is a reflection coefficient that expresses the permeability of the capillary endothelium to albumin. Albumin is particularly important in this context because more water will be lost to the interstitium when albumin is also lost to the interstitium. A $\sigma$ with a value of 1 implies that the endothelium is completely impermeable to albumin, whereas a value of 0 indicates free passage of albumin and other particles/molecules. The pulmonary endothelium normally is partially permeable to albumin, such that interstitial albumin concentration is approximately one-half that of plasma; therefore, under normal conditions $\pi i$ must be about 14 mm Hg (one-half that of plasma). Pulmonary capillary hydrostatic pressure is gravity dependent and thus depends on vertical height in the lung. It normally varies
from 0 to 15 mm Hg (average, 7 mm Hg). Because Pi is thought to be normally about –4 to –8 mm Hg, the forces favoring transudation of fluid (Pc', Pi, and πi) are usually almost balanced by the forces favoring reabsorption (πc'). The net amount of fluid that normally moves out of pulmonary capillaries is small (about 10–20 mL/h in adults) and is rapidly removed by pulmonary lymphatics, which return it into the central venous system.

The alveolar epithelial membrane is usually permeable to water and gases but is impermeable to albumin (and other proteins). A net movement of water from the interstitium into alveoli occurs only when the normally negative Pi becomes positive (relative to atmospheric pressure). Fortunately, because of the lung’s unique ultrastructure and its capacity to increase lymph flow, the pulmonary interstitium usually accommodates large increases in capillary transudation before Pi becomes positive. When this reserve capacity is exceeded, pulmonary edema develops.

**Causes of Pulmonary Edema**

Pulmonary edema usually results from either an increase in the net hydrostatic pressure across the capillaries (hemodynamic or cardiogenic pulmonary edema) or an increase in the permeability of the alveolar–capillary membrane (increased permeability edema or noncardiogenic pulmonary edema). If a pulmonary artery catheter is present, the distinction can be based on the pulmonary artery occlusion pressure, which if greater than 18 mm Hg indicates that hydrostatic pressure is involved in forcing fluid across the capillaries into the interstitium and alveoli. However, the pulmonary artery catheter may provide incorrect guidance regarding etiology: In the case of “flash” pulmonary edema the pulmonary artery occlusion pressure may now be normal despite it having been elevated at the point in time when the pulmonary edema was induced. The protein content of the edema fluid can also help differentiate the two. Fluid due to hemodynamic edema has a low protein content, whereas that due to permeability edema has a high protein content.

Less common causes of edema include prolonged severe airway obstruction (negative pressure pulmonary edema), sudden reexpansion of a collapsed lung, high altitude, pulmonary lymphatic obstruction, and severe head injury, although the same mechanisms (ie, changes in hemodynamic parameters or capillary permeability) also account for these diagnoses. Pulmonary edema associated with airway obstruction may result from an increase in the transmural pressure across pulmonary capillaries associated with a markedly negative interstitial hydrostatic pressure. Neurogenic pulmonary edema appears to be related to a
marked increase in sympathetic tone, which causes severe pulmonary hypertension and disruption of the alveolar–capillary membrane.

**1. Increased Transmural Pressure Pulmonary Edema (“Cardiogenic” Pulmonary Edema)**

Significantly increased $Pc'$ may increase extravascular lung water and result in pulmonary edema. As can be seen from the Starling equation, a decrease in $\pi c'$ may accentuate the effects of any increase in $Pc'$. Two major mechanisms increase $Pc'$; namely, pulmonary venous hypertension and a markedly increased pulmonary blood flow. Any elevation of pulmonary venous pressure is transmitted passively backward to the pulmonary capillaries and secondarily increases $Pc'$. Pulmonary venous hypertension may result from left ventricular failure, mitral stenosis, or left atrial obstruction. Increases in pulmonary blood flow that exceed the capacity of the pulmonary vasculature will also raise $Pc'$. Marked increases in pulmonary blood flow can be the result of large left-to-right cardiac or peripheral shunts, hypervolemia (fluid overload), or extremes of anemia or exercise.

**Treatment**

Management of cardiogenic pulmonary edema involves decreasing the pressure in the pulmonary capillaries. Generally, this includes measures to improve left ventricular function, correct fluid overload with diuretics, or reduce pulmonary blood flow. Pharmacological treatment of acute cardiogenic pulmonary edema has included oxygen, morphine, diuretics (especially loop diuretics), vasodilators such as nitrates, and inotropes such as dobutamine or milrinone. By reducing left atrial pressure, pulmonary congestion is relieved; by reducing systemic vascular resistance, cardiac output may be improved. Positive airway pressure therapy is also a useful adjunct for improving oxygenation. When pulmonary edema is a consequence of left ventricular failure from acute coronary ischemia, intraaortic balloon counterpulsation, acute revascularization, or other assist devices may be needed.

**2. Increased Permeability Pulmonary Edema (Noncardiogenic Pulmonary Edema): Acute Lung Injury & ARDS**
Extravascular lung water increases in patients with pulmonary edema from enhanced permeability or disruption of the capillary–alveolar membrane. The protective effect of plasma oncotic pressure is lost as increased amounts of albumin “leak” into the pulmonary interstitium; normal—or even low—capillary hydrostatic pressures are unopposed and result in transudation of fluid into the lungs. Permeability edema is seen with acute lung injury (Pao₂:Fio₂ ratio ≤300) and is often associated with sepsis, trauma, and pulmonary aspiration; when severe (Pao₂:Fio₂ ratio <200), it is referred to as the acute respiratory distress syndrome (ARDS).

**Pathophysiology**

Acute lung injury and ARDS represent the pulmonary manifestation of the systemic inflammatory response syndrome (SIRS) as a consequence of severe injury of the capillary–alveolar membrane. Regardless of the original cause of SIRS, the lung appears to respond similarly to the ensuing inflammatory response. The released secondary mediators increase pulmonary capillary permeability, induce pulmonary vasoconstriction, and inhibit hypoxic pulmonary vasoconstriction. Destruction of alveolar epithelial cells is prominent. Alveolar flooding, with decreased surfactant production (due to loss of type II pneumocytes), leads to alveolar collapse. The exudative phase of ARDS will persist for a varying period, and is often followed by a fibrotic phase (fibrosing alveolitis), which may lead to permanent scarring.

**Clinical Manifestations**

The diagnosis of acute lung injury or ARDS requires a Pao₂:Fio₂ ratio ≤300 (acute lung injury) or <200 (ARDS), and the presence of diffuse infiltrates on chest radiograph, while also excluding significant left ventricular dysfunction. The lung is often affected in a nonhomogeneous pattern, although dependent areas tend to be most affected.

Acute lung injury and ARDS are commonly seen in association with sepsis or trauma. Patients present with severe dyspnea and labored respirations. Hypoxemia due to intrapulmonary shunting is universal. Although dead space ventilation is increased, arterial CO₂ tension is typically decreased because of a marked increase in minute ventilation. Ventilatory failure may be seen in severe cases due to respiratory muscle fatigue or marked destruction of the capillary–alveolar membrane. Pulmonary hypertension and low or normal left ventricular
filling pressures are characteristic hemodynamic findings.

**Treatment**

In addition to intensive respiratory care, treatment should be directed at reversible processes such as sepsis or hypotension. Hypoxemia is treated with oxygen therapy. Milder cases may be treated with noninvasive respiratory support, but most patients require intubation and mechanical ventilation. 

**Increased Pplt pressures (>30 cm H2O) and high Vt (>6 mL/kg) should be avoided because overdistention of alveoli can induce iatrogenic lung injury, as (likely) can high Fio2 (>0.5).** While injury from high Fio2 has not been conclusively demonstrated in humans, VT of 12 mL/kg was associated with greater mortality than VT of 6 mL/kg (and Pplat of less than ⪆ 30 cm H2O) in patients with ARDS. Thus, reduced tidal volumes are associated with the greatest improvement in outcome after ARDS of any intervention subjected to a randomized clinical trial to date.

If possible, the Fio2 should be maintained at 0.5 or less, primarily by increasing positive end-expiratory pressure (PEEP). Other maneuvers to improve oxygenation may include the use of inhaled nitric oxide, inhaled prostacyclin or prostaglandin E1 (PGE1), and ventilation in the prone position. These three techniques improve oxygenation in many such patients but are not risk free and have not been associated with an improved survival. A meta-analysis concluded that moderate doses of corticosteroids likely improve morbidity and mortality outcomes in ARDS, but the underlying data remain controversial.

Morbidity and mortality from ARDS usually arise from the precipitating cause or from complications rather than from the respiratory failure itself. Among the most common serious complications are sepsis, renal failure, and gastrointestinal hemorrhage. Nosocomial pneumonia is often difficult to diagnose; antibiotics are generally indicated when there is a high index of suspicion (fever, purulent secretions, leukocytosis, and change in chest radiograph). Brushings and bronchoalveolar lavage sampling via a flexible bronchoscope may be useful. Breach of mucocutaneous barriers by catheters, malnutrition, and altered host immunity contribute to a frequent incidence of infection. Kidney failure may result from various combinations of inadequate renal blood flow and perfusion pressure, sepsis, or nephrotoxins. Kidney failure substantially increases the mortality rate for ARDS (to >60%). Prophylaxis against gastrointestinal hemorrhage is recommended.
3. Negative Pressure Pulmonary Edema

Forceful inspiration against a closed glottis or an obstructed airway may lead to negative pressure pulmonary edema. In adults this is often the consequence of laryngospasm during or after a general anesthetic, whereas in children it is often a consequence of airway obstruction from infection (eg, epiglottitis) or tumor. Other potential causes include endotracheal tube obstruction or occlusion, and virtually any other cause of airway obstruction. In adults the incidence seems greater in healthier (American Society of Anesthesiologists class 1 or 2) than sicker patients, and greater in males than females, possibly a consequence of more forceful inspiratory efforts by healthy male patients. The onset is extremely rapid and with appropriate treatment the recovery may also be much more rapid than for other forms of pulmonary edema.

4. Neurogenic Pulmonary Edema

Head injury, intracranial bleeding, and abrupt reversal of opioid overdosage with naloxone can all precipitate pulmonary edema. Although the precise pathophysiology of this condition is not well understood, it has long been assumed that an abrupt, large increase in sympathetic tone is the precipitating event. Often, neurogenic pulmonary edema presents very rapidly after the inciting event and then dissipates over 24 h or so. In other cases, the presentation may be delayed by 12 to 18 h. Major neurological injuries may produce effects on the heart, so distinguishing between neurogenic and cardiogenic pulmonary edema is not always easy, and the two conditions may overlap.

DROWNING & NEAR-DROWNING

Drowning is asphyxia and death while submerged in water. Near-drowning is suffocation while submerged with (at least temporary) survival. Survival depends on the intensity and duration of the hypoxia and on the water temperature.

Pathophysiology

Both drowning and near-drowning can occur whether or not inhalation (aspiration) of water occurs. If water does not enter the airways, the patient primarily suffers from asphyxia; however, if the patient inhales water, marked intrapulmonary shunting also takes place. Ninety percent of drowned patients
aspirate fluid: fresh water, seawater, brackish water, or other fluids. Although the amount of liquid aspirated is generally small, marked ventilation/perfusion mismatching can result from fluids in the lung, reflex bronchospasm, and loss of pulmonary surfactant. Aspiration of gastric contents can also complicate drowning before or after loss of consciousness or during resuscitation.

The hypotonic water aspirated following fresh water drowning is rapidly absorbed by the pulmonary circulation; water cannot usually be recovered from the airways. If a significant amount is absorbed (>800 mL in a 70-kg adult), transient hemodilution, hyponatremia, and even hemolysis may occur. In contrast, aspiration of salt water (which is hypertonic) draws out water from the pulmonary circulation into the alveoli, flooding them, and sometimes also causing hemoconcentration and hypernatremia. Hypermagnesemia and hypercalcemia have also been reported following near-drowning in salt water.

Patients who suffer from cold water near-drowning lose consciousness when core body temperature decreases below 32°C. Ventricular fibrillation occurs at about 28°C to 30°C, but relative to normothermic near-drowning, hypothermia has a protective effect on the brain and may improve outcome provided that resuscitation is successful.

**Clinical Manifestations**

Nearly all patients with a true near-drowning episode will have hypoxemia, hypercarbia, and metabolic acidosis. Patients may also suffer from other injuries, such as spine fractures following diving accidents. Brain damage is generally related to duration of submersion and severity of asphyxia. Cerebral edema often complicates prolonged asphyxia. Acute lung injury and ARDS develop in many patients following successful resuscitation.

**Treatment**

Initial treatment of near-drowning is directed at restoring ventilation, perfusion, oxygenation, and acid–base balance as quickly as possible. Immediate measures include establishing a secure and unobstructed airway, administering oxygen, and initiating cardiopulmonary resuscitation. In-line stabilization of the cervical spine is necessary when intubating patients who suffer from near-drowning following a dive. Institution of cardiopulmonary resuscitation should not be delayed by attempts to drain salt water from the lungs. Resuscitation efforts should not be suspended for futility until the patient is rewarmed following cold water near-drowning. Complete recovery is possible in such instances even after
prolonged periods of asphyxia. After the initial resuscitation, further management will usually include positive-pressure ventilation and PEEP. Bronchospasm should be treated with bronchodilators, electrolyte abnormalities corrected, and acute lung injury and ARDS treated as previously discussed.

**SMOKE INHALATION**

Smoke inhalation is the leading cause of death from fires. Affected persons may or may not have sustained a burn. Burn victims who suffer from smoke inhalation have a mortality rate significantly greater than other comparably burned patients without smoke inhalation. Any exposure to smoke in a fire requires a presumptive diagnosis of smoke inhalation until proved otherwise. A suggestive history might include loss of consciousness or disorientation in a patient exposed to a fire, or a burn acquired in a closed space.

**Pathophysiology**

The consequences of smoke inhalation are complex because they can involve three types of injuries: heat injury to the airways, exposure to toxic gases, and a chemical burn with deposition of carbonaceous particulates in the lower airways. The pulmonary response to smoke inhalation is equally complex and depends on the duration of the exposure, composition of the material that burned, and presence of any underlying lung disease. Combustion of synthetic materials may produce toxic gases such as carbon monoxide, hydrogen cyanide, hydrogen sulfide, hydrogen chloride, ammonia, chlorine, benzene, and aldehydes. When these gases react with water in the airways, they can produce hydrochloric, acetic, formic, and sulfuric acids. Carbon monoxide and cyanide poisoning are common.

After smoke inhalation direct mucosal injury may result in edema, inflammation, and sloughing. Loss of ciliary activity impairs the clearance of mucus and bacteria. Manifestations of acute lung injury and ARDS typically appear 2 to 3 days after the injury and seem related to the delayed development of SIRS rather than the acute smoke inhalation itself.

**Clinical Manifestations**

Patients initially may have minimal symptoms after smoke inhalation. Suggestive physical findings include facial or intraoral burns, singed nasal hairs, cough, carbonaceous sputum, and wheezing. The diagnosis is confirmed when
bronchoscopy of the upper airway and the tracheobronchial tree reveals erythema, edema, mucosal ulcerations, and carbonaceous deposits. Arterial blood gases initially may be normal or reveal only mild hypoxemia and metabolic acidosis due to carbon monoxide. The chest radiograph is often normal on presentation.

Heat injury to the airways is usually confined to supraglottic structures unless there is prolonged exposure to steam. Progressive hoarseness and stridor suggest impending airway obstruction, which may develop over 12 to 18 h. Fluid resuscitation of burn injury will frequently exacerbate airway edema.

Carbon monoxide poisoning is usually defined as greater than 15% carboxyhemoglobin in the blood. The diagnosis is made by co-oximetry of arterial blood. Carbon monoxide has 210 times the affinity of oxygen for hemoglobin. When a CO molecule combines with hemoglobin to form carboxyhemoglobin, it decreases the affinity of the other binding sites for oxygen, shifting the hemoglobin dissociation curve to the right. The net result is a marked reduction in the oxygen-carrying capacity of blood. Carbon monoxide also has a 60-fold greater affinity than oxygen for myoglobin, which may lead to myocardial depression.

Carbon monoxide dissociates slowly from hemoglobin: The half-life of approximately 5 h when breathing room air decreases to 72 min when breathing 100% oxygen. Clinical manifestations result from tissue hypoxia from impaired oxygen delivery. Carboxyhemoglobin levels greater than 20% to 40% are associated with neurological impairment, nausea, fatigue, disorientation, and shock. Lower levels may also produce symptoms because carbon monoxide also binds cytochrome c and myoglobin. Compensatory mechanisms include increased cardiac output and peripheral vasodilation.

Cyanide toxicity may occur after fires that contain synthetic materials, particularly those containing polyurethane. Cyanide, which may be inhaled or absorbed through mucosal surfaces and skin, binds the cytochrome enzymes and inhibits cellular production of adenosine triphosphate (ATP). Patients present with neurological impairment and lactic acidosis, often accompanied by arrhythmias, increased cardiac output, and marked vasodilation.

A chemical burn of the respiratory mucosa follows inhalation of large amounts of burned or burning debris, particularly when combined with toxic fumes. Inflammation of the airways results in bronchorrhea and wheezing. Bronchial edema and sloughing of the mucosa lead to obstruction of the lower airways and atelectasis. Progressive ventilation/perfusion mismatching can lead to marked hypoxemia over the course of 24 to 48 h, sometimes meeting the
criteria for acute lung injury or ARDS.

**Treatment**

Bronchoscopy can diagnose an inhalation injury. In patients who are not intubated, we suggest performing it with a tracheal tube loaded over the bronchoscope so that intubation can quickly be performed if edema threatens the patency of the airway. Early elective tracheal intubation is advisable when there are obvious signs of heat injury to the airway. Patients with hoarseness and stridor require immediate tracheal intubation or a surgical airway.

Carbon monoxide or cyanide poisoning accompanied by obtundation or coma also requires prompt tracheal intubation and ventilation with oxygen. The diagnosis of carbon monoxide poisoning requires co-oximetry: pulse oximeters cannot reliably differentiate between carboxyhemoglobin and oxyhemoglobin. The half-life of carboxyhemoglobin is markedly reduced with 100% oxygen, and hyperbaric oxygen therapy is useful when the patient does not respond to 100% oxygen. The diagnosis of cyanide poisoning is difficult because reliable measurements of cyanide are not readily available (normal levels are <0.1 mg/L). The enzyme rhodanese normally converts cyanide to thiocyanate, which is subsequently eliminated by the kidneys. Treatment for severe cyanide toxicity consists of administering sodium nitrite, 300 mg intravenously as a 3% solution over 3 to 5 min, followed by sodium thiosulfate, 12.5 g intravenously in the form of a 25% solution over 1 to 2 min. Sodium nitrite converts hemoglobin to methemoglobin, which has a higher affinity for cyanide than cytochrome oxidase; the cyanide, which is slowly released from cyanomethemoglobin, is converted by rhodanese to the less toxic thiocyanate.

Marked hypoxemia due to intrapulmonary shunting should be managed with tracheal intubation, oxygen therapy, bronchodilators, positive-pressure ventilation, and PEEP. Corticosteroids are ineffective, increase the rate of infections, and should not be used.

---

**Acute Myocardial Infarction**

Acute myocardial infarction (AMI) is a dreaded complication of ischemic heart disease, with an overall mortality rate of 25%. More than one half of these deaths occur shortly after onset, usually due to arrhythmias (ventricular fibrillation). With recent advances in interventional cardiology, the in-hospital mortality rate has been reduced to less than 10%.
Diagnosis of AMI can be made with combinations of increased troponin concentrations in blood, ECG findings, and clinical history. Perioperative diagnosis can be vexing and may depend primarily on troponin measurements. AMIs are divided into those associated with ST-segment elevation (STEMI) and those that are not associated with ST-segment elevation (NSTEMI). These latter are usually diagnosed by elevations of biomarkers, most commonly troponin. Another classification scheme divides AMI into five types (type 1, from a spontaneous event such as plaque rupture; type 2, from increased demand or decreased oxygen supply; type 3, sudden cardiac death associated with symptoms or postmortem evidence of myocardial ischemia; type 4, AMI in association with percutaneous coronary interventions; type 5, AMI in association with coronary artery bypass surgery).

**Pathophysiology**

Most myocardial infarctions occur in patients with more than one severely narrowed (>75% narrowing of the cross-sectional area) coronary artery. STEMIs (most often type 1 AMIs) occur in an area distal to a complete occlusion. Patients who die within 24 hours after AMI may have coronary atherosclerosis as the only cardiac abnormality identified upon necropsy. The occlusion is nearly always due to thrombosis at a stenotic atheromatous plaque. Coronary emboli or severe spasm is less commonly the cause. NSTEMIs (type 2 AMIs) more often occur in the setting of reduced myocardial perfusion due to hypotension or intimal hemorrhage, often in a situation of increased myocardial oxygen demand, and less commonly follow coronary plaque rupture and thrombosis. The size and location of the infarct depend on the distribution of the obstructed vessel and whether collateral vessels have formed. Anterior, apical, and septal infarcts of the left ventricle are usually due to thrombosis in the left anterior descending circulation; lateral and posterior left ventricular infarcts result from occlusions in the left circumflex system, whereas right ventricular and posterior–inferior left ventricular infarcts result from thrombosis in the right coronary artery.

Following brief episodes of severe ischemia, persisting myocardial dysfunction with only a slow and incomplete return of contractility can be observed. This phenomenon of “stunning” can contribute to ventricular dysfunction following AMI. Relief of the ischemia in these areas can restore contractile function, albeit not immediately. Stunning may be observed following aortic cross-clamping during cardiopulmonary bypass as a reduced cardiac output upon attempted separation from bypass (see Chapter 22). When severe
hypokinesis or akines is observed in the setting of severe chronic ischemia, the myocardium in these noninfarcted but poorly contractile areas may be said to be “hibernating.” This diagnosis can be confirmed by observing viable tissue with positron emission tomography, or by showing that the hypocontractile myocardium responds to dobutamine.

**Treatment**

In the absence of contraindications (eg, a contradictory advanced directive) the immediate treatment of STEMI is thrombolysis and percutaneous coronary intervention in the cardiac catheterization laboratory. Oxygen was formerly routinely administered to all AMI patients but now is reserved for those with reduced arterial saturation. Because the prognosis following AMI is generally inversely proportionate to the extent of necrosis, the focus in management of an evolving STEMI remains on prompt reperfusion. Based on local resources, timing, and anatomic findings during angiography, stenting or coronary artery bypass surgery may be indicated. NSTEMI treatment varies depending upon time of diagnosis and on perceived risk of progression. Guidelines for treatment of AMI change frequently and are regularly published by the American College of Cardiology/American Heart Association and by the European Society of Cardiology; we strongly recommend that the current guidelines be consulted.

Following AMI all patients without contraindications should receive aspirin and β-blockers. Other medications and treatments such as angiotensin-converting enzyme (ACE) inhibitors, statins, and cessation of smoking are the key to secondary prevention. Patients who have recurrent angina should be given nitrates. If angina persists or if there is a contraindication to β-blockers, calcium channel blockers should be administered. Persistent or recurrent angina signals the need for angiography.

Intraaortic balloon counterpulsation was in the past commonly used for hemodynamically compromised patients with refractory ischemia; however, there is limited evidence for improved outcomes with this therapy. Temporary pacing following AMI is indicated for Mobitz type II and complete heart block, a new bifascicular block, and bradycardia with hypotension. Emergency treatment of arrhythmias constantly evolves, and we recommend that the guidelines for Advanced Cardiac Life Support be followed. In general, ventricular tachycardia, if treated medically is best managed with amiodarone (150 mg intravenous bolus over 10 min). Synchronized cardioversion may be used in patients with ventricular tachycardia and a pulse. Patients with a stable narrow-complex supraventricular tachycardia should be treated with
amiodarone. Patients with paroxysmal supraventricular tachycardia, whose ejection fraction is preserved, should be treated with a calcium channel blocker, a β-blocker, or direct current (DC) cardioversion. Unstable hypotensive patients should be cardioverted. Patients with ectopic or multifocal atrial tachycardia should not receive DC cardioversion; instead they should be treated with calcium channel blockers, a β blocker, or amiodarone.

**Acute Kidney Injury & Failure**

Acute kidney injury (AKI) is a rapid deterioration in renal function that is not immediately reversible by normalizing blood pressure, intravascular volume, or cardiac output, or relieving urinary obstruction. The hallmark of AKI is azotemia, frequently accompanied by oliguria. Azotemia may be classified as prerenal, renal, or postrenal. The diagnosis of renal azotemia is one of exclusion: Prerenal and postrenal causes must always be excluded. However, not all patients with acute azotemia have kidney failure. Likewise, urine output of more than 500 mL/d does not imply that renal function is normal. Basing the diagnosis of AKI on creatinine levels or an increase in blood urea nitrogen (BUN) is also problematic because creatinine clearance is not always a good measure of glomerular filtration rate. The criteria developed by the Acute Kidney Injury Network are now most often used to stage AKI (see Chapter 30). AKI is diagnosed by documenting an increase in serum creatinine of more than 50%, or an absolute increase of 0.3 mg/dL, and a reduction in urine output to less than 0.5 mL/kg/h for 6 h or longer, with all findings developing over 48 h or less.

**PRERENAL AZOTEMIA**

Prerenal azotemia results from hypoperfusion of the kidneys; if untreated, it progresses to AKI. Renal hypoperfusion is typically the result of decreased arterial perfusion pressure, markedly increased venous pressure, or renal vasoconstriction (Table 57–1). Decreased perfusion pressure is usually associated with the release of norepinephrine, angiotensin II, and vasopressin. These hormones constrict cutaneous muscle and splanchnic vasculature and promote salt and water retention. The synthesis of vasodilating prostaglandins (prostacyclin and PGE₂) and nitric oxide in the kidneys and the intrarenal action of angiotensin II help maintain glomerular filtration. In the setting of marked prerenal azotemia the use of cyclooxygenase inhibitors (eg, ketorolac for postoperative pain control) or ACE inhibitors can precipitate AKI. The diagnosis
of prerenal azotemia is usually suspected from the clinical setting and confirmed by urinary laboratory indices (Table 57–2). Treatment of prerenal azotemia includes correcting intravascular volume deficits, improving cardiac function, restoring a normal blood pressure, and reversing increases in renal vascular resistance. The hepatorenal syndrome is discussed in Chapter 33.

### TABLE 57–2 Urinary indices in azotemia.
Azotemia due to urinary tract obstruction is termed *postrenal azotemia*. Obstruction of urinary flow from both kidneys is usually necessary for azotemia and oliguria/anuria in these conditions. Complete obstruction eventually develops into AKI and kidney failure, whereas prolonged partial obstruction leads to chronic renal impairment. Rapid diagnosis and relief of acute obstruction usually restore normal renal function, often accompanied by a postobstructive diuresis. Obstruction may be diagnosed by a physical examination (the upper margin of the bladder can be percussed) or ultrasound (showing a distended bladder) or suggested by a radiograph of the abdomen (revealing bilateral renal calculi), but is definitively diagnosed by demonstrating dilation of the urinary tract proximal to the site of obstruction on imaging studies. Treatment depends on the site of obstruction. Obstruction at the bladder outlet can be relieved with catheterization of the bladder or suprapubic cystostomy, whereas ureteral obstruction requires nephrostomy or ureteral stents.

### REVERSIBLE AZOTEMIA VERSUS AKI

In addition to physical diagnosis and imaging, diagnosis and treatment may be facilitated by analysis of urine (see Table 57–2); urinary composition in
postrenal azotemia is variable and depends on the duration and severity of obstruction. In prerenal azotemia, tubular concentrating ability is preserved and reflected by a low urinary sodium concentration and high urine/serum creatinine ratio. Calculation of the fractional excretion of filtered sodium (F\(\text{ENa}^+\)) may also be extremely useful in the setting of oliguria:

\[
\text{FENa}^+ = \frac{\text{Urine sodium/serum sodium}}{\text{Urine creatinine/serum creatinine}} \times 100\%
\]

\(\text{FENa}^+\) is less than 1% in oliguric patients with prerenal azotemia but typically exceeds 3% in patients with oliguric AKI. Values of 1% to 3% may be present in patients with nonoliguric AKI. The renal failure index, which is the urinary sodium concentration divided by the urine/plasma creatinine ratio, is a sensitive index for diagnosing kidney failure. The use of diuretics increases urinary sodium excretion and invalidates indices that rely on urinary sodium concentration as a measure of tubular function. Moreover, intrinsic kidney diseases that primarily affect renal vasculature or glomeruli may not affect tubular function and therefore are associated with indices that are similar to prerenal azotemia. Measurement of creatinine clearance can estimate the residual glomerular filtration rate but may underestimate the degree of renal impairment when the serum creatinine concentration is still rising.

**Etiology of AKI**

Causes of AKI are listed in Table 57–3. Up to 50% of cases follow major trauma or surgery; in the majority of instances, ischemia and nephrotoxins are responsible. AKI associated with ischemia has been termed *acute tubular necrosis*. Postischemic AKI follows certain surgical procedures more frequently than others: open abdominal aortic aneurysm resection, cardiac surgery with cardiopulmonary bypass, and operations to relieve obstructive jaundice. Aminoglycosides, amphotericin B, radiographic contrast dyes, cyclosporine, and cisplatin are the most commonly implicated exogenous nephrotoxins. Amphotericin B, contrast dyes, and cyclosporine also appear to produce direct intrarenal vasoconstriction. Hemoglobin and myoglobin are potent nephrotoxins when they are released during intravascular hemolysis and rhabdomyolysis, respectively. Nonsteroidal antiinflammatory drugs may play an important role in some patients. Inhibition of prostaglandin synthesis by the latter group of agents decreases prostaglandin-mediated renal vasodilation, allowing unopposed renal vasoconstriction. Other factors predisposing to AKI include preexisting renal...
impairment, advanced age, atherosclerotic vascular disease, diabetes, and dehydration.

**Pathogenesis of AKI**

The sensitivity of the kidneys to injury may be explained by their very high metabolic rate and ability to concentrate potentially toxic substances. The pathogenesis of AKI is complex and probably has both a vascular endothelial and a renal epithelial (tubular) basis. Inadequate oxygen deliver to the kidney is the likely triggering event, leading to afferent arteriolar constriction, decreased glomerular permeability, increased vascular permeability, altered coagulation,
inflammation, leukocyte activation, direct epithelial cell injury, and tubular obstruction. All can decrease glomerular filtration. A leak of filtered solutes through damaged portions of renal tubules may allow reabsorption of creatinine, urea, and other nitrogenous wastes.

**Oliguric versus Nonoliguric AKI**

AKI is often classified as nonoliguric (urinary volume >400 mL/d), oliguric (urinary volume <400 mL/d), or anuric (urinary volume <100 mL/d). Nonoliguric AKI accounts for up to 50% of cases. Urinary sodium concentrations in patients with nonoliguric AKI are typically lower than those in oliguric patients. For years it was speculated that one could convert oliguric AKI into nonoliguric AKI by administering mannitol, furosemide, “renal” doses of dopamine (1–2 mcg/kg/min), or fenoldopam. Theoretically, the resulting increase in urinary output might be therapeutic by preventing tubular obstruction. However, recent studies have found increased mortality in patients with AKI who received diuretics, and a meta-analysis showed no improvement in mortality or decrease in need for dialysis; therefore, diuretics should not be routinely administered in AKI.

**Treatment of AKI**

AKI accounts for approximately 15% of ICU admissions. The mortality rate for AKI remains high, and management is primarily supportive. Diuretics continue to be useful for conventional medical indications (eg, volume overload or rhabdomyolysis). AKI due to glomerulonephritis or vasculitis may respond to glucocorticoids. Standard treatment for oliguric and anuric patients includes restriction of fluid, sodium, potassium, and phosphorus. Daily weight measurements help guide fluid therapy. Hyponatremia can be treated with water restriction. Hyperkalemia may require administration of an ion-exchange resin (sodium polystyrene), glucose and insulin, calcium gluconate, or sodium bicarbonate. Sodium bicarbonate therapy may also be necessary for metabolic acidosis when the serum bicarbonate level decreases to less than 15 mEq/L. Hyperphosphatemia requires dietary phosphate restriction and phosphate binders such as aluminum hydroxide, calcium carbonate, or calcium acetate. The dosages of drugs subject to renal excretion should be adjusted to the estimated glomerular filtration rate or measured creatinine clearance.

Renal replacement therapy may be employed to treat or prevent uremic complications (see Table 31–7). A double-lumen catheter placed in the internal
jugular, subclavian, or femoral vein is usually used. The high morbidity and mortality rates associated with AKI would seem to argue for early dialysis, but dialysis does not appear to hasten recovery and may aggravate kidney injury if hypotension occurs or too much fluid is removed.

Because of concern that intermittent hemodialysis associated with hypotension may perpetuate renal injury, continuous renal replacement therapy (CRRT; continuous venovenous hemofiltration or continuous venovenous hemodialysis, which removes fluid and solutes at a slow, controlled rate) has been used in critically ill patients with uremic AKI who do not tolerate the hemodynamic effects of intermittent “standard” hemodialysis. The main problem associated with CRRT is the expense, as the membrane is prone to clot formation and, therefore, must be periodically replaced. Despite this limitation, many experts believe CRRT is the best way to manage uremic ICU patients with AKI. The indications for CRRT are being expanded from oliguria and uremia to metabolic acidosis, fluid overload, and hyperkalemia. Nevertheless, we note that recent clinical trials have failed to show benefit of continuous technique over intermittent hemodialysis in these critically ill patients.

The nutritional management of AKI with uremia continues to evolve, and there is now consensus among nephrologists, intensivists, and nutritionists that nutrition should be provided, and 1.0 to 1.5 g/kg/d of protein can be given, particularly for patients on CRRT.

---

**Infections & Sepsis**

The systemic inflammatory response to infection, termed *sepsis syndrome* (Figure 57–2), does not necessarily indicate the presence of bacteremia. Moreover, the inflammatory response is not unique to severe infections: Similar manifestations may be encountered with noninfectious illnesses. While the use of the term *systemic inflammatory response syndrome* (SIRS) was suggested by the Society of Critical Care Medicine (SCCM), European Society of Intensive Care Medicine (ESICM), American College of Chest Physicians (ACCP), American Thoracic Society (ATS), and Surgical Infection Society (SIS), these and other groups are now moving away from an emphasis on SIRS in the identification and treatment of patients with sepsis (see the ESICM’s and SCCM’s Third International Consensus Definitions for Sepsis and Septic Shock [Sepsis-3]) (Table 57–4).

TABLE 57–4 Diagnostic criteria for sepsis.¹⁻³
Sepsis may be classified based on predisposition, insult, infection, response, and organ dysfunction. Severe sepsis exists when these features are associated with organ dysfunction. The term *multiple organ dysfunction syndrome* (MODS) has been suggested to describe dysfunction of two or more organs associated with sepsis. *Septic shock* is defined as acute circulatory failure in a patient with sepsis or, more specifically, systolic blood pressure less than 90 mm Hg that is not responsive to volume resuscitation and requiring vasopressors for life support.

**Pathophysiology of SIRS**

A mild systemic inflammatory response to an injury, infection, or other bodily insult may normally have salutatory effects. However, a marked or prolonged response, such as that associated with severe infections, can result in widespread organ dysfunction. Although gram-negative organisms account for most cases of infection-related SIRS, many other infectious agents are capable of inducing the same syndrome. These organisms either elaborate toxins or stimulate release of substances that trigger this response. The most commonly recognized initiators...
are the lipopolysaccharides, which are released by gram-negative bacteria. Lipopolysaccharide is composed of an O polysaccharide, a core, and lipid A. Lipid A, an endotoxin, is responsible for the compound’s toxicity, which can affect nearly every organ.

The central mechanism in initiating SIRS appears to be the abnormal secretion of cytokines. These low-molecular-weight peptides and glycoproteins function as intercellular mediators regulating such biological processes as local and systemic immune responses, inflammation, wound healing, and hematopoiesis. The resulting inflammatory response includes release of potentially harmful phospholipids, attraction of neutrophils, and activation of the complement, kinin, and coagulation cascades.

**INFECTIONS IN THE ICU**

Infections are a leading cause of death in ICUs. Serious infections may be "community acquired" or subsequent to hospital admission for an unrelated illness. The term *nosocomial infection* describes hospital-acquired infections that develop at least 48 h following admission. Most nosocomial infections arise from the patient’s endogenous bacterial flora. Furthermore, many critically ill patients eventually become colonized with resistant bacterial strains. Urinary infections, usually due to gram-negative organisms and typically associated with indwelling catheters or urinary obstruction, account for many nosocomial infections. With scrupulous attention to hand cleansing, aseptic placement of central venous catheters, and earlier removal of bladder catheters the incidence of bloodstream and catheter-associated urinary tract infections has declined markedly. Routine elevation of the head of bed has also led to a marked reduction in ventilator-associated pneumonia. Surgical site and other wound infections and community-acquired pneumonias continue to be vexing. Enteral nutrition reduces bacterial translocation across the gut and reduces the likelihood of sepsis (see Chapter 53) relative to either starvation or parenteral nutrition.

Strains of bacteria resistant to commonly used antibiotics are often responsible for infections in patients with critical illness. Host immunity plays an important role in determining not only the course of an infection but also the types of organisms that can cause infection. Thus, organisms that normally do not cause serious infections in immunocompetent patients can produce life-threatening infections in those who are immunocompromised (*Table 57–5*).

</table>

nosocomial infections. Patients with burns involving more than 40% of body surface area have significantly increased risk of mortality from infections. After burn injury, early removal of the necrotic eschar followed by skin grafting and wound closure appears to reverse immunological defects and reduce infection risk.

Nosocomial pneumonias are usually caused by gram-negative organisms. Preservation of gastric acidity inhibits overgrowth of gram-negative organisms in the stomach and their subsequent migration into the oropharynx. Tracheal intubation does not provide complete protection because patients may aspirate gastric fluid containing bacteria despite a properly functioning cuff; nebulizers and humidifiers can also be sources of infection. Selective decontamination of the gut with nonabsorbable antibiotics may reduce the incidence of infection but does not change outcome. Elevating the head of the bed 30° or more will reduce the likelihood of ventilator-associated pneumonia.

Wounds are common sources of sepsis in postoperative and trauma patients; restricting antibiotic prophylaxis to the immediate perioperative time appears to decrease the incidence of postoperative infections. Intraabdominal infections due to perforated ulcer, diverticulitis, appendicitis, and acalculous cholecystitis can develop in critically ill patients whether or not they are recovering from a surgical procedure. Intravascular catheter-related infections are most commonly caused by *Staphylococcus epidermidis*, *Staphylococcus aureus*, streptococci, *Candida* species, and gram-negative rods. Bacterial sinusitis may be an unrecognized source of sepsis in patients ventilated through nasotracheal tubes. The widespread administration of antibiotics has led to the development of microorganisms that are resistant to most standard antimicrobials. Organisms that were formerly rare such as *Clostridium difficile* (“c. diff.”) and multidrug-resistant organisms are now vexing problems for those who care for sick patients in tertiary hospitals.

**SEPTIC SHOCK**

The SCCM/ESICM/ACCP/ATS/SIS Consensus Conference defined **septic shock** as sepsis associated with hypotension (systolic blood pressure <90 mm Hg, mean arterial pressure <60 mm Hg, or systemic blood pressure <40 mm Hg from baseline) despite adequate fluid resuscitation.

Septic shock is usually characterized by inadequate tissue perfusion and widespread cellular dysfunction. In contrast to other forms of shock (hypovolemic, cardiogenic, neurogenic, or anaphylactic), cellular dysfunction in
septic shock is not necessarily related to hypoperfusion. Instead, metabolic blocks at the cellular and microcirculation levels may contribute to impaired cellular oxidation. A different definition chosen by the Third International Consensus Definitions for Sepsis and Septic Shock was reported in 2016. This publication deemphasized the role of systemic inflammation in making the diagnosis of sepsis while emphasizing the role of organ dysfunction per se. At the present time it is unclear who will win the debate regarding systemic inflammation! Meanwhile, the qSOFA (quick Sepsis-related Organ Failure Assessment) score using only altered mental status (a Glasgow Coma Scale score of <15), tachypnea (respiratory rate of ≥20/min), and hypotension (systolic blood pressure of ≤100 mm Hg) for a maximum score of 3 and a minimal score of 0 is increasingly used to identify those patients with suspected infection who are at greater risk for a poor outcome.

**Pathophysiology**

An infectious process that induces severe or protracted systemic inflammation can result in septic shock. In hospitalized patients septic shock most commonly follows gram-negative infections in either the genitourinary tract or the lungs. In up to 50% of cases of severe sepsis no organisms can be cultured from blood. Hypotension is due to a decreased circulating intravascular volume resulting from a diffuse capillary leak. Patients may also have myocardial depression. Activation of platelets and coagulation can lead to the formation of fibrin-platelet aggregates, which further compromise tissue blood flow. Hypoxemia from ARDS accentuates tissue hypoxia. The release of vasoactive substances and formation of microthrombi in the pulmonary circulation increase pulmonary vascular resistance.

**Hemodynamic Subsets**

The circulation in patients with septic shock is often described as either hyperdynamic or hypodynamic. In reality, both represent the same process, but their expression depends on preexisting cardiac function and intravascular volume and the patient’s response. Systemic pooling of blood and transudation of fluid into tissues result in relative hypovolemia in patients with sepsis. Hyperdynamic septic shock is characterized by normal or elevated cardiac output and profoundly reduced systemic vascular resistance. Decreased myocardial contractility is often demonstrable by echocardiography even in patients with markedly increased cardiac output. Mixed venous oxygen
saturation is characteristically increased in the absence of hypoxemia and likely reflects the increased cardiac output and the cellular metabolic defect in oxygen utilization. Using an operational definition, patients with septic shock require vasopressor support to maintain a mean arterial pressure of 65 mm Hg or greater despite adequate circulating blood volume, and they have serum lactate levels greater than 2 mmol/L.

It used to be accepted wisdom that decreased cardiac output with low or normal systemic vascular resistance was usually seen later in the course of shock. This view is false. It is more likely to be seen in severely hypovolemic patients and in those with underlying cardiac disease. Myocardial depression is prominent. Mixed venous oxygen saturation is reduced in these patients. Pulmonary hypertension is often prominent and may contribute to right ventricular dysfunction.

**Clinical Manifestations**

Clinical manifestations of septic shock appear to be primarily related to host response rather than the infective agent. Septic shock classically presents following an abrupt onset of chills, fever, nausea (and often vomiting), with decreased mental status, tachypnea, hypotension, and tachycardia. The patient may appear flushed and feel warm (hyperdynamic) or pale with cool and often cyanotic extremities (hypodynamic). In old, debilitated patients and in infants, the diagnosis often is less obvious and hypothermia may be seen.

Leukocytosis with a leftward shift to premature cell forms is typical, but leukopenia, an ominous sign, can be seen with overwhelming sepsis. Progressive metabolic (usually lactic) acidosis may be partially compensated by a concomitant respiratory alkalosis. Elevated lactate levels reflect both increased production resulting from poor tissue perfusion and decreased uptake by the liver and kidneys. Hypoxemia may herald the onset of ARDS. Hypovolemia and hypotension may lead to oliguria that will often progress to AKI. Elevations in serum aminotransferases and bilirubin are due to hepatic dysfunction. Insulin resistance is uniformly present and produces hyperglycemia. Thrombocytopenia is common and is often an early sign of sepsis. Laboratory evidence of disseminated intravascular coagulation (DIC) is often present but is rarely associated with bleeding. The latter responds only to control of the sepsis. Stress ulceration of gastric mucosa is common. Respiratory and kidney failure are the leading causes of death in septic patients.

Neutropenic patients (absolute neutrophil count 500/μL) may develop skin
lesions that can ulcerate and become gangrenous (ecthyma gangrenosum). These lesions are commonly associated with *Pseudomonas* septicemia but can be caused by other organisms. Perirectal abscesses can develop very quickly in neutropenic patients with few external signs; conscious patients may complain only of perirectal pain.

**Treatment**

Septic shock is a medical emergency that requires immediate intervention. Treatment is threefold: (1) control and eradication of the infection by appropriate and timely intravenous antibiotics, drainage of abscesses, debridement of necrotic tissues, and removal of infected foreign bodies; (2) maintenance of adequate perfusion with intravenous fluids and inotropic and vasopressor agents; and (3) supportive treatment of complications such as ARDS, kidney failure, gastrointestinal bleeding, and DIC.

Antibiotic treatment usually is initiated before pathogens are identified but only after adequate cultures are obtained (commonly, blood, urine, wounds, and sputum). Pending the results of cultures and tests of antibiotic sensitivity, combination therapy with two or more antibiotics is generally indicated. The choice depends on which organisms are seen with the greatest frequency in one’s medical center. Additional diagnostic studies may be indicated (eg, thoracentesis, paracentesis, lumbar puncture, or imaging), depending on the history and physical examination.

Empiric antibiotic therapy in immunocompromised patients should be based on pathogens that are generally associated with the immune defect (see Table 57–5). Vancomycin is added if intravascular catheter-related infection is suspected. Clindamycin or metronidazole may be given to neutropenic patients if a rectal abscess is suspected. Many clinicians initiate therapy for a presumed fungal infection when an immunocompromised patient continues to experience fever despite antibiotic therapy. Granulocyte colony-stimulating factor or granulocyte–macrophage colony-stimulating factor may be used to shorten the period of neutropenia; granulocyte transfusion may occasionally be used in refractory gram-negative bacteremia. Diffuse interstitial infiltrates on a chest radiograph may suggest unusual bacterial, parasitic, or viral pathogens; many clinicians initiate empiric therapy with trimethoprim-sulfamethoxazole and erythromycin in such instances. Nodular infiltrates on a radiograph suggest a fungal pneumonia and may warrant antifungal therapy. Antiviral therapy should be considered in septic patients who are more than 1 month post–bone marrow or solid organ transplantation.
In general, therapy should follow the most recent guidelines. The presence of inadequate perfusion is determined by measurement of blood lactate. “Goal-directed” fluid therapy was also recommended by many groups in the past, but multiple randomized clinical trials have failed to show benefit in septic shock. Now, most authors recommend a more restricted approach to fluid resuscitation and invasive monitoring. Packed red blood cell transfusions are given to keep hemoglobin levels at least 8 g/dL, especially when cardiac output and central venous oxygen saturation are below targets. Marked “third-spacing” has long been regarded as characteristic of septic shock, but currently there is debate regarding the existence of the third space and the administration of large volumes of intravenous fluid as to which is cause and which is effect. Colloid solutions more rapidly restore intravascular volume compared with crystalloid solutions but otherwise offer no proven additional benefit. Vasopressor therapy is generally initiated if hypotension (mean arterial pressure <65 mm Hg) or elevated blood lactate levels persist following administration of intravenous fluids. Norepinephrine is preferred; positive inotrope drugs (eg, epinephrine) are indicated when norepinephrine “fails” despite adequate volume resuscitation. Blood glucose should be controlled with a target value of less than 180 mg/dL. In patients with hypotension that is refractory to norepinephrine plus epinephrine, vasopressin may be administered to improve blood pressure. Severe acidosis may decrease the efficacy of inotropes and should therefore generally be corrected (pH > 7.20) with bicarbonate or THAM infusion in patients with refractory hypotension. “Renal” doses of dopamine or fenoldopam may increase urinary output but do not improve or protect kidney function or patient outcomes. Clinical trials of naloxone, fibronectin, inhibitors of the coagulation cascade (drotrecogin alfa), and monoclonal antibodies directed against lipopolysaccharide have been uniformly disappointing in septic shock.

Gastrointestinal Hemorrhage

Acute gastrointestinal hemorrhage is a common reason for admission to the ICU. Older age (>60 years), comorbid illnesses, hypotension, marked blood loss (>5 units), and recurrent hemorrhage are associated with increased mortality. Management consists of stabilizing the patient with rapid identification of the site of bleeding. The clinician should differentiate between upper and lower gastrointestinal bleeding. A history of hematemesis indicates bleeding proximal to the ligament of Treitz. Melena often indicates bleeding proximal to the cecum. Hematochezia (bright red blood from the rectum) indicates either very brisk
upper gastrointestinal bleeding (likely to be associated with hypotension) or more commonly lower gastrointestinal bleeding. The presence of maroon stools usually localizes the bleeding to the area between the distal small bowel and the right colon.

At least one large-bore intravenous cannula should be placed, and blood should be sent for laboratory analysis and crossmatch. Fluid resuscitation guidelines are discussed in Chapter 51. Serial hemoglobin or hematocrit measurements may not accurately reflect acute blood loss during ongoing hemorrhage. Placement of a nasogastric tube may help identify an upper gastrointestinal source if bright red blood or “coffee grounds”–appearing material can be aspirated; inability to aspirate blood, however, does not rule out an upper gastrointestinal source.

**Upper Gastrointestinal Bleeding**

Lavage through a nasogastric tube can help assess the rate of bleeding and facilitate esophagogastroduodenoscopy (EGD). EGD should be performed whenever possible to diagnose the cause of bleeding. Arteriography should be performed if the site of bleeding cannot be visualized with endoscopy. In unselected patients the more common causes of upper gastrointestinal bleeding, in decreasing order of likelihood, are duodenal ulcer, gastric ulcer, erosive gastritis, and esophageal varices. Erosive gastritis may be due to stress, alcohol, aspirin, nonsteroidal antiinflammatory drugs, and corticosteroids. Less common causes of upper gastrointestinal bleeding include angiodysplasia, erosive esophagitis, Mallory–Weiss tear, gastric tumor, and aortoenteric fistula.

Both interventional endoscopy and interventional arteriography can be used therapeutically to stop the bleeding from peptic ulcers (gastric or duodenal). Surgery is generally indicated for severe hemorrhage (>5 units) and recurrent bleeding. H₂-receptor blockers and proton pump inhibitors are ineffective in stopping hemorrhage but may reduce the likelihood of rebleeding. Erosive gastritis is better prevented than treated. Proton pump inhibitors, H₂-receptor blockers, antacids, and sucralfate are all effective for prevention. However, overuse of proton pump inhibitors is associated with an increased incidence of hospital-acquired pneumonia. Data show that patients who require mechanical ventilation for more than 48 h or who are coagulopathic derive the greatest benefit from prophylaxis. Other groups of patients showing relative benefit from prophylaxis include those with AKI, sepsis, liver failure, hypotension, traumatic brain injury, a history of prior gastrointestinal hemorrhage, recent major surgery,
or those receiving large-dose corticosteroid therapy.

Once bleeding has begun, there is generally no specific therapy other than embolization or coagulation. Interventional endoscopy or interventional angiography reduce blood transfusions, rebleeding, hospital stay, and the need for urgent surgery. Balloon tamponade (Sengstaken–Blakemore, Minnesota, or Linton tubes) may be used as adjunctive therapy for variceal bleeding but usually requires concurrent tracheal intubation to protect the airway against aspiration.

**Lower Gastrointestinal Bleeding**

Common causes of lower gastrointestinal bleeding include diverticulosis, angiodysplasia, neoplasms, inflammatory bowel disease, ischemic colitis, infectious colitis, and anorectal disease (hemorrhoids, fissure, or fistula). Inspection and sigmoidoscopy can usually diagnose the more distal lesions. Colonoscopy usually allows definitive diagnosis (particularly for more proximal bleeding sites) and is often useful therapeutically. Interventional endoscopy or interventional angiography are the usual first choices for persistent bleeding. Surgical treatment is reserved for severe or recurrent hemorrhage.

**Delirium**

In the past, patients with critical illness and delirium were typically mechanically restrained and given sedative or paralytic drugs, or both. All of these approaches have been associated with adverse consequences. Restraints are inhumane unless used only as a last resort for patient protection. Prolonged use of propofol has led to “propofol infusion syndrome,” particularly in children. Prolonged use of neuromuscular blockers has been associated with critical illness myopathy. Fortunately, improved drugs for sedation (eg, dexmedetomidine) are more effective and have fewer adverse consequences.

**Post-Traumatic Stress Disorder**

Both surviving patients and caregivers find being in the critical care unit stressful. Increasing clinical and research attention is being paid to these concerns.
End-of-Life Care

In the United States, death is a taboo subject for many people. Some attend to last wills and testaments, estate planning, and taxes, but less than 15% of the adult population has made advance decisions about restrictions on life-supporting measures. Yet surveys consistently show widespread preference for a dignified, comfortable, and peaceful death at home and a widely shared wish to avoid dying in a hospital, particularly in an ICU.

The quandary about what to do is particularly vexing when it concerns a surgical patient who sought relief from symptoms, with improved functionality and a better quality of life, but who after suffering complications now requires ongoing life-supporting measures with little prospect of achieving the goals of the operation. Some physicians find it difficult to discuss such situations in a humane, nonadversarial manner and find it difficult to address the accusations, anger, and despair of family members and friends whose expectations have not been met. Good communication skills are the essential foundation. Communications with the family, friends, and all caregivers must be timely, consistent (having only one physician serve as the spokesman has great advantages), accurate, clear to laypersons, advisory without being dictatorial, focused on what is best for the patient, and aligned with the patient’s wishes. A gradual stepwise approach over time allows family members and friends time to digest the information, get beyond their initial reactions to the bad news, and make the difficult decision to withdraw intensive support.

Finally, it is important to recognize two ethical principles that are relevant here. The first is the principle of double effect. All medical interventions have potential benefits as well as burdens and risks. If the doses of morphine or sedative drug required to relieve pain and agitation result in unintended side effects, we accept them, even if the result is death. This is not euthanasia. The second principle is that withdrawal of medical therapies and interventions is no different from withholding them: Both may be done to respect the patient’s autonomy. There is a broad religious consensus that heroic measures are not mandated to support a heartbeat at the end of life.

CASE DISCUSSION

An Obtunded Young Woman
A 23-year-old woman is admitted to the hospital obtunded with slow respirations (7 breaths/min). Blood pressure is 90/60 mm Hg and the pulse is 90 beats/min. She was found at home in bed with empty bottles of diazepam, acetaminophen with hydrocodone, and fluoxetine lying next to her.

**How is the diagnosis of a drug overdose made?**

The presumptive diagnosis of a drug overdose usually must be made from the history, circumstantial evidence, and any witnesses. Signs and symptoms may not be helpful. Confirmation of a suspected drug overdose or poison ingestion usually requires delayed laboratory testing for the suspected agent in body fluids. Intentional overdoses (self-poisoning) are the most common mechanism and typically occur in young adults who are depressed. Ingestion of multiple drugs is common. Benzodiazepines, antidepressants, aspirin, acetaminophen, and alcohol are the most commonly ingested agents.

Accidental overdoses frequently occur in intravenous drug abusers and children. Commonly abused substances include opioids, stimulants (cocaine and methamphetamine), and hallucinogens (ketamine and phencyclidine [PCP]). Younger children occasionally accidentally ingest caustic household alkali (eg, drain cleaner), acids, and hydrocarbons (eg, petroleum products), in addition to unsecured medications of all types. Organophosphate poisoning (parathion and malathion) usually occurs in adults following agricultural exposure. Overdoses and poisoning less commonly occur as an attempted homicide.

**What are appropriate steps in managing this patient?**

Regardless of the type of drug or poison ingested, the principles of initial supportive care are the same. Airway patency with adequate ventilation and oxygenation must be obtained. Unless otherwise contraindicated, oxygen therapy (100%) should be administered. Hypoventilation and obtunded airway reflexes require tracheal intubation and mechanical ventilation. Many clinicians routinely administer naloxone (up to 2 mg), dextrose 50% (50 mL), and thiamine (100 mg) intravenously to all obtunded or comatose patients until a diagnosis is established; this may help exclude or treat opioid overdose, hypoglycemia, and Wernicke–Korsakoff syndrome, respectively. The dextrose can be omitted when a glucose measurement indicates it is not necessary. In this patient, intubation should be performed
prior to naloxone because the respiratory depression is likely due to both
the hydrocodone and the diazepam.

Blood, urine, and gastric fluid specimens should be obtained and sent for
drug screening. Blood is also sent for routine hematological and chemistry
studies (including liver function). Urine is usually obtained after bladder
catheterization, and gastric fluid can be aspirated from a nasogastric tube;
the latter should be placed after intubation to avoid pulmonary aspiration.
Alternatively, emesis material may be tested for drugs in conscious persons.

Hypotension should generally be treated with intravenous fluids unless
the patient is obviously in pulmonary edema; an inotrope or vasopressor
may be necessary in some instances. Seizure activity may be the result of
hypoxia or a pharmacological action of a drug (tricyclic antidepressants) or
poison. Seizure activity is unlikely in this patient because she ingested
diazepam, a potent anticonvulsant.

**Should flumazenil be administered?**

Flumazenil should generally not be administered to patients who
overdose on both a benzodiazepine and an antidepressant and those who
have a history of seizures. Reversal of the benzodiazepine’s anticonvulsant
action can precipitate seizure activity in such instances. Moreover, as is the
case with naloxone and opioids, the half-life of flumazenil is shorter than
that of benzodiazepines. Thus, it is often preferable to ventilate the patient
until the benzodiazepine effect dissipates, the patient regains consciousness,
and the respiratory depression resolves.

**Should any other antidotes be given?**

Because the patient also ingested an unknown quantity of acetaminophen
(paracetamol) administration of N-acetylcysteine (NAC; Mucomyst) should
be considered. Acetaminophen toxicity is due to depletion of hepatic
glutathione, resulting in the accumulation of toxic metabolic intermediates.
Hepatic toxicity is usually associated with ingestion of more than 140
mg/kg of acetaminophen. NAC prevents hepatic damage by acting as a
sulfhydryl donor and restoring hepatic glutathione levels. If the patient is
suspected of having ingested a toxic dose of acetaminophen, an initial
dosage of NAC (140 mg/kg orally or by nasogastric tube) should be
administered even before plasma acetaminophen levels are obtained;
additional doses are given according to the measured plasma level. If the
patient cannot tolerate oral or gastric administration of NAC, if the patient
is pregnant, or if the risk of hepatotoxicity is high, NAC should be given intravenously.

**What measures might limit drug toxicity?**

Toxicity might be reduced by decreasing drug absorption or enhancing elimination. Gastrointestinal absorption of an ingested substance can be reduced by emptying stomach contents and administering activated charcoal. Both methods can be effective up to 12 h following ingestion. If the patient is intubated, the stomach is lavaged carefully to avoid pulmonary aspiration. Emesis may be induced in conscious patients with syrup of ipecac 30 mL (15 mL in a child). Gastric lavage and induced emesis are generally contraindicated for patients who ingest caustic substances or hydrocarbons because of a high risk of aspiration and worsening mucosal injury.

Activated charcoal, 1 to 2 g/kg, is administered orally or by nasogastric tube with a diluent. The charcoal irreversibly binds most drugs and poisons in the gut, allowing them to be eliminated in stools. In fact, charcoal can create a negative diffusion gradient between the gut and the circulation, allowing the drug or poison to be effectively removed from the body.

Alkalinization of the serum with sodium bicarbonate for tricyclic antidepressant overdose is beneficial because, by increasing pH, protein binding is enhanced; if seizures occur, the alkalinization prevents acidosis-induced cardiotoxicity.

**What other methods can enhance drug elimination?**

The easiest method of increasing drug elimination is forced diuresis. Unfortunately, this method is of limited use for drugs that are highly protein bound or have large volumes of distribution. Mannitol or furosemide with saline may be used. Concomitant administration of alkali (sodium bicarbonate) enhances the elimination of weakly acidic drugs such as salicylates and barbiturates; alkalinization of the urine traps the ionized form of these drugs in the renal tubules and enhances urinary elimination. Hemodialysis is usually reserved for patients with severe toxicity who continue to deteriorate despite aggressive supportive therapy.

CHAPTER 58

Inhalation Therapy & Mechanical Ventilation in the PACU & ICU

KEY CONCEPTS

1. Hyperoxia and hypoxia are risk factors for but not the primary causes of retinopathy of prematurity (ROP). Neonates’ risk of ROP increases with low birth weight and complexity of comorbidities (eg, sepsis).

2. The disadvantage of conventional PCV is that tidal volume (VT) is not guaranteed (although there are modes in which the consistent delivered pressure of PCV can be combined with a predefined volume delivery).

3. Pressure control ventilation (PCV) is similar to pressure support ventilation in that peak airway pressure is controlled but is different in that a mandatory rate and inspiratory time are selected. As with pressure support, gas flow ceases when the pressure level is reached; however, the ventilator does not cycle to expiration until the preset inspiration time has elapsed.

4. Both nasotracheal and orotracheal intubation appear to be relatively safe for at least 2 to 3 weeks.

5. When left in place for more than 2 to 3 weeks, both orotracheal and nasotracheal tubes predispose patients to subglottic stenosis. If longer periods of mechanical ventilation are necessary, the tracheal tube should generally be replaced by a cuffed tracheostomy tube.

6. The major effect of positive end-expiratory pressure (PEEP) on the lungs is to increase functional residual capacity (FRC). In patients with decreased lung volume, appropriate levels of either PEEP or continuous positive airway pressure (CPAP) will increase FRC and tidal ventilation above closing capacity. This will improve lung compliance and will correct ventilation/perfusion abnormalities.

7. Compared with a VT of 12 mL/kg, a VT of 6 mL/kg and plateau
pressure ($P_{plt}$) less than 30 cm H$_2$O have been associated with reduced mortality in patients with acute respiratory distress syndrome.

A higher incidence of pulmonary barotrauma is observed with excessive PEEP or CPAP at levels greater than 20 cm H$_2$O.

Maneuvers that produce sustained maximum lung inflation, such as the use of an incentive spirometer, can be helpful in inducing cough as well as preventing atelectasis and preserving normal lung volume.

Respiratory care includes both the delivery of pulmonary therapy and performance of diagnostic tests. Respiratory therapists’ scope of practice encompasses medical gas therapy, delivery of aerosolized medications, airway management, mechanical ventilation, positive airway pressure therapy, critical care monitoring, cardiopulmonary rehabilitation, and the application of various techniques collectively termed chest physiotherapy. The latter includes administering aerosols, clearing pulmonary secretions, reexpansion of atelectatic lung, and preserving normal lung function postoperatively or during illness. Diagnostic services may include pulmonary function testing, arterial blood gas analysis, and evaluation of sleep-disordered breathing. These procedures and services are well described in clinical practice guidelines developed by the American Association for Respiratory Care.

**MEDICAL GAS THERAPY**

Therapeutic medical gases include oxygen at ambient or hyperbaric pressure, helium–oxygen mixtures (heliox), and nitric oxide. Oxygen is made available in high-pressure cylinders, via pipeline systems, from oxygen concentrators, as well as in liquid form. Heliox is occasionally used to reduce the increased work of breathing caused by partial upper airway obstruction. Nitric oxide is administered as a direct, selective pulmonary vasodilator.

The primary goal of oxygen therapy is to prevent or correct hypoxemia or tissue hypoxia. Table 58–1 identifies classic categories of hypoxia. Having a patient inhale an increased concentration of oxygen alone may not correct either hypoxemia or hypoxia. Continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) may be required to recruit collapsed alveoli. Patients with profound hypercapnia may require ventilatory assistance. Increased concentrations of oxygen (possibly at hyperbaric pressures) may be indicated for conditions requiring removal of entrapped gas (eg, nitrogen) from body cavities.
or vessels. The short-term inhalation of increased concentrations of oxygen is relatively free of complications.

Supplemental oxygen is indicated for adults, children, and infants (older than 1 month) when \( P_{aO_2} \) is less than 60 mm Hg (8 kPa) or \( SaO_2 \) or \( SpO_2 \) is less than 90% while breathing room air. In neonates, therapy is recommended if \( P_{aO_2} \) is less than 50 mm Hg (6.7 kPa) or \( SaO_2 \) is less than 88% (or capillary \( PO_2 \) is less than 40 mm Hg [5.3 kPa]). Therapy may be indicated for patients when hypoxemia or hypoxia is suspected based on a medical history and physical examination. Supplemental oxygen is given during the perioperative period because general anesthesia commonly causes a decrease in \( P_{aO_2} \) secondary to increased pulmonary ventilation/perfusion mismatching and decreased functional residual capacity (FRC). Supplemental oxygen should be provided before procedures such as tracheal suctioning or bronchoscopy, which commonly cause arterial desaturation. There is evidence that supplemental oxygen is effective in prolonging survival of patients with chronic obstructive pulmonary disease (COPD) whose resting \( P_{aO_2} \) is lower than 60 mm Hg at sea level. Supplemental oxygen therapy also appears to have a mild beneficial effect on the mean pulmonary arterial pressure and subjective indices of patients’ dyspnea.

**AMBIENT OXYGEN THERAPY EQUIPMENT**

**Classifying Oxygen Therapy Equipment**

Oxygen given alone or in a gas can be mixed with air as a partial supplement to patients’ tidal volume or serve as the entire source of the inspired volume. The
devices or systems used for this are classified based on their maximal flow rates and a range of fractions of inspired oxygen (FiO₂). Other considerations in selecting an oxygen delivery technique include patient compliance, the presence and type of artificial airway, and the need for humidification or an aerosol delivery system.

A. Low-Flow or Variable-Performance Equipment
Oxygen (usually 100%) is supplied at a fixed flow that is only a portion of inspired gas. Such devices (eg, nasal “prongs”) are usually intended for patients with stable breathing patterns. As ventilatory demands change, variable amounts of room air will dilute the oxygen flow. Low-flow systems are adequate for patients with:

- Minute ventilation less than ~8 to 10 L/min
- Breathing frequencies less than ~20 breaths/min
- Tidal volumes (Vₜ) less than ~0.8 L
- Normal inspiratory flow (10–30 L/min)

B. High-Flow or Fixed-Performance Equipment
Inspired gas at a preset FiO₂ is supplied continuously at high flow or by providing a sufficiently large reservoir of premixed gas. Ideally, the delivered FiO₂ is not affected by variations in ventilatory level or breathing pattern. High-flow systems are indicated for patients who require:

- Consistent FiO₂
- Larger inspiratory flows of gas (>40 L/min)

1. Variable-Performance Equipment
Nasal Cannulas
The nasal cannula is available as either a single-ended soft plastic tube with an over-the-ear head-elastic or dual-flow (to both nares) with under-the-chin lariat adjustment. Sizes appropriate for adults, children, and infants are available. Cannulas are connected to flowmeters with small-bore tubing. The tubing should be adjusted to avoid pressure sores on the ears, cheeks, and nose. Patients receiving long-term oxygen therapy most commonly use a nasal cannula. The
appliance is usually well tolerated, allowing unencumbered speech, eating, and drinking. Cannulas can be combined with spectacle frames for convenience or to improve cosmesis. Since oxygen flows continuously, approximately 80% of the gas is wasted during expiration.

The actual Fio₂ delivered to adults with nasal cannulas is determined by oxygen flow, nasopharyngeal volume, and the patient’s inspiratory flow (the latter depends both on VT and inspiratory time) (see Table 58–2). Oxygen from the cannula can fill the nasopharynx after exhalation, yet with inspiration, oxygen and entrained air are drawn into the trachea. The inspired percent oxygen in inspired air increases by approximately 2% (above 21%) per liter of oxygen flow with quiet breathing in adults; thus, cannulas can be expected to provide inspired oxygen concentrations up to 30% with normal breathing and oxygen flows of 4 L/min. Levels of 40% or greater can be attained with oxygen flows of 10 L/min or greater; however, flows greater than 5 L/min are poorly tolerated because of the discomfort of gas jetting into the nasal cavity and because of drying and crusting of the nasal mucosa.

### TABLE 58–2  Oxygen delivery devices and systems.
Data from “normal-breathing subjects” may not be accurate for acutely ill tachypneic patients. Increasing $V_t$ and reducing inspiratory time will dilute the small flow of oxygen. Different proportions of mouth-only versus nose-only breathing and varied inspiratory flow can alter $Fio_2$ by up to 40%. In clinical practice, flow should be titrated according to vital signs and pulse oximetry (or arterial blood gas measurements). Some patients with COPD tend to hypoventilate with even modest oxygen flows, yet are hypoxemic on room air. They may do well with cannula flows of less than less than 2 L/min.

Special cannulas allow infants to nurse and produce less trauma of the face and nose than oxygen masks. Because of the reduced minute ventilation of infants, flow through the cannula must be proportionately reduced. This generally requires a pressure-compensated flowmeter accurate at delivering oxygen flows in the less than 3 L/min range. Hypopharyngeal oxygen sampling from infants breathing with cannulas has demonstrated mean $Fio_2$ of 0.35, 0.45,

0.6, and 0.68 with flows of 0.25, 0.5, 0.75, and 1.0 L/min, respectively.

**Nasal Mask**

The nasal mask is a hybrid of the nasal cannula and a face mask. The lower edge of the mask’s flanges rests on the upper lip, surrounding the external nose. Nasal masks provide supplemental oxygen equivalent to the nasal cannula under low-flow conditions in adult patients. Many patients find the nasal mask more comfortable than a nasal cannula. The nasal mask does not produce sores around the external nares and dry oxygen is not “jetted” into the nasal cavity. The nasal mask should be considered if it improves patient comfort and compliance.

**“Simple” Oxygen Mask**

The “simple” oxygen mask is a disposable lightweight plastic device that covers both nose and mouth. It has no reservoir bag. Masks are secured to the patient’s face by adjustment of an elastic headband. The seal is rarely complete: usually there is “inboard” leaking. Thus, patients receive a mixture of oxygen and secondarily entrained room air, depending on the size of the leak, oxygen flow, and breathing pattern.

The body of the mask functions as a reservoir for both oxygen and expired carbon dioxide. A minimum oxygen flow of approximately 5 L/min is applied to the mask to limit rebreathing and the resulting increased respiratory work. Wearing any mask appliance for long periods of time is uncomfortable. Speech is muffled and drinking and eating are difficult.

It is difficult to predict delivered Fi \(_{O_2}\) at specific oxygen flow rates. During normal breathing, it is reasonable to expect an Fi \(_{O_2}\) of 0.3 to 0.6 with flows of 5 to 10 L/min, respectively. Oxygen levels can be increased with smaller \(V_T\) or slower breathing rates. With higher flows and ideal conditions, Fi \(_{O_2}\) may approach 0.7 or 0.8.

Masks lacking oxygen reservoirs may be best suited for patients who require concentrations of oxygen not easily attainable using cannulas, but who require oxygen therapy for short periods of time. Examples would include medical transport or therapy in the postanesthesia care unit or emergency department. It is not the device of choice for patients who are profoundly hypoxemic, tachypneic, or unable to protect their airway from aspiration.
Masks with Gas Reservoirs

Incorporating a gas reservoir expands the applicability of the simple mask. Two types of reservoir mask are commonly used: the partial rebreathing mask and the nonrebreathing mask. Both are disposable, lightweight, transparent plastic under-the-chin reservoirs. The difference between the two relates to use of valves on the mask and between the mask and the bag reservoir. Mask reservoirs commonly hold less than 600 mL of gas volume. The phrase “partial rebreather” is used because “part” of the patient’s expired VT refills the bag. Because expired gas is largely from “dead space ventilation,” significant rebreathing of carbon dioxide usually does not occur.

The nonrebreather uses the same basic system as the partial rebreather but incorporates flap-type valves between the bag and mask and on at least one of the mask’s exhalation ports. Inboard leaking is common, and room air will enter during brisk inspiratory flows, even when the bag contains gas. The lack of a complete facial seal and a relatively small reservoir limit the delivered oxygen concentration. The key factor in successful application of the mask is to use a sufficiently high flow of oxygen, so that the reservoir bag is at least partially full during inspiration. Typical minimum flows of oxygen are 10 to 15 L/min. Well-fitting partial rebreathing masks provide a range of Fio₂ from 0.35 to 0.60 with oxygen flows up to 10 L/min. With inlet flows of 15 L/min or more and ideal breathing conditions, Fio₂ may approach 1.0. Either style of mask is indicated for patients with significant hypoxemia, but relatively normal spontaneous minute ventilation.

2. Fixed-Performance (High-Flow) Equipment

Profoundly dyspneic patients with gasping respiration may be served by a fixed-performance, high-flow oxygen system.

Anesthesia Bag or Bag-Mask-Valve Systems

Self-inflating bags consist of a roughly 1.5 L bladder, usually with an oxygen inlet reservoir. Anesthesia bags are 1-, 2-, or 3-L non–self-inflating reservoirs with a tailpiece gas inlet. Masks are designed to provide a comfortable leak-free seal for manual ventilation. The inspiratory/expiratory valve systems may vary. The flow to the reservoir should be kept high so that the bags do not deflate substantially. When using an anesthesia bag, operators may frequently have to adjust the oxygen flow and exhaust valve to respond to changing breathing
patterns or demands, particularly when maintaining a complete seal between the mask and face is difficult.

The most common systems for disposable and permanent self-inflating resuscitation bags use a unidirectional gas flow. Although these devices offer the potential for a constant $\text{FiO}_2$ greater than 0.9, tailpiece inlet valves will not open for a spontaneously breathing patient. Opening the valves requires negative-pressure bag recoil after compression. If this situation is not recognized, clinicians might be misled into thinking the patient is receiving a greater concentration of oxygen than is the case.

There are limits to the ability of each system to maintain its fixed-performance characteristics. Delivered $\text{FiO}_2$ can approach 1.0 with either anesthesia or self-inflating bags. Spontaneously breathing patients are allowed to breathe only the contents of the system if the mask seal is tight and the reservoir is adequately maintained.

Failure to maintain an adequate oxygen supply in the reservoir and inlet flow is a concern. The spring-loaded valve of anesthesia bags must be adjusted to prevent overdistention of the bag. Self-inflating bags look the same whether or not oxygen flow to the unit is adequate, and they will entrain room air into the bag, thus lowering the delivered $\text{FiO}_2$.

**Air-Entraining Venturi Masks**

The gas delivery approach with air-entraining masks is different than with an oxygen reservoir. The goal is to create an open system with high flow about the nose and mouth, with a fixed $\text{FiO}_2$. Oxygen is directed by small-bore tubing to a mixing jet; the final oxygen concentration depends on the ratio of air drawn in through entrainment ports. Manufacturers have developed both fixed and adjustable entrainment selections over an $\text{FiO}_2$ range. Most provide instructions for the operator to set a minimum flow of oxygen. *Table 58–3* identifies total flow at various inlet flows and $\text{FiO}_2$.

| TABLE 58–3 | Air-entrainment mask input flow versus total flow at varying $\text{FiO}_2$. |
Despite the high-flow concept, $\text{FiO}_2$ can vary up to 6% from the anticipated setting. The air-entraining masks are a logical choice for patients who require greater $\text{FiO}_2$ than can be provided by devices such as the nasal cannula. Patients with COPD who tend to hypoventilate with a moderate $\text{FiO}_2$ are candidates for the Venturi mask. Clinicians providing oxygen therapy with Venturi masks should be aware of the previously mentioned problems involving the mask itself. $\text{FiO}_2$ can increase if the air entrainment ports are obstructed by the patient’s hands, bed sheets, or water condensate. Clinicians should encourage the patient and caregivers to keep the mask on the face continuously: Interruption of oxygen delivery may be life threatening in unstable patients with hypoxemia. Accurate analysis of the delivered $\text{FiO}_2$ during air-entrainment mask breathing is difficult. Pulse oximetry (or arterial blood gas analysis) and the patient’s respiratory rate should guide clinicians as to whether the patient’s demands are being met by the mask’s flow.

### Air-Entraining Nebulizers

Large-volume, high-output or “all-purpose” nebulizers have been used in

respiratory care for many years to provide mist therapy with some control of the Fio₂. These units are commonly placed on patients following extubation for their aerosol-producing properties. Like the air-entraining masks, nebulizers use a pneumatic jet and an adjustable orifice to vary entrained air for varying Fio₂ levels. Many commercial devices have an inlet orifice diameter that maximally allows only 15 L/min when the source pressure is 50 psi. This means that on the 100% setting (no air entrainment) output flow is only 15 L/min. Only patients breathing slowly with small Vṭ will receive 100% oxygen. This problem has been addressed by high-flow, high-Fio₂ nebulizers. For more common applications that use an Fio₂ of 0.3 to 0.5, room air is entrained, reducing the Fio₂ and increasing the total flow output to 40 to 50 L/min.

Knowledge of the air/oxygen ratio and the input flow rate of oxygen allows the total outflow to be calculated. Nebulizer systems can be applied to the patient with many different devices, including tracheostomy dome/collar, face tent, and T-piece adapter. These appliances can all be attached via large-bore tubing to the nebulizer. This open system freely vents inspiratory and expiratory gases around the patient’s face or out a distal port of a T-piece adapter. Unfortunately, the lack of any valves allows patients to secondarily entrain room air. It is common practice to use either a reservoir bag before the T-piece or a reservoir tube on the distal side of the T-piece to provide a larger volume of gas than that coming from the nebulizer. A typical concern of those applying air-entrainment aerosol therapy with controlled oxygen concentration is whether the system will provide adequate flow. Clinicians should observe the mist like a tracer to determine adequacy of flow. When a T-piece is used and the visible mist (exiting the distal port) disappears during inspiration, the flow is inadequate.

A common clinical problem occurs when excess water collects in the tubing, completely obstructing gas flow or increasing resistance to flow. Other complications include bronchospasm or laryngospasm as a consequence of airway irritation from sterile water droplets (condensate of the aerosol). In such circumstances, a heated (nonaerosol) humidification system should be substituted.

**High-Flow Air–Oxygen Systems**

Dual air–oxygen flowmeters and air–oxygen blenders are commonly used for oxygen administration as well as freestanding CPAP and “add-on” ventilator systems. These systems differ from the air-entraining nebulizers, as their total output flows do not diminish at Fio₂ greater than 0.4. With these high-flow
systems, the total flow to the patient and FiO₂ can be set independently to meet patient needs. This can be done using a large reservoir bag or constant flows in the range of 50 to more than 100 L/min. Clinicians can use a variety of appliances with these systems, including aerosol masks, face tents, or well-fitted nonrebreathing system masks with air–oxygen blenders. Face-sealing mask systems can also be constructed with a reservoir bag and a safety valve to allow breathing if the blender fails. The high flows of gas require use of heated humidifiers of the type commonly used on mechanical ventilators. Humidification offers an advantage for patients with reactive airways. Because of the high flows, such systems are used to apply CPAP or bilevel positive airway pressure (BiPAP) for spontaneously breathing patients.

**Oxygen Hoods**

Many infants and neonates will not tolerate facial appliances. Oxygen hoods cover only the head, allowing access to the child’s lower body while still permitting use of a standard incubator or radiant warmer. The hood is ideal for relatively short-term oxygen therapy for newborns and inactive infants. However, for mobile infants requiring longer term therapy, the nasal cannula, face mask, or full-bed enclosure allow for greater mobility.

Normally, oxygen and air are premixed by an air–oxygen blender and passed through a heated humidifier. Nebulizers should be avoided. Most pneumatic jet-type nebulizers create noise levels (>65 dB) that may cause newborn hearing loss. Hoods come in different sizes. Some are simple Plexiglas boxes; others have elaborate systems for sealing the neck opening. There is no attempt to completely seal the system, as a constant flow of gas is needed to remove carbon dioxide (minimum flow >7 L/min). Hood inlet flows of 10 to 15 L/min are adequate for a majority of patients.

**Helium–Oxygen Therapy**

Helium–oxygen (heliox) mixtures have notable medical applications. Helium is premixed with oxygen in several standard blends. The most popular mixture is 79%/21% helium–oxygen, which has a density that is 40% that of pure oxygen. Helium–oxygen mixtures are available in large-sized compressed gas cylinders.

In anesthetic practice, pressures needed to ventilate patients with small-diameter tracheal tubes can be substantially reduced when the 79%/21% mixture is used. Heliox can provide patients with upper airway–obstructing lesions (eg,
subglottic edema, foreign bodies, and tracheal tumors) with relief from acute distress until more definitive care can be delivered. The benefit is less convincing in treating lower airway obstruction from COPD or acute asthma. Helium mixtures may also be used as the driving gas for small-volume nebulizers in bronchodilator therapy for asthma. However, with heliox, the nebulizer flow needs to be increased to 11 L/min versus the usual 6 to 8 L/min with oxygen. Patients’ work of breathing can be reduced with heliox as compared to a conventional oxygen/nitrogen gas mixture.

**Hyperbaric Oxygen**

Hyperbaric oxygen therapy uses a pressurized chamber to expose the patient to oxygen tensions exceeding ambient barometric pressure (at sea level the ambient pressure is 760 mm Hg). With a one-person hyperbaric chamber, 100% oxygen is usually used to pressurize the chamber. Larger chambers allow for the simultaneous treatment of multiple patients and for the presence of medical personnel in the chamber with patients. Multiplace chambers use air to pressurize the chamber, whereas patients receive 100% oxygen by mask, hood, or tracheal tube. Common indications for hyperbaric oxygen where outcome benefits have been shown include decompression sickness (the “bends”), certain forms of gas embolism, gas gangrene, anaerobic bacterial infections, carbon monoxide poisoning, and treatment of certain wounds.

3. **Hazards of Oxygen Therapy**

Oxygen therapy can result in both respiratory and nonrespiratory toxicity. Important factors include patient susceptibility, the FiO₂, and duration of therapy.

**Hypoventilation**

This complication is often seen in patients with COPD who have chronic CO₂ retention or in patients receiving opioids. Patients who retain CO₂ have a respiratory drive that becomes at least partly dependent on the maintenance of relative hypoxemia. Elevation of arterial oxygen tension to “normal” can therefore cause severe hypoventilation in these patients. Oxygen therapy can be indirectly hazardous for patients being monitored with pulse oximetry while receiving opioids for pain. Opioid-induced hypoventilation may not cause arterial oxygen desaturation, despite markedly reduced respiratory rates. Thus,
supplemental oxygen renders pulse oximetry a poor monitor for opioid-induced respiratory depression.

**Absorption Atelectasis**

High concentrations of oxygen can cause pulmonary atelectasis in areas of low $V′/Q′$ ratios. As nitrogen is “washed out” of the lungs, the lowered gas tension in pulmonary capillary blood results in increased uptake of alveolar gas and absorption atelectasis. If the area remains perfused but nonventilated, the resulting intrapulmonary shunt with increasing “venous admixture” can lead to progressive widening of the alveolar-to-arterial ($A–a$) gradient.

**Pulmonary Toxicity**

Prolonged high concentrations of oxygen may damage the lungs. Toxicity is dependent both on the partial pressure of oxygen in the inspired gas and the duration of exposure. Alveolar rather than arterial oxygen tension is most important in the development of oxygen toxicity. Although 100% oxygen for up to 10 to 20 h is generally considered safe, concentrations greater than 50% to 60% are undesirable for longer periods as they may lead to pulmonary toxicity.

Oxygen toxicity is thought to be due to intracellular generation of highly reactive $O_2$ metabolites (free radicals) such as superoxide and activated hydroxyl ions, singlet $O_2$, and hydrogen peroxide. A high concentration of $O_2$ increases the likelihood of generating toxic species. These metabolites are cytotoxic because they readily react with DNA, proteins, and lipids. Two cellular enzymes, superoxide dismutase and catalase, protect against toxicity by sequentially converting superoxide first to hydrogen peroxide and then to water. Additional protection may be provided by antioxidants and free radical scavengers; however, there is no good clinical evidence that these agents prevent pulmonary toxicity. Oxygen toxicity may present as tracheobronchitis initially in some patients. Pulmonary $O_2$ toxicity in newborn infants is manifested as bronchopulmonary dysplasia. In experimental animals oxygen-mediated injury of the alveolar–capillary membrane produces a condition that is indistinguishable from acute respiratory distress syndrome (ARDS).

**Retinopathy of Prematurity**

Retinopathy of prematurity (ROP), formerly termed *retrolental fibroplasia*, is a
neovascular retinal disorder that develops in the great majority of premature survivors born at less than 28 weeks’ gestation. ROP may include disorganized vascular proliferation and fibrosis and may lead to retinal detachment and blindness. ROP resolves in approximately 80% of these cases without visual loss from retinal detachments or scars. ROP was very common in the 1940s–1950s when unmonitored high (>0.5 Fio₂) oxygen was often administered to premature infants. However, it is now known that hyperoxia and hypoxia are risk factors for but not the primary causes of ROP. Neonates’ risk of ROP increases with low birth weight and complexity of comorbidities (eg, sepsis). In contrast to pulmonary toxicity, ROP correlates better with arterial than with alveolar O₂ tension. The recommended arterial concentrations for premature infants receiving oxygen are 50 to 80 mm Hg (6.6–10.6 kPa). If an infant requires arterial O₂ saturations of 96% to 99% for cardiopulmonary reasons, fear about causing or worsening ROP is not a reason to withhold the oxygen.

Hyperbaric Oxygen Toxicity
The increased inspired O₂ tensions associated with hyperbaric O₂ therapy greatly accelerate O₂ toxicity. The risk and expected degree of toxicity are directly related to the pressures used as well as the duration of exposure. Prolonged exposure to O₂ partial pressures in excess of 0.5 atmosphere can cause pulmonary O₂ toxicity. This may present initially with retrosternal burning, cough, and chest tightness. There will be progressive impairment of pulmonary function with continued exposure. Patients exposed to O₂ at 2 atmospheres or greater are also at risk for central nervous system toxicity that may be expressed as behavior changes, nausea, vertigo, muscular twitching, or convulsions.

Fire Hazard
Oxygen vigorously supports combustion. The potential for uncontained oxygen enriched gas mixtures to promote fires and explosions is discussed in Chapter 2.

MECHANICAL VENTILATION
Patients with critical illness often require mechanical ventilation. Mechanical ventilation can replace or supplement normal spontaneous ventilation. In some instances, the problem is primarily that of impaired CO₂ elimination (ventilatory
failure). In other instances, mechanical ventilation may be used as an adjunct (usually to positive-pressure therapy, as discussed next) in the treatment of hypoxemia. The decision to initiate mechanical ventilation is made on clinical grounds, but certain parameters have been suggested as guidelines (Table 58–4).

**TABLE 58–4 Indicators of the need for mechanical ventilation.**

Of the two available techniques, positive-pressure ventilation and negative-pressure ventilation (iron lung), the former has much wider applications and is almost universally used. Although negative-pressure ventilation does not require tracheal intubation, it cannot overcome substantial increases in airway resistance or decreases in pulmonary compliance, and it also limits access to the patient.

During positive-pressure ventilation, lung inflation is achieved by periodically applying positive pressure to the upper airway through a tight-fitting mask (noninvasive mechanical ventilation) or through a tracheal or tracheostomy tube. Increased airway resistance and decreased lung compliance can be overcome by manipulating inspiratory gas flow and pressure. The major disadvantages of positive-pressure ventilation are altered ventilation-to-perfusion relationships, potentially adverse circulatory effects, and risk of pulmonary barotrauma and volutrauma. Positive-pressure ventilation increases physiological dead space because gas flow is preferentially directed to the more
compliant, nondependent areas of the lungs, whereas blood flow (influenced by gravity) favors dependent areas. Reductions in cardiac output are primarily due to impaired venous return to the heart from increased intrathoracic pressure. Barotrauma is closely related to repetitive high peak inflation pressures and underlying lung disease, whereas volutrauma is related to the repetitive collapse and reexpansion of alveoli.

1. Positive-Pressure Ventilators

Positive-pressure ventilators periodically create a pressure gradient between the machine circuit and alveoli that results in inspiratory gas flow. Exhalation occurs passively. Ventilators and their control mechanisms can be powered pneumatically (by a pressurized gas source), electrically, or by both mechanisms. Gas flow is either derived directly from the pressurized gas source or produced by the action of a rotary or linear piston. This gas flow then either goes directly to the patient (single-circuit system) or, as commonly occurs with operating room ventilators, compresses a reservoir bag or bellows that is part of the patient circuit (double-circuit system).

All ventilators have four phases: inspiration, the changeover from inspiration to expiration (cycling), expiration, and the changeover from expiration to inspiration (trigger) (see Chapter 4). These phases are defined by $V_T$, ventilatory rate, inspiratory time, inspiratory gas flow, and expiratory time.

Classification of Ventilators

Modern ventilators are complicated and defy simple classification. Incorporation of microprocessors into ventilators has further complicated this task. Complexity of ventilator nomenclature combined with proprietary naming schema for similar ventilator functionality has led to calls for uniform taxonomy for ventilator modes. Chatburn provides one such nomenclature, and its salient points are used to frame the following discussion on ventilator modes.

Phase Variables

The breathing period can be divided into four phases: (1) change from expiration to inspiration (trigger), (2) inspiration (target), (3) change from inspiration to expiration (cycle), and (4) expiration. The trigger variable starts inspiration when it (pressure, volume, flow, or time) reaches a preset value. When time is the trigger, breaths are initiated on a defined frequency regardless of patient effort.
(see Figure 58–1). Alternatively, pressure, flow, or volume triggers initiate a breath when the ventilator detects a change in pressure, flow, or volume, respectively caused by patient effort.

**FIGURE 58–1** Trigger and synchronization windows. If a patient signal occurs within the trigger window, inspiration is patient triggered. If a patient signal occurs within a synchronization window, inspiration is ventilator triggered (or cycled if at the end of inspiration) and patient synchronized. Note that, in general, a trigger window is used with continuous mandatory ventilation, and a synchronization window is used with intermittent mandatory ventilation.

The target variable (pressure, volume, or flow) must reach a specified level before inspiration ends. This used to be called “limit” but nomenclatures have changed. The target variable does not define the end of inspiration, but only the upper boundary for each breath. When the cycle variable is reached, inspiration ends. Options include pressure, volume, flow, or time.
Pressure-cycled ventilators cycle into the expiratory phase when airway pressure reaches a predetermined level. \( V_t \) and inspiratory time vary, being related to airway resistance and pulmonary and circuit compliance. A significant leak in the patient circuit can prevent the necessary rise in circuit pressure and machine cycling. Conversely, an acute increase in airway resistance, or decrease in pulmonary compliance, or circuit compliance (eg, a kinked tube) causes premature cycling and decreases the delivered \( V_t \). Pressure-cycled ventilators have been most often used for short-term indications (eg, transport).

Volume-cycled ventilators terminate inspiration when a preselected volume is delivered. Many adult ventilators are volume cycled but also have secondary limits on inspiratory pressure to guard against pulmonary barotrauma. If inspiratory pressure exceeds the pressure limit, the machine cycles into expiration even if the selected volume has not been delivered.

Properly functioning volume-cycled ventilators do not deliver the set \( V_t \) to the patient. A percentage of the set \( V_t \) is always lost due to expansion of the breathing circuit during inspiration. Circuit compliance is usually about 3 to 5 mL/cm H\(_2\)O; thus, if a pressure of 30 cm H\(_2\)O is generated during inspiration, 90 to 150 mL of the set \( V_t \) is lost to the circuit. Loss of \( V_t \) from expansion of the breathing circuit is therefore inversely related to lung compliance. For accurate measurement of the exhaled \( V_t \), the spirometer must be placed at the tracheal tube rather than the exhalation valve of the ventilator.

Flow-cycled ventilators have pressure and flow sensors that allow the ventilator to monitor inspiratory flow at a preselected fixed inspiratory pressure; when this flow reaches a predetermined level (usually 25% of the initial peak mechanical inspiratory flow rate), the ventilator cycles from inspiration into expiration (see the later sections on pressure support and pressure-controlled ventilation).

Time-cycled ventilators cycle to the expiratory phase once a predetermined interval elapses from the start of inspiration. \( V_t \) is the product of the set inspiratory time and inspiratory flow rate. Time-cycled ventilators are commonly used for neonates and in the operating room.

**Ventilator Modes**

A ventilator mode is a combination of control variable, breath sequence, and target scheme. Additionally, to understand ventilator mechanics one must consider the phase variables (introduced earlier).
Control Variables

The control variable is the independent variable in the ventilator mode (see Figure 58–2). Choice are pressure, volume, and flow. In pressure-controlled ventilation (PCV), pressure is independent variable, and pressure waveform is specified (eg, rectangular waveform). In volume-controlled ventilation (VCV), similarly a volume waveform is defined. In common terminology, flow-controlled ventilation is not commonly used because flow is derivative of volume. When one directly controls volume, one indirectly controls flow.

FIGURE 58–2 Rubric for determining the control variable of a mode. E,
elastance; P, pressure; P_{aw}, airway pressure; R, resistance; SIMV, synchronized intermittent mandatory ventilation; V, volume; V', inspiratory flow; V_{T}, tidal volume. (Reproduced with permission from Mandu Press. Cleveland, Ohio.)

**Targeting Scheme**

Targeting scheme is a feedback control design to deliver a specific pattern. A type of targeting scheme called *set point targeting* is the most basic. One sets a value, and ventilator seeks to deliver it. For VCV, set points would be V_{T} and flow. For PCV, commonly it would be inspiratory pressure and inspiratory time.

**Breath Sequence**

Breath sequence is the pattern of mandatory or spontaneous breaths in a ventilator mode, or both (see **Figure 58–3**). A spontaneous breath is defined as a breath in which a patient determines both timing and size of the breath. It is patient triggered and patient cycled. A mandatory breath is any breath that is not spontaneous. An assisted breath is a breath in which the ventilator does some of the work for a patient-initiated breath.
FIGURE 58–3 Rubric for determining the breath sequence of a mode. APRV, airway pressure release ventilation; C, compliance; CMV, continuous mandatory ventilation; CSV, continuous spontaneous ventilation; HFV, high-frequency ventilation; IMV, intermittent mandatory ventilation; $P_{\text{mus}}$, ventilatory muscle pressure; R, resistance. (Reproduced with permission from Mandu Press. Cleveland, Ohio.)

There are three possible breath sequences. Continuous spontaneous ventilation (CSV) is a sequence in which all breaths are spontaneous. Intermittently mandatory ventilation (IMV) is a sequence in which spontaneous breaths are permitted in between mandatory breaths. If a mandatory breath is
triggered by the patient, it a “synchronized” mandatory breath. In continuous mandatory ventilation (CMV), all breaths (including those by patient effort) are mandatory.

Combining the two types of control variables (pressure control [PC] and volume control [VC]) with three breath sequences gives us five breathing patterns: VC-CMV, VC-IMV, PC-CMV, PC-IMV, and PC-CSV. The sixth, VC-CSV, would mean that patient would specify time and size of breath; however, in VC mode, a patient could not specify the size of breath.

A. IMV Breath Sequences
IMV permits spontaneous ventilation while the patient is on the ventilator. A selected number of mechanical breaths (with fixed $V_T$) are given to supplement spontaneous breathing. At high mandatory rates (10–12 breaths/min), IMV essentially provides all of the patient’s ventilation; at low rates (1–2 breaths/min), it provides minimal mechanical ventilation and allows the patient to breathe relatively independently. The frequency and $V_T$ of spontaneous breaths are determined by the patient’s ventilatory drive and muscle strength. The IMV rate can be adjusted to maintain a desired minute ventilation. IMV has found greatest use as a weaning technique.

Synchronized intermittent mandatory ventilation (SIMV) times the mechanical breath, whenever possible, to coincide with the beginning of a spontaneous effort. Proper synchronization prevents superimposing (stacking) a mechanical breath in the middle of a spontaneous breath, which might otherwise result in a very large $V_T$. As with CMV and assist-control (AC) ventilation (discussed next), settings to limit inspiratory pressure guard against pulmonary barotrauma. The great advantage of SIMV over IMV is that it provides for increased patient comfort. When IMV or SIMV are used for weaning, the machine breaths provide a backup if the patient becomes fatigued. However, if the rate is set too low (4 breaths/min), the backup may be insufficient, particularly for weak patients who may not be able to overcome the added work of breathing during spontaneous breaths.

IMV circuits provide a continuous flow of gas for spontaneous ventilation between mechanical breaths. Modern ventilators incorporate SIMV into their design, but older models required modification with a parallel circuit, a continuous flow system, or a demand flow valve. Regardless of the system, proper functioning of one-way valves and sufficient gas flow are necessary to prevent an increase in the patient’s work of breathing, particularly when PEEP is also used.
Thus far the discussion of IMV has assumed this to be a volume-limited format; however, IMV can also be provided in pressure-limited format if desired (as described next).

**B. Pressure-Controlled Breath Sequences (PC-CMV, PC-IMV, and PC-CSV)**

PC breath sequences may be used in both the AC and IMV modes. In AC mode, all breaths (either machine initiated or patient initiated) are time cycled and pressure limited. In IMV, machine-initiated breaths are time cycled and pressure limited. The patient may breathe spontaneously between the set rate, and the Vₜ of the spontaneous breaths is determined by the patient. The advantage of PCV is that by limiting inspiratory pressure, the risks of barotrauma and volutrauma may be decreased. Also, by extending inspiratory time, better mixing and recruitment of collapsed or flooded alveoli may be achieved, when used with adequate levels of PEEP levels. The disadvantage of conventional PCV is that Vₜ is not guaranteed (although there are modes in which the consistent delivered pressure of PCV can be combined with a predefined volume delivery). Changes in compliance or resistance will affect the delivered Vₜ. This is a major issue in patients with acute lung injury because if the compliance decreases and the pressure limit is not increased, adequate Vₜ may not be attained. PCV has been used for patients with acute lung injury or ARDS, often with a prolonged inspiratory time or inverse inspiratory/expiratory (I:E) ratio ventilation (IRV) (see later discussion) in an effort to recruit collapsed and flooded alveoli. The disadvantage of using IRV with PCV is that patients will require deep sedation, perhaps with paralysis to tolerate this ventilatory mode.

With PCV, pressure and inspiratory time are preset, whereas flow and volume are variable and dependent on the patient’s resistance and compliance. With volume ventilation, on the other hand, inspiratory time is also preset but flow and Vₜ are also preset, and with increased resistance or reduced compliance the inspiratory pressure can be greatly increased.

PCV is similar to pressure support ventilation (PSV) in that peak airway pressure is controlled but is different in that a mandatory rate and inspiratory time are selected. As with pressure support, gas flow ceases when the pressure level is reached; however, the ventilator does not cycle to expiration until the preset inspiration time has elapsed.

**Mode Examples**
A. Continuous Mandatory Ventilation (Example of VC-CMV Breathing Pattern)

In this mode, the ventilator cycles from expiration to inspiration after a fixed time interval. The interval determines the ventilatory rate. Typical settings on this mode provide a fixed $V_T$ and fixed rate (and, therefore, minute ventilation) regardless of patient effort, because the patient cannot breathe spontaneously. Settings to limit inspiratory pressure guard against pulmonary barotrauma, and indeed CMV can be provided in a pressure-limited (rather than volume-limited) way. Controlled ventilation is best reserved for patients capable of little or no ventilatory effort. Awake patients with active ventilatory effort require sedation, possibly with muscle paralysis, to safely receive CMV.

B. Assist-Control Ventilation (Example of VC-CMV Breathing Pattern, or Can Be Set as PC-CMV)

Incorporation of a pressure sensor in the breathing circuit of AC ventilators permits the patient’s inspiratory effort to be used to trigger inspiration. A sensitivity control allows selection of the inspiratory effort required. The ventilator can be set for a fixed ventilatory rate, but each patient effort of sufficient magnitude will trigger the set $V_T$. If spontaneous inspiratory efforts are not detected, the machine functions as if in the control mode. Most often, AC ventilation is used in a volume-limited format, but it can also be provided in a pressure-limited way (as discussed later).

C. Pressure Support Ventilation (Example of PC-CSV Breathing Pattern)

PSV was designed to augment the $V_T$ of spontaneously breathing patients and overcome any increased inspiratory resistance from the tracheal tube, breathing circuit (tubing, connectors, and humidifier), and ventilator (pneumatic circuitry and valves). Microprocessor-controlled machines have this mode, which delivers sufficient gas flow with every inspiratory effort to maintain a predetermined positive pressure throughout inspiration. When inspiratory flow decreases to a predetermined level, the ventilator’s feedback (servo) loop cycles the machine into the expiratory phase, and airway pressure returns to baseline (Figure 58–4). The only setting in this mode is inspiratory pressure. The patient determines the respiratory rate and $V_T$ varies according to inspiratory gas flow, lung mechanics, and the patient’s own inspiratory effort. Low levels of PSV (5–10 cm H$_2$O) are usually sufficient to overcome any added resistance imposed by the breathing
apparatus. Higher levels (10–40 cm H₂O) can function as a standalone ventilatory mode if the patient has sufficient spontaneous ventilatory drive and stable lung mechanics. The principal advantages of PSV are its ability to augment spontaneous VT, decrease the work of breathing, and increase patient comfort. However, if the patient fatigues or lung mechanics change, VT may be inadequate, and there is no backup rate if the patient’s intrinsic respiratory rate decreases (eg, after opioid dosing). Note that one can add “pressure support” to IMV breathing breath sequences (Figure 58–5). The IMV machine mandatory breaths provide backup, and a low level of pressure support is used to offset the increased work of breathing resulting from the breathing circuit and machine during the spontaneous breaths.

FIGURE 58–4 Pressure support ventilation. The patient initiates a breath; the machine is set to deliver 15 cm H₂O pressure (above 5 cm H₂O of continuous positive airway pressure [CPAP]). When flow ceases, the machine cycles into the expiratory mode.
Interruption mechanical ventilation with pressure support. $M =$ machine breath $→$ set tidal volume ($V_T$) delivered. $S =$ spontaneous breath, 15 cm of pressure support over 5 cm of positive end-expiratory pressure. $V_T$ depends on patient effort and lung mechanics. $V$, flow; $P_{aw}$, partial airway pressure.

**D. Inverse I:E Ratio Ventilation Modes, Including Airway Pressure Release Ventilation (Usually Examples of PC-IMV Breathing Pattern)**

IRV reverses the normal I:E time ratio of 1:3 or greater to a ratio of greater than 1:1 (eg, 1.5:1). This may be achieved by adding an end-inspiratory pause, by decreasing peak inspiratory flow during volume-controlled ventilation (CMV), or by setting an inspiratory time such that inspiration is longer than expiration during PCV (PC-IRV). Intrinsic PEEP may be produced during IRV and is caused by air trapping or incomplete emptying of the lung to the baseline pressure prior to the initiation of the next breath. This air trapping increases FRC until a new equilibrium is reached. This mode does not allow spontaneous breathing and requires heavy sedation or neuromuscular blockade. IRV with PEEP is effective for improving oxygenation in patients with decreased FRC.

**E. Airway Pressure Release Ventilation**

Airway pressure release ventilation (APRV), or bilevel ventilation, is a mode in which a relatively high PEEP is used, despite the patient being allowed to breathe spontaneously. Intermittently, the PEEP level decreases to help augment the elimination of $CO_2$ (Figure 58–6). The inspiratory and expiratory times, high
and low PEEP levels, and spontaneous respiratory activity determine minute ventilation. Initial settings include a minimum PEEP of 10 to 12 cm H₂O and a release level of 5 to 10 cm H₂O. Commonly, 10 to 12 releases are chosen as a starting point, along with a time at low PEEP to allow only 50% to 70% of expiratory flow (to provide “autoPEEP”). Advantages of APRV appear to be less circulatory depression and pulmonary barotrauma as well as less need for sedation. This technique appears to be an attractive alternative to PC-IRV for overcoming problems with high peak inspiratory pressures in patients with reduced lung compliance.

**FIGURE 58–6** Airway pressure release ventilation.

**Basic Mechanics of Ventilators**

Most modern ventilators behave like flow generators. Constant flow generators deliver a constant inspiratory gas flow regardless of airway circuit pressure. Constant flow is produced by the use of either a solenoid (on–off) valve with a high-pressure gas source (5–50 psi) or via a gas injector (Venturi) with a lower-pressure source. Machines with high-pressure gas sources allow inspiratory gas flow to remain constant despite large changes in airway resistance or pulmonary compliance. Ventilator performance varies with airway pressure for gas injectors. Nonconstant flow generators consistently vary inspiratory flow with each inspiratory cycle (such as by a rotary piston); a sine wave pattern of flow is typical.

Constant-pressure generators maintain airway pressure constant throughout inspiration and irrespective of inspiratory gas flow. Gas flow ceases when airway pressure equals the set inspiratory pressure. Pressure generators typically operate at low gas pressures (just above peak inspiratory pressure).

**Cycling (Changeover from Inspiration to Expiration)**

Time-cycled ventilators cycle to the expiratory phase once a predetermined interval elapses from the start of inspiration. \( V_T \) is the product of the set
inspiratory time and inspiratory flow rate. Time-cycled ventilators are commonly used for neonates and in the operating room.

Volume-cycled ventilators terminate inspiration when a preselected volume is delivered. Many adult ventilators are volume cycled but also have secondary limits on inspiratory pressure to guard against pulmonary barotrauma. If inspiratory pressure exceeds the pressure limit, the machine cycles into expiration even if the selected volume has not been delivered.

Pressure-cycled ventilators cycle into the expiratory phase when airway pressure reaches a predetermined level. VT and inspiratory time vary, being related to airway resistance and pulmonary and circuit compliance. A significant leak in the patient circuit can prevent the necessary rise in circuit pressure and machine cycling. Conversely, an acute increase in airway resistance, or decrease in pulmonary compliance, or circuit compliance (kink) causes premature cycling and decreases the delivered VT. Pressure-cycled ventilators have been most often used for short-term indications (transport).

Flow-cycled ventilators have pressure and flow sensors that allow the ventilator to monitor inspiratory flow at a preselected fixed inspiratory pressure; when this flow reaches a predetermined level (usually 25% of the initial peak mechanical inspiratory flow rate), the ventilator cycles from inspiration into expiration (see the earlier sections on pressure support and pressure-controlled ventilation).

Microprocessor-Controlled Ventilators

These versatile machines can be set to function in any one of a variety of inspiratory flow and cycling patterns. Microprocessor-controlled ventilators are the norm in modern critical care units and on newer anesthesia machines.

High-Frequency Ventilation

High-frequency ventilation is sufficiently different from conventional modes of mechanical ventilation that its mechanics require separate mention. Three forms of high-frequency ventilation (HFV) are available. High-frequency positive-pressure ventilation involves delivering a small “conventional” VT at a rate of 60 to 120 breaths/min. High-frequency jet ventilation (HFJV) utilizes a small cannula at or in the airway through which a pulsed jet of high-pressure gas is delivered at a set frequency of 120 to 600 times/min (2–10 Hz). The jet of gas may entrain air (Bernoulli effect), which may augment VT. High-frequency oscillation employs a driver (usually a piston) that creates to-and-fro gas
movement in the airway at rates of 180 to 3000 times/min (3–50 Hz).

These forms of ventilation all produce $V_T$ at or below anatomic dead space. The exact mechanism of gas exchange is unclear but is probably a combination of effects. Jet ventilation has found widest use in the operating room. It may be used for laryngeal, tracheal, and bronchial procedures and can be lifesaving in emergency airway management when tracheal intubation and conventional positive-pressure ventilation are unsuccessful (see Chapter 19). In the intensive care unit (ICU), HFJV may be useful in managing some patients with bronchopleural and tracheoesophageal fistulas when conventional ventilation has failed. Occasionally, HFJV or high-frequency oscillation is used in patients with ARDS to try to improve oxygenation. Inadequate heating and humidification of inspired gases during prolonged HFV, however, can be a problem. Initial settings for HFJV are typically a rate of 120 to 240 breaths/min, an inspiratory time of 33%, and a drive pressure of 15 to 30 psi. Mean airway pressure should be measured in the trachea at least 5 cm below the injector to avoid an artifactual error from gas entrainment. Carbon dioxide elimination is generally increased by increasing the drive pressure, whereas adequacy of oxygenation relates to the mean airway pressure. An intrinsic PEEP effect is seen during HFJV at high drive pressures and inspiratory times greater than 40%.

**Differential Lung Ventilation**

This technique, also referred to as independent lung ventilation, may be used in patients with severe unilateral lung disease or those with bronchopleural fistulae. Use of conventional positive-pressure ventilation and PEEP in such instances can aggravate ventilation/perfusion mismatching or, in patients with fistula, result in inadequate ventilation of the unaffected lung. In patients with restrictive disease of one lung, overdistention of the normal lung can lead to worsening hypoxemia or barotrauma. After separation of the lungs with a double-lumen tube, positive-pressure ventilation can be applied to each lung independently using two ventilators. When two ventilators are used, the timing of mechanical breaths is often synchronized, with one ventilator, the “master,” setting the rate for the “slave” ventilator.

**2. Care of Patients Requiring Mechanical Ventilation**

**Tracheal Intubation**

Tracheal intubation is most commonly undertaken in ICU patients to manage
pulmonary failure with mechanical ventilation. Both nasotracheal and orotracheal intubation appear to be relatively safe for at least 2 to 3 weeks. When compared with orotracheal intubation, nasotracheal intubation may be more comfortable for the patient and more secure (fewer instances of accidental extubation). Nasal intubation, however, has its own set of associated adverse events, including nasal bleeding, transient bacteremia, submucosal dissection of the nasopharynx or oropharynx, and sinusitis or otitis media (from obstruction of sinus outflow or of the auditory tubes). Nasal intubations will also generally incorporate a smaller diameter tube than orotracheal intubations, and this can make it more difficult to clear secretions and can force the clinician to use smaller fiberoptic bronchoscopes.

Intubation often can be carried out without the use of sedation or muscle paralysis in agonal or unconscious patients. However, topical anesthesia of the airway and sedation are helpful in patients who still have active airway reflexes. More vigorous and uncooperative patients require varying degrees of sedation. Small doses of relatively short-acting agents are generally used; popular agents include midazolam, etomidate, dexmedetomidine, and propofol. If necessary, a neuromuscular blocker can be used for paralysis after a hypnotic is given.

The time of tracheal intubation and initiation of mechanical ventilation can be a period of great hemodynamic instability. Hypertension or hypotension and bradycardia or tachycardia may be encountered. Responsible factors include activation of autonomic reflexes from stimulation of the airway, myocardial depression and vasodilation from sedative-hypnotic agents, straining by the patient, withdrawal of intense sympathetic activity, and reduced venous return due to positive pressure in the airways. Careful monitoring is required during and immediately following intubation of patients with critical illness.

When left in place for more than 2 to 3 weeks, both orotracheal and nasotracheal tubes predispose patients to subglottic stenosis. If longer periods of mechanical ventilation are necessary, the tracheal tube should be replaced by a cuffed tracheostomy tube. If it is clear that a tracheal tube will be required for more than 2 weeks, a tracheostomy may be performed soon after intubation. While earlier tracheostomy does not reduce mortality, it may reduce the incidence of pneumonia, the duration of mechanical ventilation, and the length of stay.

**Initial Ventilator Settings**

Depending on the type of pulmonary failure, mechanical ventilation is used to
provide either partial or full ventilatory support. For full ventilatory support, CMV, AC, or PCV is generally employed with a respiratory rate of 10 to 14 breaths/min, a VT of 6 mL/kg, and PEEP of 5 to 10 cm H₂O. These settings reduce the likelihood of high peak inflation pressures (greater than 35 to 40 cm H₂O), barotrauma, and volutrauma. High airway pressures that overdistend alveoli (transalveolar pressure >35 cm H₂O) promote experimental lung injury. Likewise, compared with a VT of 12 mL/kg, a VT of 6 mL/kg and plateau pressure (Pplat) less than 30 cm H₂O have been associated with reduced mortality in patients with ARDS. Partial ventilatory support is usually provided by lower SIMV settings (<8 breaths/min), either with or without pressure support. Lower Pplat (<20–30 cm H₂O) is recommended to better preserve cardiac output, and lessen adverse effects on ventilation/perfusion relationships.

Patients breathing spontaneously on SIMV must overcome the additional resistances of the tracheal tube, demand valves, and breathing circuit of the ventilator. These imposed resistances increase the work of breathing. Smaller tubes (<7.0 mm internal diameter in adults) increase resistance and should be avoided if possible. The simultaneous use of pressure support of 5 to 15 cm H₂O during SIMV can compensate for tube and circuit resistance.

The addition of 5 to 8 cm H₂O of PEEP during positive-pressure ventilation preserves FRC and gas exchange. This “physiological” PEEP is purported to compensate for the loss of a similar amount of intrinsic PEEP (and decrease in FRC) in patients following tracheal intubation. Periodic sigh breaths (large VT) are not necessary when a PEEP of 5 to 8 cm H₂O accompanies VT of appropriate volumes.

**Sedation & Paralysis**

Sedation and paralysis may be necessary in patients who become agitated and “fight” the ventilator. Repetitive coughing (“bucking”) and straining can have adverse hemodynamic effects, can interfere with gas exchange, and may predispose to pulmonary barotrauma and self-inflicted injury. Sedation with or without paralysis may also be desirable when patients continue to be tachypneic despite high mechanical respiratory rates (>16–18 breaths/min).

Commonly used sedatives include opioids (morphine or fentanyl), benzodiazepines (usually midazolam), propofol, and dexmedetomidine. These agents may be used alone or in combination and are often administered by continuous infusion. Propofol is uncommonly used for prolonged sedation due to
concerns about propofol infusion syndrome (see Chapter 9). Nondepolarizing paralytic agents are used in combination with sedation when ventilation cannot otherwise be accomplished.

Monitoring

Critically ill patients receiving mechanical ventilation should be cared for a head-up position to reduce the risk of ventilator-associated pneumonia. Such patients require continuous monitoring for adverse hemodynamic and pulmonary effects arising from positive pressure in the airways. Continuous electrocardiography, pulse oximetry, and capnometry are useful. Direct intraarterial pressure monitoring is often employed for sampling of arterial blood for respiratory gas analysis. Accurate recording of fluid intake and output is necessary to assess fluid balance. An indwelling urinary catheter will lead to an increased risk of urinary tract infections and should be avoided when possible, but it is helpful for monitoring urinary output. Chest radiographs are commonly obtained to confirm tracheal tube and central venous catheter positions, evaluate for evidence of pulmonary barotrauma or pulmonary disease, and determine whether there are signs of pulmonary edema.

Airway pressures (baseline, peak, plateau, and mean), inhaled and exhaled $V_T$ (mechanical and spontaneous), and fractional concentration of oxygen should be closely monitored. Monitoring these parameters not only allows optimal adjustment of ventilator settings but helps detect problems with the tracheal tube, breathing circuit, and ventilator. For example, an increasing $P_{plt}$ for a set $V_T$ can indicate worsening compliance. A declining blood pressure and increasing $P_{plt}$ from dynamic hyperinflation (autoPEEP) can be quickly diagnosed (and treated) by disconnecting the patient from the ventilator. Inadequate suctioning of airway secretions and the presence of large mucus plugs are often manifested as increasing peak inflation pressures (a sign of increased resistance to gas flow) and decreasing exhaled $V_T$. An abrupt increase in peak inflation pressure together with sudden hypotension strongly suggests a pneumothorax.

3. Discontinuing Mechanical Ventilation

There are two phases to discontinuing mechanical ventilation. In the first, “readiness testing,” so-called weaning parameters and other subjective and objective assessments are used to determine whether the patient can sustain progressive withdrawal of mechanical ventilator support. The second phase,
“weaning” or “liberation,” describes the way in which mechanical support is removed.

Readiness testing should include determining whether the process that necessitated mechanical ventilation has been reversed or controlled. Complicating factors such as bronchospasm, heart failure, infection, malnutrition, increased CO$_2$ production due to increased carbohydrate loads, acid–base derangements, anemia, altered mental status, and sleep deprivation should be adequately treated. Chronic lung disease, respiratory muscle wasting from prolonged disuse, and heart failure may lead to complicated (or failed) weaning.

Weaning from mechanical ventilation should be considered when patients no longer meet criteria for mechanical ventilation (see Table 58–4). In general, this occurs when patients have a pH greater than 7.25, show adequate arterial oxygen saturation while receiving FiO$_2$ less than 0.5, are able to spontaneously breathe, are hemodynamically stable, and have no current signs of myocardial ischemia. Additional mechanical indices have also been suggested (Table 58–5). Useful weaning parameters include arterial blood gas tensions, respiratory rate, and rapid shallow breathing index (RSBI). Intact airway reflexes are mandatory and a cooperative patient is helpful for successful weaning and extubation, unless the patient will retain a cuffed tracheostomy tube. Similarly, adequate oxygenation (arterial oxygen saturation >90% on 40–50% O$_2$ with <5 cm H$_2$O of PEEP) is mandatory prior to extubation. When the patient is weaned from mechanical ventilation and extubation is planned, the RSBI is frequently used to help predict who can be successfully weaned from mechanical ventilation and extubated. With the patient breathing spontaneously on a T-piece, the $V_T$ (in liters) and respiratory rate ($f$) are measured:

$$RSBI = \frac{f(\text{breaths/min})}{V_T(\text{L})}$$

**TABLE 58–5** Mechanical criteria for weaning/extubation.
Most patients with an RSBI less than 105 can be successfully extubated. Those with an RSBI greater than 120 should retain some degree of mechanical ventilator support.

The common techniques to wean a patient from the ventilator include SIMV, pressure support, or periods of spontaneous breathing alone on a T-piece or on low levels of CPAP. Many institutions use “automated tube compensation” to provide just enough pressure support to compensate for the resistance of breathing through an endotracheal tube. Newer mechanical ventilators have a setting that will automatically adjust gas flows to make this adjustment. In practice in adults breathing through conventionally sized tubes (7.5–8.5), the adjustment will typically amount to pressure support of 5 cm H₂O and PEEP of 5 cm H₂O.

### Weaning with SIMV

With SIMV the number of mechanical breaths is progressively decreased (by 1–2 breaths/min) as long as the arterial CO₂ tension and respiratory rate remain acceptable (generally <45–50 mm Hg and <30 breaths/min, respectively). If pressure support is concomitantly used, it should generally be reduced to 5 to 8 cm H₂O. In patients with acid–base disturbances or chronic CO₂ retention, arterial blood pH (>7.35) is more useful than CO₂ tension. Blood gas measurements can be checked after a minimum of 15 to 30 min at each setting. When an IMV of 2 to 4 breaths is reached, mechanical ventilation is discontinued if arterial oxygenation remains acceptable.

### Weaning with PSV

<table>
<thead>
<tr>

<tr>
<td>Rapid shallow breathing index</td>
<td>&lt;100</td>
</tr>
</tbody>
</table>

---
Weaning with PSV alone is accomplished by gradually decreasing the pressure support level by 2 to 3 cm H₂O while \( V_t \), arterial blood gas tensions, and respiratory rate are monitored (using the same criteria as for IMV). The goal is to try to ensure a \( V_t \) of 4 to 6 mL/kg and an \( f \) of less than 30 with acceptable \( Pao_2 \) and \( Paco_2 \). When a pressure support level of 5 to 8 cm H₂O is reached, the patient is considered weaned.

**Weaning with a T-Piece or CPAP**

T-piece trials allow observation while the patient breathes spontaneously without any mechanical breaths. The T-piece attaches directly to the tracheal tube or tracheostomy tube and has corrugated tubing on the other two limbs. A humidified oxygen–air mixture flows into the proximal limb and exits from the distal limb. Sufficient gas flow must be given in the proximal limb to prevent the mist from being completely drawn back at the distal limb during inspiration; this ensures that the patient is receiving the desired oxygen concentration. The patient is observed closely during this period; obvious new signs of fatigue, chest retraction, tachypnea, tachycardia, arrhythmias, or hypertension or hypotension should terminate the trial. If the patient appears to tolerate the trial period and the RSBI is less than 100, mechanical ventilation can be discontinued permanently. If the patient can also protect and clear the airway, the tracheal tube can be removed.

If the patient has been intubated for a prolonged period or has severe underlying lung disease, sequential T-piece trials may be necessary. Periodic trials of 10 to 30 min are initiated and progressively increased, typically by 5 to 10 min per trial as long as the patient appears comfortable, maintains acceptable arterial saturation, and does not become hypercarbic.

Many patients develop progressive atelectasis during prolonged T-piece trials. This may reflect the absence of a normal “physiological” PEEP when the larynx is bypassed by a tracheal tube. If this is a concern, spontaneous breathing trials on low levels (5 cm H₂O) of CPAP can be tried. The CPAP helps maintain FRC and prevent atelectasis.

**POSITIVE AIRWAY PRESSURE THERAPY**

Positive airway pressure therapy can be used in patients who are breathing spontaneously as well as those who are mechanically ventilated. The principal indication for positive airway pressure therapy is a decrease in FRC resulting in
absolute or relative hypoxemia. By increasing transpulmonary distending pressure, positive airway pressure therapy can increase FRC, improve (increase) lung compliance, and reverse ventilation/perfusion mismatching. Improvement in the latter parameter will show as a decrease in venous admixture and an improvement in arterial $O_2$ tension.

**Positive End-Expiratory Pressure**

Application of positive pressure during expiration as an adjunct to a mechanically delivered breath is referred to as PEEP. The ventilator’s PEEP valve provides a pressure threshold that allows expiratory flow to occur only when airway pressure exceeds the selected PEEP level.

**Continuous Positive Airway Pressure**

Application of a positive-pressure threshold during both inspiration and expiration with spontaneous breathing is referred to as CPAP. Constant levels of pressure can be attained only if a high-flow (inspiratory) gas source is provided. When the patient does not have an artificial airway, tightly fitting full-face masks, nasal masks, or nasal “pillows” can be used. Because of the risks of gastric distention and regurgitation, CPAP masks should be used only on patients with intact airway reflexes and with CPAP levels less than 15 cm H$_2$O (less than lower esophageal sphincter pressure in normal persons). Expiratory pressures greater than 15 cm H$_2$O should only be administered by tracheal or tracheostomy tube.

**CPAP versus PEEP**

The distinction between PEEP and CPAP is often blurred in the clinical setting because patients may breathe with a combination of mechanical and spontaneous breaths. Therefore, the two terms are often used interchangeably. In the strictest sense, “pure” PEEP is provided as a ventilator-cycled breath. In contrast, a “pure” CPAP system provides only sufficient continuous or “on-demand” gas flows (60–90 L/min) to prevent inspiratory airway pressure from falling perceptibly below the expiratory level during spontaneous breaths (Figure 58–7). Some ventilators with demand valve–based CPAP systems may not be adequately responsive and result in increased inspiratory work of breathing. This situation can be corrected by adding low levels of (inspiratory) PSV if in a
volume-targeted mode or changing to a pressure-targeted mode. In clinical practice, controlled ventilation, PSV, and CPAP/PEEP support can be delivered by most modern ICU ventilators. Manufacturers have also developed specific devices to deliver bilevel inspiratory positive airway pressure (IPAP) with expiratory positive airway pressure (EPAP) in either a spontaneous or time-cycled fashion. The term *bilevel positive airway pressure* (BiPAP) has become a commonly used phrase, adding to the confusion of airway pressure terminology.

![Diagram of airway pressure during positive end-expiratory pressure (PEEP) and continuous positive airway pressure (CPAP).](image)

**FIGURE 58–7** Airway pressure during positive end-expiratory pressure (PEEP) and continuous positive airway pressure (CPAP). Note that by increasing inspiratory gas flows, PEEP progressively becomes CPAP.

### Pulmonary Effects of PEEP & CPAP

The major effect of PEEP and CPAP on the lungs is to increase FRC. In patients with decreased lung volume, appropriate levels of either PEEP or CPAP will increase FRC and tidal ventilation above closing capacity, will improve lung compliance, and will correct ventilation/perfusion abnormalities. The resulting decrease in intrapulmonary shunting improves arterial oxygenation. The principal mechanism of action for both PEEP and CPAP appears to be expansion of partially collapsed alveoli. Recruitment (reexpansion) of collapsed alveoli occurs at PEEP or CPAP levels above the inflection point, defined as the pressure level on a pressure–volume curve at which collapsed alveoli are
recruited (open); with small changes in pressure there are large changes in volume (Figure 58–8). Although neither PEEP nor CPAP decreases total extravascular lung water, studies suggest that they do redistribute extravascular lung water from the interstitial space between alveoli and endothelial cells toward peribronchial and perihilar areas. Both effects can potentially improve arterial oxygenation.

**FIGURE 58–8** Pressure–volume curve for pulmonary system (eg, lung, thoracic). Inflection point (IP) above which the majority of alveoli are recruited. E, result of excessive pressure when alveoli are overdistended and pulmonary compliance decreases.

Excessive PEEP or CPAP, however, can overdistend alveoli (and bronchi), increasing dead space ventilation and reducing lung compliance; both effects can significantly increase the work of breathing. By compressing alveolar capillaries, overdistention of normal alveoli can also increase pulmonary vascular resistance and right ventricular afterload.

A higher incidence of pulmonary barotrauma is observed with PEEP or CPAP at levels greater than 20 cm H$_2$O. Disruption of alveoli allows air to track interstitially along bronchi into the mediastinum (pneumomediastinum). From the mediastinum, air can then rupture into the pleural space (pneumothorax) or the pericardium (pneumopericardium) or can dissect along tissue planes.
subcutaneously (subcutaneous emphysema) or into the abdomen (pneumoperitoneum or pneumoretroperitoneum). A bronchopleural fistula results when an air leak fails to seal (close). Although barotrauma must be considered in any discussion of CPAP and PEEP, in fact, it may be more clearly associated with higher peak inspiratory pressures that result with increasing level of PEEP or CPAP. Other factors that may increase the risk of barotrauma include underlying lung disease (asthma, interstitial lung disease, COPD), dynamic hyperinflation (too frequent breaths or too short expiratory times leading to intrinsic [or auto] PEEP), and excessive \( V\tau >10–15 \text{ mL/kg} \).

**Adverse Nonpulmonary Effects of PEEP & CPAP**

Nonpulmonary adverse effects are primarily circulatory and the result of transmission of the elevated airway pressure to the contents of the chest. Transmission is directly related to lung compliance; thus, patients with decreased lung compliance (most patients requiring PEEP) are least affected.

Progressive reductions in cardiac output may be seen as mean airway pressure and mean intrathoracic pressure rise. The principal mechanism appears to be inhibition of return of venous blood to the heart from increased intrathoracic pressure. Other mechanisms may include reduced left ventricular filling from leftward displacement of the interventricular septum (when overdistention of alveoli and increased pulmonary vascular resistance lead to increased right ventricular volume). When this occurs, left ventricular compliance may be reduced, necessitating a higher filling pressure to achieve the same cardiac output. An increase in intravascular volume will usually at least partially offset the effects of CPAP and PEEP on cardiac output. Circulatory depression is most often associated with end-expiratory pressures greater than 15 cm H\(_2\)O.

PEEP-induced elevations in intrathoracic pressure and reductions in cardiac output decrease both renal and hepatic blood flow. Urinary output, glomerular filtration, and free water clearance decrease.

Increased end-expiratory pressures impede blood return from the brain to the heart and may increase intracranial pressure in patients whose intracranial compliance is decreased. Therefore, with evidence of increased intracranial pressure, the level of PEEP must be carefully chosen to balance oxygenation requirements against potential adverse effects on intracranial pressure.

**Optimum Use of PEEP & CPAP**
The goal of positive-pressure therapy is to increase oxygen delivery to tissues, while avoiding the adverse sequelae of excessively increased (>0.5) Fio₂. The need for excessive Fio₂ is most easily avoided with an adequate cardiac output and hemoglobin concentration. Ideally, mixed venous oxygen tensions should be followed. As we have repeatedly emphasized, the salutary effect of PEEP (or CPAP) on arterial oxygen tension must be balanced against any detrimental effect on cardiac output. Volume infusion or inotropic support may be necessary.

At optimal PEEP the benefits of PEEP exceed any risks. Practically, PEEP is usually added in increments of 2 to 5 cm H₂O until the desired therapeutic endpoint is reached. The most commonly suggested endpoint is an arterial oxygen saturation of hemoglobin of greater than 88% to 90% on a nontoxic inspired oxygen concentration (≤50%). Many clinicians favor reducing the inspired oxygen concentration to 50% or less because of the potentially adverse effect of greater oxygen concentrations on the lung. Alternatively, PEEP may be titrated to the mixed venous artery oxygen saturation (SVO₂ >50–60%).

OTHER RESPIRATORY CARE TECHNIQUES

Other respiratory care techniques, including administration of aerosolized water or bronchodilators and clearing of pulmonary secretions, preserve or improve pulmonary function.

An aerosol mist is a gas or gas mixture containing a suspension of liquid particles. Aerosolized water may be administered to loosen inspissated secretions and facilitate their removal from the tracheobronchial tree. Aerosol mists are also used to administer bronchodilators, mucolytic agents, or vasoconstrictors (metered-dose inhalers are preferred for administration of bronchodilators). A normal cough requires an adequate inspiratory capacity, an intact glottis, and adequate muscle strength (abdominal muscles and diaphragm). Aerosol mists with or without bronchodilators may induce cough as well as loosen secretions. Instillation of hypertonic saline has been used as a mucolytic and to induce cough. Additional effective measures include chest percussion or vibration therapy and postural drainage of the various lung lobes. Maneuvers that produce sustained maximum lung inflation, such as the use of an incentive spirometer, can be helpful in inducing cough as well as preventing atelectasis and preserving normal lung volume. Patients should be instructed to inhale maximally and to hold their breath for 2 to 3 s before exhalation.

When thick, copious secretions are associated with atelectasis and hypoxemia, more aggressive measures may be indicated. These include
suctioning the patient with a catheter or fiberoptic bronchoscope. When there is atelectasis without retention of secretions, a brief period of CPAP by mask or positive-pressure ventilation through a tracheal tube is often effective.

**SUGGESTED READINGS**

In the 1980s, anesthesiology was recognized as the first medical specialty to adopt mandatory safety-related clinical practice guidelines. Adoption of these guidelines, describing standards for basic monitoring during general anesthesia, was associated with a reduction in the number of patients suffering brain damage or death secondary to ventilation mishaps during general anesthesia.

In 1999 the Institute of Medicine of the (U.S.) National Academy of Sciences summarized available safety information in its report, To Err Is Human: Building a Safer Healthcare System, which highlighted many opportunities for improved quality and safety.

It has long been recognized that quality and safety are closely related to consistency and reduction in practice variation.

In manufacturing and in medicine, there is a natural tendency to assume that errors can be prevented by better education or better management of individual workers (ie, to look at errors as individual failures made by individual workers rather than as failures of a system or a process). To reduce errors, one changes the system or process to reduce unwanted variation so that random errors are less likely.

PATIENT SAFETY ISSUES
As a profession, anesthesiology has spearheaded efforts to improve patient safety. Some of the first studies to evaluate safety of care focused on provision and sequelae of anesthesia. When spinal anesthesia was virtually abandoned in
the United Kingdom (as a response to two patients developing subsequent paraplegia), Drs Robert Dripps and Leroy Vandam helped prevent spinal anesthesia from being abandoned in North America by carefully reporting outcomes of 10,098 patients who received this technique. They determined that only one patient (who proved to have a previously undiagnosed spinal meningioma) developed severe, long-term neurological sequelae.

After halothane was introduced into clinical practice in 1954, concerns arose about whether it might be associated with an increased risk of hepatic injury. The National Halothane Study, a very early clinical outcomes study, was performed (long before the term outcomes research gained widespread use), demonstrating the remarkable safety of the then relatively new agent compared with the alternatives. It failed, however, to settle the question of whether “halothane hepatitis” actually existed.

In the 1980s, anesthesiology was recognized as the first medical specialty to adopt mandatory safety-related clinical practice guidelines. Adoption of these guidelines was not without controversy, given that for the first time the American Society of Anesthesiologists (ASA) was “dictating” how physicians should practice. Adoption of standards for basic monitoring during general anesthesia (that included detection of carbon dioxide in exhaled gas) was associated with a reduction in the number of patients suffering brain damage or death secondary to ventilation mishaps. A fortunate associated result was that the cost of medical liability insurance coverage for American anesthesiologists also declined.

In 1984, Dr Ellison Pierce, president of the ASA, created its Patient Safety and Risk Management Committee. The Anesthesia Patient Safety Foundation (APSF), which celebrated its 30th anniversary in 2016, was also Dr Pierce’s creation. The APSF continues to spearhead efforts to make anesthesia and perioperative care safer for patients and practitioners. Similarly, through its guidelines, statements, advisories, and practice parameters, the ASA continues to promote safety and provide guidance to clinicians. As Dr Pierce noted, “Patient safety is not a fad. It is not a preoccupation of the past. It is not an objective that has been fulfilled or a reflection of a problem that has been solved. Patient safety is an ongoing necessity. It must be sustained by research, training, and daily application in the workplace.”

Meanwhile, other specialties of medicine began to place greater emphasis on quality and safety. In 1999 the Institute of Medicine (IOM) of the (U.S.) National Academy of Sciences summarized available safety information in a report entitled To Err Is Human: Building a Safer Healthcare System. That
document highlighted many opportunities for improved quality and safety in the U.S. health care system. A subsequent IOM report, *Crossing the Quality Chasm: A New Health System for the 21st Century*, explored the way that variation in medical practice reduced quality and safety of health care system. More recently, the Institute for Healthcare Improvement has been “motivating and building the will for change; identifying and testing new models of care in partnership with both patients and health care professionals; and ensuring the broadest possible adoption of best practices and effective innovations,” as described on its web site. Meanwhile, the ASA has continued its involvement in quality improvement by funding and sponsoring the Anesthesia Quality Institute, which allows individual departments and even individual physicians to compare their performance on a long list of outcomes and other metrics to those in a national database of tens of millions of anesthetics.

**QUALITY OF CARE & PERFORMANCE IMPROVEMENT ISSUES**

It has long been recognized that quality and safety are closely related to consistency and reduction in process variation. The quality and safety movement(s) in medicine have their origins in the work of Walter Shewhart and his associate W. Edwards Deming, who popularized the use of statistics and control charts in improving the reliability of a process. In manufacturing (where these ideas were initially applied), reducing an error rate reduces the frequency of defective products, reduces the need for product inspections, and increases the customer’s satisfaction with the product and the manufacturer. In medicine, reducing the error rate (for everything from accurate timing and delivery of prophylactic antibiotics to ensuring “correct side and site” surgery or regional anesthetic blocks) reduces preventable injuries to patients, eliminates the additional costs resulting from those errors, and improves quality.

**Strategies to Reduce Performance Errors**

In manufacturing and in medicine, there is a natural tendency to assume that errors can be prevented by better education, better performance, or better management of *individual workers*. In other words, there is a tendency to look at errors as individual failures made by individual workers, rather than as failures of a system or a process. This is exemplified by the so-called “root cause analysis.” But there often are multiple factors, not a single “root cause,” that lead
to a system failure. As was first stated by Arthur Jones and then popularized by Paul Batalden, “All organizations are perfectly designed to get the results they get!” “Accidents” are included among the results about which he speaks! Therefore, in taking an organizational or systems point of view (as advocated by Deming) to reduce errors, one changes the system or process so that random errors will be less likely. An outstanding example of this is adoption of the “universal protocol” prior to invasive procedures. Adherence to this protocol ensures that the correct procedure is performed on the correct part of the correct patient by the correct physician, that the patient has given informed consent, that all needed equipment and images are available, and that (if needed) the correct prophylactic antibiotic was given at the correct time.

A related example of a simple approach to improve safety and quality of a procedure is the use of a cognitive aid, such as a standardized checklist, as described in the popular press by Dr Atul Gawande. The importance of checklists is addressed elsewhere in this text, for example, in Chapter 2 in the context of developing a culture of safety in the operating room. Such checklists provide the “script” for the preprocedure universal protocol (Figure 59–1). Studies have shown that the incidence of catheter-related bloodstream infections can be reduced when central venous catheters are inserted after adequate cleansing and disinfection of the operator’s hands by an operator wearing a surgical hat and mask, sterile gown, and gloves; using chlorhexidine (rather than povidone iodide) skin preparation of the insertion site; and with sterile drapes of adequate size to maintain a sterile field. Individual elements in this central line “bundle” are much less likely to be omitted when a checklist is required prior to every central line insertion; a sample checklist is shown in Figure 59–2.
FIGURE 59–1 The “time out” checklist used at the Virginia Commonwealth University Health System before all regional anesthesia procedures. There is space for two separate time outs. An additional time out is performed whenever a patient’s position is changed for a second regional block (most commonly for lower extremity surgery). For convenience, the regional anesthesia time out checklist is printed on the reverse of the Consent for Anesthesia acknowledgment form. (Reproduced with permission from Virginia Commonwealth University Health System.)
**FIGURE 59–2** Mandatory checklist for insertion of central venous catheters in patients who are not currently undergoing anesthesia and surgery at the Virginia Commonwealth University Health System. A similar electronic document is contained within the Anesthesia Information Management electronic record for central venous lines. (Reproduced with permission from Virginia Commonwealth University Health System.)

**Benefits of Standardized Checklists**
Checklists emphasize two important principles about improving quality and safety in the surgical environment. First, proper use of a checklist requires that a physician communicate with other members of the team. Good communication among team members improves quality, prevents errors, and increases satisfaction with the work environment. It is easy to find examples of good communication strategies. By clearly and forcefully announcing that protamine infusion has been started (after extracorporeal perfusion has been discontinued during a cardiac operation), the anesthesiologist helps prevent the surgeon and perfusionist from making a critical error, such as resuming extracorporeal perfusion when the patient is no longer anticoagulated. By accurately describing the intended surgical procedure (at the time the patient is “posted” on the surgical schedule), the surgeon helps prevent the operating room nurses from making the critical error of not having the necessary instrumentation for the procedure, and helps ensure that the appropriate regional anesthetic will be performed. We have selected these examples of good communication because we are aware of adverse patient outcomes that have resulted from failure to transfer these specific points of information.

Second, team participation in a checklist reminds every member of the surgical team that everyone has a stake in patient safety and good surgical outcomes. The team member who records the checklist “results” is usually not a physician but has the implicit authority to enforce adherence to the checklist. On poorly functioning teams in which there is excessive deference to authority figures, team members may feel that their opinions are not wanted or valued, or may be afraid to bring up safety concerns for fear of retaliation. On well-functioning teams, there is a “flattening” of the hierarchy such that every team member has the authority and every team member feels an obligation to halt the proceedings to prevent potential patient harm. The Toyota Corporation is famous for allowing any team member to shut down the automotive production line when a problem is suspected.

Quality Improvement & Quality Assurance Measures

In surgery, there are well-recognized indicators of good quality, such as a very low incidence of surgical site infections or of perioperative mortality. However, at present there is no consensus as to the important measurements that can be used to assess quality of anesthesia care. Nevertheless, surrogate anesthesia indicators have been monitored by a variety of well-meaning agencies. Examples include selection and timing of preoperative antibiotics and temperature of patients in the postanesthesia care unit after colorectal surgery.
The Physician Quality Reporting System (PQRS) is a quality reporting program that encourages individual eligible professionals and practice groups to submit information on their quality of care to the U.S. Medicare program. PQRS was initiated by the Centers for Medicare and Medicaid Services in 2006 as a way to increase quality in healthcare. This program began as a “pay for performance” program that paid bonuses to those who reported quality measures. Since 2015, PQRS no longer pays out bonuses for quality reporting, but issues a 0.5% penalty for those who do not report these measures. Since 2013, anesthesiologists, pain physicians, and certified registered nurse anesthetists must all report Medicare PQRS quality measures.

Mindful of the importance of having accurate and relevant outcome measures, the ASA charged the Anesthesia Quality Institute (in 2009) with developing and collecting valid quality indicators for anesthetic care that can be used for quality improvement programs. Aggregation of the large amounts of data required for statistical validity is dependent on widespread adoption of electronic medical records (EMRs) and anesthesia information management systems (AIMS) (discussed in Chapter 18). It is our hope that as their use becomes more widespread, the data and indicators that are collected and aggregated will provide greater insight into how quality of anesthesia care may influence clinical outcomes that are important to patients.

In any individual department or medical center there should be myriad opportunities to improve the quality of care; members of the anesthesiology department need to be involved with many of them. The Accreditation Council for Graduate Medical Education now specifies that house officers participate in quality improvement exercises. This is a very welcome development, but only a limited number of anesthesiologists are familiar with the methodology. The Institute for Health Care Improvement (IHI) offers a variety of teaching tools to facilitate performance improvement in health care.

We strongly recommend that every medical center use a standard format for planning and conducting such projects. Some medical centers favor the so-called “6 sigma” program. This is a reasonable approach, but it does mandate more specialized training. We favor Dr Shewhart’s (as adapted by Dr Deming and also by the IHI) plan-do-study-act (PDSA) cycles, as being simple, straightforward, and readily accomplished without need for a specialized training program. Regardless of the rubric, success requires proper planning. Specifically, one cannot improve quality if one does not define a goal and define how success toward achieving that goal will be measured. On the other hand, a group cannot allow itself to be frozen in a perpetual state of planning. After “doing” the
change and studying the results, the group can act on them in deciding how best to evolve the current process improvement plan. In a true “continuous quality improvement” program, unless the PDSA cycles continue indefinitely there will be an inevitable “drift” toward poorer performance.
