the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs. In this publication we use the terms “female” and “male” in accordance with the guidelines established by the World Health Organization. Specifically, references to female and male are based on the anatomy of the reproductive systems, which define humans as biologically female or male.

TERMS OF USE

This is a copyrighted work and McGraw-Hill Education and its licensors reserve all rights in and to the work. Use of this work is subject to these terms. Except as permitted under the Copyright Act of 1976 and the right to store and retrieve one copy of the work, you may not decompile, disassemble, reverse engineer, reproduce, modify, create derivative works based upon, transmit, distribute, disseminate, sell, publish or sublicense the work or any part of it without McGraw-Hill Education’s prior consent. You may use the work for your own noncommercial and personal use; any other use of the work is strictly prohibited. Your right to use the work may be terminated if you fail to comply with these terms.

When a new residency training program in anesthesia was beginning in Rwanda in 2006, we were looking for a suitable textbook to recommend to the trainees. We chose Clinical Anesthesiology by Morgan and Mikhail. I am happy to state that today, 12 years later, the residents are still making the same choice. Over one third of all copies of the last edition were sold outside of North America thus underlining the popularity of this textbook around the world.

A major change in editors and authors occurred with the 5th edition and it is clear that they stayed true to the ideals of the original editors. Now in 2018, the 6th edition is presented to us. The text continues to be simple, concise, and easily readable. The use of Key Concepts at the beginning of each chapter is very useful and focuses the reader’s attention on the important points. The authors have worked hard not to increase the size of the book but to update the material. Expanded chapters on critical care, on enhanced recovery after anesthesia, and on the use of ultrasound will be very useful to readers. This textbook continues to provide a comprehensive introduction to the art and science of anesthesia.

Congratulations to the authors and editors on their fine work.

Angela Enright MB, FRCPC
Past President, World Federation of Societies of Anaesthesiologists (WFSA)
Preface

My, how time flies! Can half a decade already have passed since we last edited this textbook? Yet, the time has passed and our field has undergone many changes. We are grateful to the readers of the fifth edition of our textbook. The widespread use of this work have ensured that the time and effort required to produce a sixth edition are justified.

As was true for the fifth edition, the sixth edition represents a significant revision. A few examples are worth noting:

• Those familiar with the sequence and grouping of content in the fifth edition will notice that chapters have been reordered and content broken out or consolidated to improve the flow of information and eliminate redundancy.

• The alert reader will note that the section on critical care medicine has been expanded, reflecting the increasing number of very sick patients for whom we care.

• Enhanced recovery after surgery has progressed from an important concept to a commonly used acronym (ERAS), a specialty society, and (soon) standard of care.

• Ultrasound has never been more important in anesthesia practice, and its use in various procedures is emphasized throughout the textbook.

Some things remain unchanged:

• We have not burdened our readers with large numbers of unnecessary references. We hope that long lists of references at the end of textbook chapters will soon go the way of the library card catalog and long-distance telephone charges. We assume that our readers are as fond of (and likely as facile with) Google Scholar and PubMed as are we, and can generate their own lists of references whenever they like. We continue to provide URLs for societies, guidelines, and practice advisories.

• We continue to emphasize Key Concepts at the beginning of each chapter that link to the chapter discussion, and case discussions at the end.
• We have tried to provide illustrations and images whenever they improve the flow and understanding of the text.

Once again, the goal expressed in the first edition remains unchanged: “to provide a concise, consistent presentation of the basic principles essential to the modern practice of anesthesia.” And, once again, despite our best intentions, we fear that errors will be found in our text. We are grateful to the many readers who helped improve the last edition. Please email us at mm6edition@gmail.com when you find errors. This enables us to make corrections in reprints and future editions.

John F. Butterworth, IV, MD
David C. Mackey, MD
John D. Wasnick, MD, MPH
The Practice of Anesthesiology

KEY CONCEPTS

1 Oliver Wendell Holmes in 1846 was the first to propose use of the term *anesthesia* to denote the state that incorporates amnesia, analgesia, and narcosis to make painless surgery possible.

2 Ether was used for frivolous purposes (“ether frolics”) and was not used as an anesthetic agent in humans until 1842, when Crawford W. Long and William E. Clark independently used it on patients. On October 16, 1846, William T.G. Morton conducted the first publicized demonstration of general anesthesia for surgical operation using ether.

3 The original application of modern local anesthesia is credited to Carl Koller, at the time a house officer in ophthalmology, who demonstrated topical anesthesia of the eye with cocaine in 1884.

4 Curare greatly facilitated tracheal intubation and muscle relaxation during surgery. For the first time, operations could be performed on patients without the requirement that relatively deep levels of inhaled general anesthetic be used to produce muscle relaxation.

5 John Snow, often considered the father of the anesthesia specialty, was the first to scientifically investigate ether and the physiology of general anesthesia.

6 The “captain of the ship” doctrine, which held the surgeon responsible for every aspect of the patient’s perioperative care (including anesthesia), is no longer a valid notion when an anesthesiologist is present.

The Greek philosopher Dioscorides first used the term *anesthesia* in the first century AD to describe the narcotic-like effects of the plant *mandragora*. The term subsequently was defined in Bailey’s *An Universal Etymological English...*
Dictionary (1721) as “a defect of sensation” and again in the Encyclopedia Britannica (1771) as “privation of the senses.” Oliver Wendell Holmes in 1846 was the first to propose use of the term to denote the state that incorporates amnesia, analgesia, and narcosis to make painless surgery possible. In the United States, use of the term anesthesiology to denote the practice or study of anesthesia was first proposed in the second decade of the twentieth century to emphasize the growing scientific basis of the specialty.

Although anesthesia now rests on scientific foundations comparable to those of other specialties, the practice of anesthesia remains very much a mixture of science and art. Moreover, the practice has expanded well beyond rendering patients insensible to pain during surgery or obstetric delivery (Table 1–1). Anesthesiologists require a working familiarity with a long list of other specialties, including surgery and its subspecialties, internal medicine, pediatrics, palliative care, and obstetrics, as well as imaging techniques (particularly ultrasound), clinical pharmacology, applied physiology, safety science, process improvement, and biomedical technology. Advances in scientific underpinnings of anesthesia make it an intellectually stimulating and rapidly evolving specialty. Many physicians entering residency positions in anesthesiology will already have multiple years of graduate medical education and perhaps certification in other medical specialties.

**TABLE 1–1** Aspects of the practice of medicine that are included within the scope of anesthesiology."
This chapter reviews the history of anesthesia, emphasizing its British and American roots, and considers the current scope of the specialty.

The History of Anesthesia

The specialty of anesthesia began in the mid-nineteenth century and became firmly established in the following century. Ancient civilizations had used opium poppy, coca leaves, mandrake root, alcohol, and even phlebotomy (to the point of unconsciousness) to allow surgeons to operate. Ancient Egyptians used the combination of opium poppy (containing morphine) and hyoscyamus (containing scopolamine) for this purpose. A similar combination, morphine and
scopolamine, was widely used for premedication until recent times. What passed for regional anesthesia in ancient times consisted of compression of nerve trunks (nerve ischemia) or the application of cold (cryoanalgesia). The Incas may have practiced local anesthesia as their surgeons chewed coca leaves and applied them to operative wounds, particularly prior to trephining for headache.

The evolution of modern surgery was hampered not only by a poor understanding of disease processes, anatomy, and surgical asepsis but also by the lack of reliable and safe anesthetic techniques. These techniques evolved first with inhalation anesthesia, followed by local and regional anesthesia, intravenous anesthesia, and neuromuscular blockers. The development of surgical anesthesia is considered one of the most important discoveries in human history, and it was introduced to practice without a supporting randomized clinical trial.

**INHALATION ANESTHESIA**

Because the hypodermic needle was not invented until 1855, the first general anesthetics were destined to be inhalation agents. Diethyl ether (known at the time as “sulfuric ether” because it was produced by a simple chemical reaction between ethyl alcohol and sulfuric acid) was originally prepared in 1540 by Valerius Cordus. Ether was used for frivolous purposes (“ether frolics”), but not as an anesthetic agent in humans until 1842, when Crawford W. Long and William E. Clark independently used it on patients for surgery and dental extraction, respectively. However, neither Long nor Clark publicized his discovery. Four years later, in Boston, on October 16, 1846, William T.G. Morton conducted the first publicized demonstration of general anesthesia for surgical operation using ether. The dramatic success of that exhibition led the operating surgeon to exclaim to a skeptical audience: “Gentlemen, this is no humbug!”

Chloroform was independently prepared by Moldenhawer, von Liebig, Guthrie, and Soubeiran around 1831. Although first used by Holmes Coote in 1847, chloroform was introduced into clinical practice by the Scot Sir James Simpson, who administered it to his patients to relieve the pain of labor. Ironically, Simpson had almost abandoned his medical practice after witnessing the terrible despair and agony of patients undergoing operations without anesthesia.

Joseph Priestley produced nitrous oxide in 1772, and Humphry Davy first noted its analgesic properties in 1800. Gardner Colton and Horace Wells are
credited with having first used nitrous oxide as an anesthetic for dental extractions in humans in 1844. Nitrous oxide’s lack of potency (an 80% nitrous oxide concentration results in analgesia but not surgical anesthesia) led to clinical demonstrations that were less convincing than those with ether.

Nitrous oxide was the least popular of the three early inhalation anesthetics because of its low potency and its tendency to cause asphyxia when used alone (see Chapter 8). Interest in nitrous oxide was revived in 1868 when Edmund Andrews administered it in 20% oxygen; its use was, however, overshadowed by the popularity of ether and chloroform. Ironically, nitrous oxide is the only one of these three agents still in use today. Chloroform superseded ether in popularity in many areas (particularly in the United Kingdom), but reports of chloroform-related cardiac arrhythmias, respiratory depression, and hepatotoxicity eventually caused practitioners to abandon it in favor of ether, particularly in North America.

Even after the introduction of other inhalation anesthetics (ethyl chloride, ethylene, divinyl ether, cyclopropane, trichloroethylene, and fluoroxyne), ether remained the standard inhaled anesthetic until the early 1960s. The only inhalation agent that rivaled ether’s safety and popularity was cyclopropane (introduced in 1934). However, both are highly combustible and both have since been replaced by a succession of nonflammable potent fluorinated hydrocarbons: halothane (developed in 1951; released in 1956), methoxyflurane (developed in 1958; released in 1960), enflurane (developed in 1963; released in 1973), and isoflurane (developed in 1965; released in 1981).

Currently, sevoflurane is by far the most popular inhaled agent in developed countries. It is far less pungent than isoflurane and has low blood solubility. Ill-founded concerns about the potential toxicity of its degradation products delayed its release in the United States until 1994 (see Chapter 8). These concerns have proved to be theoretical. Sevoflurane is very suitable for inhaled inductions and has largely replaced halothane in pediatric practice. Desflurane (released in 1992) has many of the desirable properties of isoflurane as well as more rapid uptake and elimination (nearly as fast as nitrous oxide). Sevoflurane, desflurane, and isoflurane are the most commonly used inhaled agents in developed countries worldwide.

LOCAL & REGIONAL ANESTHESIA

The medicinal qualities of coca had been recognized by the Incas for centuries before its actions were first observed by Europeans. Cocaine was isolated from
coca leaves in 1855 by Gaedicke and was purified in 1860 by Albert Niemann. Sigmund Freud performed seminal work with cocaine. Nevertheless, the original application of cocaine for anesthesia is credited to Carl Koller, at the time a house officer in ophthalmology, who demonstrated topical anesthesia of the eye in 1884. Later in 1884 William Halsted used cocaine for intradermal infiltration and nerve blocks (including blocks of the facial nerve, brachial plexus, pudendal nerve, and posterior tibial nerve). August Bier is credited with administering the first spinal anesthetic in 1898. He was also the first to describe intravenous regional anesthesia (Bier block) in 1908. Procaine was synthesized in 1904 by Alfred Einhorn and within a year was used clinically as a local anesthetic by Heinrich Braun. Braun was also the first to add epinephrine to prolong the duration of local anesthetics. Ferdinand Cathelin and Jean Sicard introduced caudal epidural anesthesia in 1901. Lumbar epidural anesthesia was described first in 1921 by Fidel Pages and again (independently) in 1931 by Achille Dogliotti. Additional local anesthetics subsequently introduced include dibuacaine (1930), tetracaine (1932), lidocaine (1947), chloroprocaine (1955), mepivacaine (1957), prilocaine (1960), bupivacaine (1963), and etidocaine (1972). The most recent additions, ropivacaine (1996) and levobupivacaine (1999), have durations of action similar to bupivacaine but less cardiac toxicity (see Chapter 16). Another, chemically dissimilar local anesthetic, articaine, has been widely applied for dental anesthesia.

**INTRAVENTOUS ANESTHESIA**

**Induction Agents**

Intravenous anesthesia required the invention of the hypodermic syringe and needle by Alexander Wood in 1855. Early attempts at intravenous anesthesia included the use of chloral hydrate (by Oré in 1872), chloroform and ether (Burkhardt in 1909), and the combination of morphine and scopolamine (Bredenfeld in 1916). Barbiturates were first synthesized in 1903 by Fischer and von Mering. The first barbiturate used for induction of anesthesia was diethylbarbituric acid (barbital), but it was not until the introduction of hexobarbital in 1927 that barbiturate induction became popular. Thiopental, synthesized in 1932 by Volwiler and Tabern, was first used clinically by John Lundy and Ralph Waters in 1934 and for many years it remained the most common agent for intravenous induction of anesthesia. Methohexital was first used clinically in 1957 by V.K. Stoelting. Methohexital continues to be very popular for brief general anesthetics for electroconvulsive therapy. After
Neuromuscular Blocking Agents

The introduction of curare by Harold Griffith and Enid Johnson in 1942 was a milestone in anesthesia. Curare greatly facilitated tracheal intubation and muscle relaxation during surgery. For the first time, operations could be performed on patients without the requirement for relatively deep planes of inhaled general anesthetic to produce muscle relaxation. Such deep planes of general anesthesia often resulted in excessive cardiovascular and respiratory depression as well as prolonged emergence. Moreover, deep planes of inhalation anesthesia often were not tolerated by frail patients.

Succinylcholine was synthesized by Bovet in 1949 and released in 1951; it remains a standard agent for facilitating tracheal intubation during rapid sequence induction. Until recently, succinylcholine remained unchallenged in its rapid onset of profound muscle relaxation, but its side effects prompted the search for a comparable substitute. Other neuromuscular blockers (NMBs; discussed in Chapter 11)—gallamine, decamethonium, metocurine, alcuronium, and pancuronium—were subsequently introduced. Unfortunately, these agents were often associated with side effects (see Chapter 11), and the search for the ideal NMB continued. Recently introduced agents that more closely resemble an ideal NMB include vecuronium, atracurium, rocuronium, mivacurium, and cis-atracurium.

Opioids
Morphine, first isolated from opium in between 1803 and 1805 by Sertürner, was also tried as an intravenous anesthetic. The adverse events associated with opioids in early reports caused many anesthetists to favor pure inhalation anesthesia. Interest in opioids in anesthesia returned following the synthesis and introduction of meperidine in 1939. The concept of balanced anesthesia was introduced in 1926 by Lundy and others and evolved to include thiopental for induction, nitrous oxide for amnesia, an opioid for analgesia, and curare for muscle relaxation. In 1969, Lowenstein rekindled interest in “pure” opioid anesthesia by reintroducing the concept of large doses of opioids as complete anesthetics. Morphine was the first agent so employed, but fentanyl and sufentanil have been preferred by a large margin as sole agents. As experience grew with this technique, its multiple limitations—unreliably preventing patient awareness, incompletely suppressing autonomic responses during surgery, and prolonged respiratory depression—were realized. Remifentanil, an opioid subject to rapid degradation by nonspecific plasma and tissue esterases, permits profound levels of opioid analgesia to be employed without concerns regarding the need for postoperative ventilation, albeit with an increased risk of acute opioid tolerance.

EVOLUTION OF THE SPECIALTY

British Origins

Following its first public demonstration in the United States, ether anesthesia quickly was adopted in England. John Snow, often considered the father of the anesthesia specialty, was the first physician to take a full-time interest in this new anesthetic. He was the first to scientifically investigate ether and the physiology of general anesthesia. Of course, Snow was also a pioneer in epidemiology who helped stop a cholera epidemic in London by proving that the causative agent was transmitted by ingestion of contaminated well water rather than by inhalation. In 1847, Snow published the first book on general anesthesia, On the Inhalation of Ether. When the anesthetic properties of chloroform were made known, he quickly investigated and developed an inhaler for that agent as well. He believed that an inhaler should be used in administering ether or chloroform to control the dose of the anesthetic. His second book, On Chloroform and Other Anaesthetics, was published posthumously in 1858.

After Snow’s death, Dr. Joseph T. Clover took his place as England’s leading anesthetist. Clover emphasized continuously monitoring the patient’s pulse during anesthesia, a practice that was not yet standard at the time. He was the
first to use the jaw-thrust maneuver for relieving airway obstruction, the first to insist that resuscitation equipment always be available during anesthesia, and the first to use a cricothyroid cannula (to save a patient with an oral tumor who developed complete airway obstruction). After Clover, Sir Frederic Hewitt became England’s foremost anesthetist in the 1890s. He was responsible for many inventions, including the oral airway. Hewitt also wrote what many consider to be the first true textbook of anesthesia, which went through five editions. Snow, Clover, and Hewitt established the tradition of physician anesthetists in England, but it was Hewitt who made the most sustained and strongest arguments for educating specialists in anesthesia. In 1893, the first organization of physician specialists in anesthesia, the London Society of Anaesthetists, was formed in England by J.F. Silk.

The first elective tracheal intubations during anesthesia were performed in the late nineteenth century by surgeons Sir William MacEwen in Scotland, Joseph O’Dwyer in the United States, and Franz Kuhn in Germany. Tracheal intubation during anesthesia was popularized in England by Sir Ivan Magill and Stanley Rowbotham in the 1920s.

**North American Origins**

In the United States, only a few physicians had specialized in anesthesia by 1900. The task of providing general anesthesia was often delegated to junior surgical house officers, medical students, or general practitioners.

The first organization of physician anesthetists in the United States was the Long Island Society of Anesthetists, formed in 1905, which, as it grew, was renamed the New York Society of Anesthetists in 1911. The group now known as the International Anesthesia Research Society (IARS) was founded in 1922, and in that same year the IARS-sponsored scientific journal *Current Researches in Anesthesia and Analgesia* (now called *Anesthesia and Analgesia*) began publication. In 1936, the New York Society of Anesthetists became the American Society of Anesthetists, and later, in 1945, the American Society of Anesthesiologists (ASA). The scientific journal *Anesthesiology* was first published in 1940.

Harold Griffith and others founded the Canadian Anesthetists Society in 1943, and Griffith (now better known for introducing curare) served as its first president. Twelve years later the journal now known as the *Canadian Journal of Anesthesia* was first published. Five physicians stand out in the early development of anesthesia in the United States after 1900: James Tayloe
Gwathmey, F.H. McMechan, Arthur E. Guedel, Ralph M. Waters, and John S. Lundy. Gwathmey was the author (with Charles Baskerville) of the first major American textbook of anesthesia in 1914 and was the highly influential first president of the New York State Society of Anesthetists. McMechan, assisted by his wife, was the driving force behind both the IARS and Current Researches in Anesthesia and Analgesia, and until his death in 1939 tirelessly organized physicians specializing in anesthesia into national and international organizations. Guedel was the first to describe the signs and four stages of general anesthesia. He advocated cuffed tracheal tubes and introduced artificial ventilation during ether anesthesia (later termed controlled respiration by Waters). Ralph Waters made a long list of contributions to the specialty, probably the most important of which was his insistence on the proper education of specialists in anesthesia. Waters developed the first academic department of anesthesiology at the University of Wisconsin in Madison. Lundy, working at the Mayo Clinic in Minnesota, was instrumental in the formation of the American Board of Anesthesiology (1937) and chaired the American Medical Association’s Section on Anesthesiology for 17 years.

Because of the scarcity of physicians specializing in anesthesia in the United States, surgeons at both the Mayo Clinic and Cleveland Clinic began training and employing nurses as anesthetists in the early 1900s. As the numbers of nurse anesthetists increased, a national organization (now called the American Association of Nurse Anesthetists [AANA]) was incorporated in 1932. The AANA first offered a certification examination in 1945. In 1969 two Anesthesiology Assistant programs began accepting students, and in 1989 the first certification examinations for anesthesiologist assistants were administered. Certified registered nurse anesthetists and anesthesiologist assistants represent important members of the anesthesia workforce in the United States and in other countries.

**Official Recognition**

In 1889 Henry Isaiah Dorr, a dentist, was appointed Professor of the Practice of Dentistry, Anaesthetics and Anaesthesia at the Philadelphia College of Dentistry. Thus he was the first known professor of anesthesia worldwide. Thomas D. Buchanan, of the New York Medical College, was the first physician to be appointed Professor of Anesthesia (in 1905). When the American Board of Anesthesiology was established in 1938, Dr. Buchanan served as its first president. Certification of specialists in anesthesia was first available in Canada in 1946. In England, the first examination for the Diploma in Anaesthetics took
place in 1935, and the first Chair in Anaesthetics was awarded to Sir Robert Macintosh in 1937 at Oxford University. Anesthesia became an officially recognized specialty in England only in 1947, when the Royal College of Surgeons established its Faculty of Anaesthetists. In 1992 an independent Royal College of Anaesthetists was granted its charter. Momentous changes occurred in Germany during the 1950s, progress likely having been delayed by the isolation of German medical specialists from their colleagues in other countries that began with World War I and continued until the resolution of World War II. First the journal Der Anaesthetist began publication in 1952. The following year, requirements for specialist training in anesthesia were approved and the German Society of Anesthetists was founded.

The Scope of Anesthesiology

The practice of anesthesia has changed dramatically since the days of John Snow. The modern anesthesiologist must be both a perioperative consultant and a deliverer of care to patients. In general, anesthesiologists are responsible for nearly all “noncutting” aspects of the patient’s medical care in the immediate perioperative period. The “captain of the ship” doctrine, which held the surgeon responsible for every aspect of the patient’s perioperative care (including anesthesia), is no longer a valid notion when an anesthesiologist is present. The surgeon and anesthesiologist must function together as an effective team, and both are ultimately answerable to the patient rather than to each other.

The modern practice of anesthesia is not confined to rendering patients insensible to pain (Table 1–1). Anesthesiologists monitor, sedate, and provide general or regional anesthesia outside the operating room for various imaging procedures, endoscopy, electroconvulsive therapy, and cardiac catheterization. Anesthesiologists such as Peter Safar have been pioneers in cardiopulmonary resuscitation, and anesthesiologists continue to be integral members of resuscitation teams.

An increasing number of practitioners pursue subspecialty fellowships in anesthesia for cardiothoracic surgery (see Chapter 22), critical care (see Chapter 57), neuroanesthesia (see Chapter 27), obstetric anesthesia (see Chapter 41), pediatric anesthesia (see Chapter 42), palliative care, regional anesthesia, and acute pain management (see Chapters 45, 46, 48) or chronic pain medicine (see Chapter 47). Certification requirements for special competence in critical care, pediatric anesthesia, and pain medicine already exist in the United States. Fellowship programs in Adult Cardiothoracic Anesthesia, Critical Care
Medicine, Pediatric Anesthesiology, Obstetric Anesthesiology, Regional Anesthesia and Acute Pain Management, Sleep Medicine, Palliative Care, and Interventional Pain have specific accreditation requirements. Education and certification in anesthesiology can also be used as the basis for certification in Sleep Medicine or in Palliative Medicine.

Anesthesiologists are actively involved in the administration and medical direction of many ambulatory surgery facilities, operating room suites, intensive care units, and respiratory therapy departments. They have also assumed administrative and leadership positions on the medical staffs of many hospitals and ambulatory care facilities. They serve as deans of medical schools and chief executives of health systems. In the United States they have served in state legislatures, in the U.S. Congress, and as the Surgeon General. The future of the specialty has never looked brighter.

### SECTION I

**Anesthetic Equipment & Monitors**
The Operating Room Environment
Charles E. Cowles, Jr., MD, MBA, FASA

KEY CONCEPTS

1. A pressure of 1000 psig indicates an E-cylinder that is approximately half full and represents 330 L of oxygen.
2. The only reliable way to determine residual volume of nitrous oxide is to weigh the cylinder.
3. To discourage incorrect cylinder attachments, cylinder manufacturers have adopted a pin index safety system.
4. A basic principle of radiation safety is to keep exposure “as low as reasonably practical” (ALARP). The principles of ALARP optimize protection from radiation exposure by the use of time, distance, and shielding.
5. The magnitude of a leakage current is normally imperceptible to touch (<1 mA, and well below the fibrillation threshold of 100 mA). If the current bypasses the high resistance offered by skin, however, and is applied directly to the heart (microshock), current as low as 100 μA may be fatal. The maximum leakage allowed in operating room equipment is 10 μA.
6. To reduce the chance of two coexisting faults, a line isolation monitor measures the potential for current flow from the isolated power supply to the ground. Basically, the line isolation monitor determines the degree of isolation between the two power wires and the ground and predicts the amount of current that could flow if a second short circuit were to develop.
7. Almost all surgical fires can be prevented. Unlike medical complications, fires are a product of simple physical and chemistry properties. Occurrence is guaranteed given the proper combination of
factors, but can be almost entirely eliminated through understanding the basic principles of fire risk.

8. The most common risk factor for surgical fire relates to the open delivery of oxygen.

9. Administration of oxygen in concentrations of greater than 30% should be guided by the clinical presentation of the patient and not solely by protocols or habits.

10. The sequence of stopping gas flow and removal of the endotracheal tube when fire occurs in the airway is not as important as ensuring that both actions are performed immediately.

11. Before beginning laser surgery, the laser device should be in the operating room, warning signs should be posted on the doors, and protective eyewear should be issued. The anesthesia provider should ensure that the warning signs and eyewear match the labeling on the device, as laser protection is specific to the type of laser.

Anesthesiologists, who spend more time in operating rooms than any other physician specialty, are responsible for protecting patients and operating room personnel from a multitude of dangers during surgery. Some of these threats are unique to the operating room. As a result, the anesthesiologist may be responsible for ensuring proper functioning of the operating room’s medical gases, fire prevention and management, environmental factors (eg, temperature, humidity, ventilation, and noise), and electrical safety. Anesthesiologists often coordinate, or assist with, layout and design of surgical and procedural suites, including workflow enhancements. This chapter describes the major operating room features that are of special interest to anesthesiologists and the potential hazards associated with these systems.

---

**Culture of Safety**

Patients often think of the operating room as a safe place where the care given is centered around protecting the patient. Anesthesia providers, surgeons, nurses, and other medical personnel are responsible for carrying out critical tasks safely and efficiently. Unless members of the operating room team remain vigilant, errors can occur that may result in harm to the patient or to members of the operating room team. The best way of preventing serious harm to the patient or to the operating room team is by creating a *culture of safety*, which identifies and
stops unsafe acts before harm occurs.

One tool that fosters the safety culture is the use of a surgical safety checklist. Such checklists must be used prior to incision on every case and include components agreed upon by the facility as crucial. Many surgical checklists are derived from the surgical safety checklist published by the World Health Organization (WHO). For checklists to be effective, they must first be used; second, all members of the surgical team must be focused on the checklist when it is being used. Checklists are most effective when performed in an interactive fashion. An example of a suboptimally executed checklist is one that is read in entirety, after which the surgeon asks whether everyone agrees. This format makes it difficult to identify possible problems. A better method is one that elicits a response after each point; eg, “Does everyone agree this patient is John Doe?”, followed by “Does everyone agree we are performing a removal of the left kidney?”, and so forth. Optimal checklists do not attempt to cover every possibility, but address only key components, allowing them to be completed in less than 90 seconds.

Some practitioners argue that checklists waste too much time; they fail to realize that cutting corners to save time often leads to problems later, resulting in a net loss of time and harm to the patient. If safety checklists were followed in every case, significant reductions would be seen in the incidence of preventable surgical complications such as wrong-site surgery, procedures on the wrong patient, retained foreign objects, and administration of a medication to a patient with a known allergy to that medication. Anesthesia providers are leaders in patient safety initiatives and should take a proactive role to utilize checklists and other activities that foster the culture of safety.

Medical Gas Systems

The medical gases commonly used in operating rooms are oxygen, nitrous oxide, air, and nitrogen. Although technically not a gas, vacuum exhaust for disposal or scavenging of waste anesthetic gas and surgical suction must also be provided, and these are considered integral parts of the medical gas system. Patients are endangered if medical gas systems, particularly oxygen, are misconfigured or malfunction. The anesthesiologist must understand the sources of the gases and the means of their delivery to the operating room to prevent or detect medical gas depletion or supply line misconnection. Estimates of a particular hospital’s peak demand determine the type of medical gas supply system required. Design and standards follow National Fire Protection Association (NFPA) 99 in the
United States and HTM 2022 in the United Kingdom.

**SOURCES OF MEDICAL GASES**

**Oxygen**

A reliable supply of oxygen is a critical requirement in any surgical area. Medical grade oxygen (99% or 99.5% pure) is manufactured by fractional distillation of liquefied air. Oxygen is stored as a compressed gas at room temperature or refrigerated as a liquid. Most small hospitals store oxygen in two separate banks of high-pressure cylinders (H-cylinders) connected by a manifold (Figure 2–1). Only one bank is utilized at a time. The number of cylinders in each bank depends on anticipated daily demand. The manifold contains valves that reduce the cylinder pressure (approximately 2000 pounds per square inch [psig]) to line pressure (55 ± 5 psig) and automatically switch banks when one group of cylinders is exhausted.

![Figure 2–1](image)

**FIGURE 2–1** A bank of oxygen H-cylinders connected by a manifold.

A liquid oxygen storage system (Figure 2–2) is more economical for large hospitals. Liquid oxygen must be stored well below its critical temperature of –119°C because gases can be liquefied by pressure only if stored below their critical temperature. A large hospital may have a smaller liquid oxygen supply or a bank of compressed gas cylinders that can provide one day’s oxygen requirements as a reserve. To guard against a hospital gas-system failure, the
anesthesiologist must always have an emergency (E-cylinder) supply of oxygen available during anesthesia.

**FIGURE 2–2** A liquid storage tank with reserve oxygen tanks in the background.

Most anesthesia machines accommodate E-cylinders of oxygen (Table 2–1). As oxygen is expended, the cylinder’s pressure falls in proportion to its content. A pressure of 1000 psig indicates an E-cylinder that is approximately half full and represents 330 L of oxygen at atmospheric pressure and a temperature of 20°C. If the oxygen is exhausted at a rate of 3 L/min, a cylinder that is half full will be empty in 110 min. Oxygen cylinder pressure should be assessed prior to use and periodically during use. Anesthesia machines usually also accommodate E-cylinders for medical air and nitrous oxide, and may accept cylinders of helium. Compressed medical gases utilize a pin index safety system for these cylinders to prevent inadvertent crossover and connections for different gas types. As a safety feature, oxygen E-cylinders have a “plug” made from Wood’s metal. This metallurgic alloy has a low melting point, allowing dissipation of pressure in a fire that might otherwise heat the cylinder to the point of explosion. This pressure-relief “valve” is designed to rupture at 3300 psig, well below the pressure E-cylinder walls should be able to withstand (more than 5000 psig), preventing “overfilling” of the cylinder.

**TABLE 2–1** Characteristics of medical gas cylinders.
Nitrous Oxide

Nitrous oxide is almost always stored by hospitals in large H-cylinders connected by a manifold with an automatic crossover feature. Bulk liquid storage of nitrous oxide is economical only in very large institutions.

Because the critical temperature of nitrous oxide (36.5°C) is above room temperature, it can be kept liquefied without an elaborate refrigeration system. If the liquefied nitrous oxide rises above its critical temperature, it will revert to its gaseous phase. Because nitrous oxide is not an ideal gas and is easily compressible, this transformation into a gaseous phase is not accompanied by a great rise in tank pressure. Nonetheless, as with oxygen cylinders, all nitrous oxide E-cylinders are equipped with a Wood’s metal plug to prevent explosion under conditions of unexpectedly high gas pressure (eg, unintentional overfilling or during a fire).

Although a disruption in supply is usually not catastrophic, most anesthesia machines have reserve nitrous oxide E-cylinders. Because these smaller cylinders also contain nitrous oxide in its liquid state, the volume remaining in a cylinder is not proportional to cylinder pressure. By the time the liquid nitrous oxide is expended and the tank pressure begins to fall, only about 400 L of nitrous oxide remains. If liquid nitrous oxide is kept at a constant temperature (20°C), it will vaporize at the same rate at which it is consumed and will maintain a constant pressure (745 psig) until the liquid is exhausted.

The only reliable way to determine residual volume of nitrous oxide is to weigh the cylinder. For this reason, the tare weight (TW), or empty weight, of cylinders containing a liquefied compressed gas (eg, nitrous oxide) is often stamped on the shoulder of the cylinder. The pressure gauge of a nitrous oxide cylinder should not exceed 745 psig at 20°C. A higher reading implies gauge malfunction, tank overfill (liquid fill), or a cylinder containing a gas other than nitrous oxide.

Because energy is consumed in the conversion of a liquid to a gas (the latent heat of vaporization), liquid nitrous oxide cools during this process. The drop in

\(^1\)Depending on the manufacturer.
temperature results in a lower vapor pressure and lower cylinder pressure. The cooling is so pronounced at high flow rates that there is often frost on the tank, and the pressure regulator may freeze in such circumstances.

**Medical Air**

The use of air is becoming more frequent in anesthesiology as the popularity of nitrous oxide and unnecessarily high concentrations of oxygen has declined. Cylinder air is medical grade and is obtained by blending oxygen and nitrogen. Dehumidified (but unsterile) air is provided to the hospital pipeline system by compression pumps. The inlets of these pumps must be distant from vacuum exhaust vents and machinery to minimize contamination. Because the critical temperature of air is \(-140.6^\circ\text{C}\), it exists as a gas in cylinders whose pressures fall in proportion to their content.

**Nitrogen**

Although compressed nitrogen is not administered to patients, it may be used to drive operating room equipment, such as saws, drills, and surgical handpieces. Nitrogen supply systems incorporate either the use of H-cylinders connected by a manifold or a wall system supplied by a compressor-driven central supply.

**Vacuum**

A central hospital vacuum system usually consists of independent suction pumps, each capable of handling peak requirements. Traps at every user location prevent contamination of the system with foreign matter. The medical-surgical vacuum system may be used for waste anesthetic gas disposal (WAGD) as long as it does not affect performance of the system. Medical vacuum receptacles are usually black in color with white lettering. A dedicated WAGD vacuum system is required with modern anesthesia machines. The WAGD outlet may incorporate the use of a suction regulator with a float indicator that should be maintained between the designated markings. Excess suction may result in inadequate patient ventilation, and insufficient suction levels may result in the failure to evacuate waste anesthetic gases. WAGD receptacles and tubing are usually lavender in color.

**Carbon Dioxide**
Many surgical procedures are performed using laparoscopic or robotic-assisted techniques requiring insufflation of body cavities with carbon dioxide, an odorless, colorless, nonflammable and slightly acidic gas. Large cylinders containing carbon dioxide, such as M-cylinders or LK-cylinders, are frequently found in the operating room; these cylinders share a common size orifice and thread with oxygen cylinders and can be inadvertently interchanged.

**DELIVERY OF MEDICAL GASES**

Medical gases are delivered from their central supply source to the operating room through a network of pipes that are sized such that the pressure drop across the whole system never exceeds 5 psig. Gas pipes are usually constructed of seamless copper tubing using a special welding technique. Internal contamination of the pipelines with dust, grease, or water must be avoided. The hospital’s gas delivery system appears in the operating room as hose drops, gas columns, or elaborate articulating arms (Figure 2–3). Operating room equipment, including the anesthesia machine, connects to pipeline system outlets by color-coded hoses. Quick-coupler mechanisms, which vary in design with different manufacturers, connect one end of the hose to the appropriate gas outlet. The other end connects to the anesthesia machine through a non-interchangeable diameter index safety system fitting that prevents incorrect hose attachment.
Typical examples of A: gas columns, B: ceiling hose drops, and C: articulating arms. One end of a color-coded hose connects to the hospital medical gas supply system by way of a quick-coupler mechanism. The other end connects to the anesthesia machine through the diameter index safety system.

E-cylinders of oxygen, nitrous oxide, and air attach directly to the anesthesia machine. To discourage incorrect cylinder attachments, cylinder manufacturers have adopted a pin index safety system. Each gas cylinder (sizes A–E) has two holes in its cylinder valve that mate with corresponding pins in the yoke of the anesthesia machine (Figure 2–4). The relative positioning of the pins and holes is unique for each gas. Multiple washers placed between the cylinder and yoke, which prevent proper engagement of the pins and holes, have unintentionally defeated this system and thus must not be used. The pin index safety system is also ineffective if yoke pins are damaged or if the cylinder is filled with the incorrect gas.

The functioning of medical gas supply sources and pipeline systems is constantly monitored by central and area alarm systems. Indicator lights and audible signals warn of changeover to secondary gas sources and abnormally high (eg, pressure regulator malfunction) or low (eg, supply depletion) pipeline
pressures (Figure 2–5).

![Master Alarm Panel](image)

**FIGURE 2–5** An example of a master alarm panel that monitors gasline pressure.

Modern anesthesia machines and anesthetic gas analyzers continuously measure the fraction of inspired oxygen (Fio₂). Analyzers have a variable threshold setting for the minimal Fio₂ but must be configured to prevent disabling this alarm. The monitoring of Fio₂ does not reflect the oxygen concentration distal to the monitoring port and thus should not be used to reference the oxygen concentration within distal devices such as endotracheal tubes. Due to gas exchange, flow rates, and shunting, a marked difference may exist between the indicated Fio₂ and the actual oxygen concentration at the tissue level.

---

**Environmental Factors in the Operating Room**

**TEMPERATURE**

The temperature in most operating rooms seems uncomfortably cold to many conscious patients and, at times, to anesthesia providers. However, scrub nurses and surgeons stand in surgical garb for hours under hot operating room lights. As a general principle, the comfort of operating room personnel must be reconciled with patient care, and in adult patients temperatures should be maintained
between 68°F (20°C) and 75°F (24°C). Hypothermia has been associated with wound infection, impaired coagulation, greater intraoperative blood loss, and prolonged hospitalization (see Chapter 52).

**HUMIDITY**

In past decades, static discharges were a feared source of ignition in an operating room filled with flammable anesthetic gas vapors. Now humidity control is more relevant to infection control practices. Humidity levels in the operating room should be maintained between 20% and 60%. Below this range the dry air facilitates airborne mobility of particulate matter, which can be a vector for infection. At high humidity, dampness can affect the integrity of barrier devices such as sterile cloth drapes and pan liners.

**VENTILATION**

A high rate of operating room airflow decreases contamination of the surgical site. These flow rates, usually achieved by blending up to 80% recirculated air with fresh air, are engineered in a manner to decrease turbulent flow and to be unidirectional. Although recirculation conserves energy costs associated with heating and air conditioning, it is unsuitable for WAGD. Therefore, a separate waste anesthetic gas scavenging system must always supplement operating room ventilation. The operating room should maintain a slightly positive pressure to drive away gases that escape scavenging and should be designed so fresh air is introduced through, or near, the ceiling and air return is handled at, or near, floor level. Ventilation considerations must address both air quality and volume changes. The National Fire Protection Agency (NFPA) recommends 20 air volume exchanges per hour to decrease risk of stagnation and bacterial growth. Air quality should be maintained by adequate air filtration using a 90% filter, defined simply as one that filters out 90% of particles presented. Although high-efficiency particulate filters (HEPA) are frequently used, these are not required by engineering or infection control standards.

**NOISE**

Multiple studies have demonstrated that exposure to noise can have a detrimental effect on human cognitive function, and prolonged exposure may result in hearing impairment. Operating room noise has been measured at 70 to 80 decibels (dB) with frequent sound peaks exceeding 80 dB. As a reference, if
the speaking voice has to be raised above conversational level, then ambient noise is approximated at 80 dB. Noise levels in the operating room approach the time-weighted average (TWA) for which the Occupational Safety and Health Administration (OSHA) requires hearing protection. Orthopedic air chisels and neurosurgical drills can approach the noise levels of 125 dB, the level at which most human subjects begin to experience pain.

IONIZING RADIATION
Anesthesia providers are exposed to radiation as a component of either diagnostic imaging or radiation therapy; examples include fluoroscopy, linear accelerators, computed tomography, directed beam therapy, proton therapy, and diagnostic radiographs. Human effects of radiation are measured by units of absorbed doses such as the gray (Gy) and rads, or by equivalent dose units such as the Sievert (Sv) and Roentgen equivalent in man (REM). Radiation-sensitive organs such as eyes, thyroid, and gonads must be protected, as well as blood, bone marrow, and the fetus. Radiation levels must be monitored if individuals are exposed to greater than 40 REM, and the most common method of measurement is by film badge. Lifetime exposure can be tabulated by a required database of film badge wearers.

A basic principle of radiation safety is to keep exposure “as low as reasonably practical” (ALARP). The principles of ALARP optimize protection from radiation exposure by the use of time, distance, and shielding. The length of time of exposure is usually not an issue for simple radiographs such as chest films but can be significant in fluoroscopic procedures such as those commonly performed during interventional radiology or pulmonology, c-arm use, and in a diagnostic gastroenterology center. Exposure can be reduced to the provider by increasing the distance between the beam and the provider. Radiation exposure over distance follows the inverse square law. To illustrate, intensity is represented as $1/d^2$ (where $d =$ distance) so that 100 millirads (mRads) at 1 inch will be 0.01 mRads at 100 inches. Shielding is the most reliable form of radiation protection; typical personal shielding is in the form of leaded aprons, thyroid collars, and glasses. Physical shields are usually incorporated into radiological suites and can be as simple as a wall to stand behind or a rolling leaded shield to place between the beam and the provider. Although most modern facilities are designed in a very safe manner, providers can still be exposed to scattered radiation as atomic particles are bounced off shielding. For this reason radiation protection should be donned whenever ionizing radiation is used.
As use of reliable shielding has increased, the incidence of radiation-associated diseases of sensitive organs has decreased, with the exception of radiation-induced cataracts. Because protective eyewear has not been consistently used to the same degree as other types of personal protection, radiation-induced cataracts are increasing among employees working in interventional radiology suites. Anesthesia providers who work in these environments should consider the use of leaded goggles or glasses to decrease the risk of such problems.

---

**Electrical Safety**

**THE RISK OF ELECTROCUTION**

The use of electronic medical equipment subjects patients and health care personnel to the risk of shock and electrocution. Anesthesia providers must have an understanding of electrical hazards and their prevention.

Body contact with two conductive materials at different voltage potentials may complete a circuit and result in an electrical shock. Usually, one point of exposure is a live 110-V or 240-V conductor, with the circuit completed through a ground contact. For example, a grounded person need contact only one live conductor to complete a circuit and receive a shock. The live conductor could be the frame of a patient monitor that has developed a fault to the hot side of the power line. A circuit is now complete between the power line (which is earth grounded at the utility company’s pole-top transformer) through the victim and back to the ground (Figure 2–6). The physiological effect of electrical current depends on the location, duration, frequency, and magnitude (more accurately, current density) of the shock.
Leakage current is present in all electrical equipment as a result of capacitive coupling, induction between internal electrical components, or defective insulation. Current can flow as a result of capacitive coupling between two conductive bodies (e.g., a circuit board and its casing) even though they are not physically connected. Some monitors are doubly insulated to decrease the effect of capacitive coupling. Other monitors are designed to be connected to a low-impedance ground (the safety ground wire) that should divert the current away from a person touching the instrument’s case. The magnitude of such leaks is normally imperceptible to touch (<1 mA, and well below the fibrillation threshold of 100 mA). If the current bypasses the high resistance offered by skin, however, and is applied directly to the heart, current as low as 100 μA (microshock) may be fatal. The maximum leakage allowed in operating room equipment is 10 μA. Cardiac pacing wires and invasive monitoring catheters provide a direct
conductive pathway to the myocardium. In fact, blood and normal saline can serve as electrical conductors. The exact amount of current required to produce fibrillation depends on the timing of the shock relative to the vulnerable period of heart repolarization (the T wave on the electrocardiogram). Even small differences in potential between the ground connections of two electrical outlets in the same operating room can place a patient at risk for microelectrocution.

**PROTECTION FROM ELECTRICAL SHOCK**

Most patient electrocutions are caused by current flow from the live conductor of a grounded circuit through the body and back to a ground ([Figure 2–6](#)). This would be prevented if everything in the operating room were grounded except the patient. Although direct patient grounds should be avoided, complete patient isolation is not feasible during surgery. Instead, the operating room power supply can be isolated from grounds by an isolation transformer ([Figure 2–7](#)).

![Diagram of an isolation transformer and monitor](#)

**FIGURE 2–7** A circuit diagram of an isolation transformer and monitor.

Unlike the utility company’s pole-top transformer, the secondary wiring of an isolation transformer is not grounded and provides two live ungrounded voltage lines for operating room equipment. Equipment casing—but not the electrical circuits—is grounded through the longest blade of a three-pronged plug (the *safety ground*). If a live wire is then unintentionally contacted by a grounded patient, current will not flow through the patient since no circuit back to the secondary coil has been completed ([Figure 2–8](#)).
FIGURE 2–8 Even though a person is grounded, no shock results from contact with one wire of an isolated circuit. The individual is in simultaneous contact with two separate voltage sources but does not close a loop including either source. (Modified with permission from Bruner J, Leonard PF. Electricity, Safety, and the Patient. St Louis, MO: Mosby Year Book; 1989.)

Of course, if both power lines are contacted, a circuit is completed and a shock is possible. In addition, if either power line comes into contact with a ground through a fault, contact with the other power line will complete a circuit through a grounded patient. To reduce the chance of two coexisting faults, a line isolation monitor measures the potential for current flow from the isolated power supply to the ground (Figure 2–9). Basically, the line isolation monitor determines the degree of isolation between the two power wires and the ground and predicts the amount of current that could flow if a second short circuit were to develop. An alarm is activated if an unacceptably high current flow to the ground becomes possible (usually 2 mA or 5 mA), but power is not interrupted unless a ground-fault circuit interrupter is also activated. The latter, a common feature in household bathrooms and kitchens, is usually not installed in locations such as operating rooms, where discontinuation of life support systems (eg, cardiopulmonary bypass machine) is more hazardous than the risk of electrical shock. The alarm of the line isolation monitor merely indicates that the power supply has partially reverted to a grounded system. In other words, while the line
isolation monitor warns of the existence of a single fault (between a power line and a ground), two faults are required for a shock to occur. Since the line isolation monitor alarms when the sum of leakage current exceeds the set threshold, the last piece of equipment added is usually the defective one; however, if this item is life-sustaining, other equipment can be removed from the circuit to evaluate whether the life safety item is truly at fault.

FIGURE 2–9 A line isolation monitor.

Even isolated power circuits do not provide complete protection from the small currents capable of causing microshock fibrillation. Furthermore, the line isolation monitor cannot detect all faults, such as a broken safety ground wire within a piece of equipment. There are, however, modern equipment designs that decrease the possibility of microelectrocution. These include double insulation of the chassis and casing, ungrounded battery power supplies, and patient isolation from equipment-connected grounds by using optical coupling or transformers.

In the latest edition of the U.S. NPFA 99 Health Care Facilities Code, building system requirements for facilities—including electrical systems—are
based upon a risk assessment carried out by facilities personnel with the input of health care providers. The risk levels are categorized in levels as follows:

*Category 1*—Facility systems in which failure of such equipment or system is likely to cause major injury or death of patients or caregivers

*Category 2*—Facility systems in which failure of such equipment is likely to cause minor injury to patients or caregivers

*Category 3*—Facility systems in which failure of such equipment is not likely to cause injury to patients or caregivers, but can cause patient discomfort

*Category 4*—Facility systems in which failure of such equipment would have no impact on patient care

Category 1 locations and systems will have the greatest amount of reliability and redundancy; lesser categories will have less stringent requirements. All codes under the 2012 edition of the NPFA 99 will be determined by the risk assessment category. Under the electrical code, operating rooms are defined as a wet location requiring electrical systems that reduce the risk of electrical shock hazards. If an operating room is used for procedures without liquid exposure, such as rooms used for central line placement or eye procedures, facilities can perform a risk assessment and reclassify the operating room as a nonwet area.

**SURGICAL DIATHERMY (ELECTROCAUTERY, ELECTROSURGERY)**

Electrosurgical units (ESUs) generate an ultrahigh-frequency electrical current that passes from a small active electrode (the cautery tip) through the patient and exits by way of a large plate electrode (the dispersal pad, or return electrode). The high current density at the cautery tip is capable of tissue coagulation or cutting, depending on the electrical waveform. Ventricular fibrillation is prevented by the use of ultrahigh electrical frequencies (0.1–3 MHz) compared with line power (50–60 Hz). The large surface area of the low-impedance return electrode avoids burns at the current’s point of exit by providing a low current density (the concept of *exit* is technically incorrect, as the current is alternating rather than direct). The high power levels of ESUs (up to 400 W) can cause inductive coupling with monitor cables, leading to electrical interference.

Malfunction of the dispersal pad may result from disconnection from the ESU, inadequate patient contact, or insufficient conductive gel. In these situations, the current will find another place to exit (eg, electrocardiogram pads
or metal parts of the operating table), which may result in a burn (Figure 2–10). Precautions to prevent diathermy burns include proper return electrode placement, avoiding prostheses and bony protuberances, and elimination of patient-to-ground contacts. Current flow through the heart may lead to malfunction of an implanted cardiac pacemaker or cardioverter defibrillator. This risk can be minimized by placing the return electrode as close to the surgical field and as far from the implanted cardiac device as practical.

**FIGURE 2–10** Electrosurgical burn. If the intended path is compromised, the circuit may be completed through other routes. Because the current is of high frequency, recognized conductors are not essential; capacitances can complete gaps in the circuit. Current passing through the patient to a contact of small area may produce a burn. (A leg drape would not offer protection in the situation depicted.) The isolated output electrosurgical unit (ESU) is much less likely than the ground-referenced ESU to provoke burns at ectopic sites. *Ground-referenced* in this context applies to the ESU output and has nothing to do with isolated versus grounded power systems. (Modified with permission from Bruner J, Leonard PF. *Electricity, Safety, and the Patient*. St Louis, MO: Mosby Year Book; 1989.)

Newer ESUs are isolated from grounds using the same principles as the isolated power supply (isolated output versus ground-referenced units). Because this second layer of protection provides ESUs with their own isolated power supply, the operating room’s line isolation monitor may not detect an electrical fault. Although some ESUs are capable of detecting poor contact between the return electrode and the patient by monitoring impedance, many older units trigger the alarm only if the return electrode is unplugged from the machine.
Bipolar electrodes confine current propagation to a few millimeters, eliminating the need for a return electrode. Because pacemaker and electrocardiogram interference is possible, pulse or heart sounds should be closely monitored when any ESU is used. Automatic implanted cardioverter defibrillator devices may need to be suspended if monopolar ESU is used, and any implanted cardiac device should be interrogated after use of a monopolar ESU.

Surgical Fires & Thermal Injury

FIRE PREVENTION & PREPARATION

Surgical fires are relatively rare, with an incidence of about 1:87,000 cases, which is close to the incidence rate of other events such as retained foreign objects after surgery and wrong-site surgery. Almost all surgical fires can be prevented (Figure 2–11). Unlike medical complications, fires are a product of simple physical and chemical properties. Occurrence is guaranteed given the proper combination of factors, but can be almost entirely eliminated by understanding the basic principles of fire risk. The most common risk factor for surgical fire relates to the open delivery of oxygen.
Situations classified as carrying a high risk for a surgical fire are those that
involve an ignition source in close proximity to an oxidizer. The simple chemical combination required for any fire is commonly referred to as the fire triad or fire triangle. The triad is composed of fuel, oxidizer, and ignition source (heat). Table 2–2 lists potential contributors to fires and explosions in the operating room. Surgical fires can be managed and possibly avoided completely by incorporating education, fire drills, preparation, prevention, and response into educational programs provided to operating room personnel.

**TABLE 2–2 Potential contributors to operating room fires and explosions.**

For anesthesia providers, fire prevention education should place a heavy emphasis on the risk relating to the open delivery of oxygen. The Anesthesia
Patient Safety Foundation has developed an educational video and online teaching module that provides fire safety education from the perspective of the anesthesia provider.

Operating room fire drills increase awareness of the fire hazards associated with surgical procedures. In contrast to the typical institutional fire drill, these drills should be specific to the operating room and should place a greater emphasis on the particular risks associated with that setting. For example, consideration should be given to both vertical and horizontal evacuation of surgical patients, movement of patients requiring ventilatory assistance, and unique situations such as prone or lateral positioning and movement of patients who may be fixed in neurosurgical pins.

Surgical fire preparedness can be incorporated into the time-out process of the universal protocol. Team members should be introduced and specific roles agreed upon should a fire erupt. Items needed to properly manage a fire can be assembled or identified beforehand (eg, ensuring the proper endotracheal tube for patients undergoing laser surgery; having water or saline ready on the surgical field; identifying the location of fire extinguishers, gas cutoff valves, and escape routes). A poster or flowsheet to standardize the preparation may be of benefit.

Preventing catastrophic fires in the operating room begins with a strong level of communication among all members of the surgical team. Different aspects of the fire triad are typically under the domain of particular surgical team members. Fuels such as alcohol-based solutions, adhesive removers, and surgical drapes and towels are typically controlled by the circulating nurse. Ignition sources such as electrocautery, lasers, drills, burrs, and light sources for headlamps and laparoscopes are usually controlled by the surgeon. The anesthesia provider maintains control of the oxidizer concentration of oxygen and nitrous oxide. Communication between operating room personnel is exemplified by a surgeon verifying the oxygen concentration before using electrocautery in an airway, or by an anesthesia provider asking the operating room circulator to configure drapes to prevent the accumulation of oxygen in a case that involves use of nasal cannula oxygen delivery.

Administration of oxygen in concentrations of greater than 30% should be guided by clinical presentation of the patient and not solely by protocols or habits. Increased flows of oxygen delivered via nasal cannula or face mask are potentially dangerous. When increased oxygen levels are needed, especially when the surgical site is above the level of the xiphoid, the airway should be secured by either endotracheal tube or supraglottic device.
When the surgical site is in or near the airway and a flammable tube is present, the oxygen concentration should be reduced for a sufficient period of time before use of an ignition device (eg, laser or cautery) to allow reduction of oxygen concentration at the site. Laser airway surgery should incorporate either jet ventilation without an endotracheal tube or the appropriate protective endotracheal tube specific for the wavelength of the laser. Precautions for laser cases are outlined below.

Alcohol-based skin preparations are extremely flammable and require an adequate drying time. Pooling of solutions must be avoided. Large prefilled swabs of alcohol-based solution should be used with caution on the head or neck to avoid both oversaturation of the product and excess flammable waste. Product inserts are a good source of information about these preparations. Surgical gauze and sponges should be moistened with sterile water or saline if used in close proximity to an ignition source.

Should a fire occur in the operating room, it is important to determine whether the fire is located on the patient, in the airway, or elsewhere in the operating room. For fires occurring in the airway, the delivery of fresh gases to the patient must be stopped. Effective means of stopping fresh gases to the patient can be accomplished by turning off flowmeters, disconnecting the circuit from the machine, or disconnecting the circuit from the endotracheal tube. The endotracheal tube should be removed and either sterile water or saline should be poured into the airway to extinguish any burning embers. The sequence of stopping gas flow and removal of the endotracheal tube when fire occurs in the airway is not as important as ensuring that both actions are performed immediately. The two tasks can be accomplished at the same time and by the same individual. If carried out by different team members, the personnel should act without waiting for a predetermined sequence of events. After these actions are carried out, ventilation may be resumed, preferably using room air and avoiding oxygen or nitrous oxide–enriched gases. The tube should be examined for missing pieces. The airway should be reestablished and, if indicated, examined with a fiberoptic bronchoscope. Treatment for smoke inhalation and transfer to a burn center should be considered.

For fires on the patient, the flow of oxidizing gases should be stopped, the surgical drapes removed, and the fire extinguished by water or smothering. The patient should be assessed for injury. If the fire is not immediately extinguished by first attempts, then a carbon dioxide (CO$_2$) fire extinguisher may be used. Further actions may include evacuation of the patient and activation of the nearest alarm pull station. As noted previously, prior to an actual emergency, the
location of fire extinguishers, emergency exits, and fresh gas cutoff valves should be established by the operating room team.

Fires that result in injuries requiring medical treatment or death must be reported to the fire marshal, who retains jurisdiction over the facility. Providers should gain basic familiarity with local reporting standards, which can vary according to location.

Cases in which supplemental oxygen delivery is used and the surgical site is above the xiphoid constitute the most commonly-reported scenario for surgical fires. Frequently, the face or airway is involved, resulting in life-threatening or severely disfiguring injuries. These fires can almost always be avoided by the elimination of the open delivery of oxygen.

**FIRE EXTINGUISHERS**

For fires not suppressed by initial attempts, or those in which evacuation may be hindered by the location or intensity of the fire, the use of a portable fire extinguisher is warranted. A CO₂ extinguisher is safe for fires on the patient in the operating room. CO₂ readily dissipates, is not toxic, and as used in an actual fire is not likely to result in thermal injury. FE-36, a more expensive DuPont product, also can be used.

“A”-rated extinguishers contain water, which makes their use in the operating room problematic because of the presence of electrical equipment. A water mist “AC”-rated extinguisher is excellent but requires time and an adequate volume of mist over multiple attempts to extinguish the fire. Furthermore, these devices are large and difficult to maneuver. Both can be made cheaply in a nonferromagnetic extinguisher, making them the best choice for fires involving magnetic resonance imaging equipment. Halon extinguishers, although very effective, are being phased out because of concerns about depletion of the ozone layer and because of the hypoxic atmosphere that results for rescuers. Halotrons are halon-type extinguishers that may have fewer effects on the ozone layer.

**LASER SAFETY**

Lasers are commonly used in operating rooms and procedure areas. When lasers are used in the airway or for procedures involving the neck and face, the case should be considered high risk for surgical fire and managed as previously discussed. The type of laser (CO₂, neodymium–yttrium aluminum garnet [Nd:YAG], or potassium titanyl phosphate [KTP]), wavelength, and focal length
are all important considerations for the safe operation of medical lasers. Without this vital information, operating room personnel cannot adequately protect themselves or the patient from harm. Before beginning laser surgery, the laser device should be in the operating room, warning signs should be posted on the doors, and protective eyewear should be issued. The anesthesia provider should ensure that the warning signs and eyewear match the labeling on the device as protection is specific to the type of laser. The American National Standards Institute (ANSI) standards specify that eyewear and laser devices must be labeled for the wavelength emitted or protection offered. Some ophthalmologic lasers and vascular mapping lasers have such a short focal length that protective eyewear is not needed. For other devices, protective goggles should be worn by personnel at all times during laser use, and eye protection in the form of either goggles or protective eye patches should be used on the patient.

Laser endotracheal tube selection should be based on laser type and wavelength. The product insert and labeling for each type of tube should be compared to the type of laser used. Tubes less than 4.0 mm in diameter are not compatible with the Nd:YAG or argon laser, and Nd:YAG-compatible tubes are not available in half sizes. Attempts to wrap conventional endotracheal tubes with foil should be avoided. This obsolete method is not approved by either manufacturers or the U.S. Food and Drug Administration, is prone to breaking or unraveling, and does not confer complete protection against laser penetration. Alternatively, jet ventilation without an endotracheal tube can offer a reduced risk of airway fire.

CREW RESOURCE MANAGEMENT: CREATING A CULTURE OF SAFETY IN THE OPERATING ROOM

Crew resource management (CRM) was developed in the aviation industry to promote teamwork and to allow personnel to intervene or call for investigation of any situation thought to be unsafe. Comprising seven principles, its goal is to avoid errors caused by human actions. In the airline model CRM gives any crew member the authority to question situations that fall outside the range of normal practice. Before the implementation of CRM, crew members other that the captain had little or no input on aircraft operations. After CRM was instituted, anyone identifying a safety issue could take steps to ensure adequate resolution of the situation. The benefit of this method in the operating room is clear, given the potential for a deadly mistake to be made.
The seven principles of CRM are (1) adaptability/flexibility, (2) assertiveness, (3) communication, (4) decision making, (5) leadership, (6) analysis, and (7) situational awareness. Adaptability/flexibility refers to the ability to alter a course of action when new information becomes available. For example, if a major blood vessel is unintentionally cut in a routine procedure, the anesthesiologist must recognize that the anesthetic plan has changed and volume resuscitation must be made even in presence of medical conditions that typically contraindicate large-volume fluid administration.

Assertiveness is the willingness and readiness to actively participate, state, and maintain a position until convinced by the facts that other options are better; this requires the initiative and the courage to act. For instance, if a senior and well-respected surgeon tells the anesthesiologist that the patient’s aortic stenosis is not a problem because it is a chronic condition and the procedure will be relatively quick, the anesthesiologist should respond by voicing concerns about the management of the patient and should not proceed until a safe anesthetic and surgical plan have been agreed upon.

Communication is defined simply as the clear and accurate sending and receiving of information, instructions, or commands, and providing useful feedback. Communication is a two-way process and should continue in a loop fashion.

Decision making is the ability to use logical and sound judgment to make decisions based on available information. Decision-making processes are involved when a less experienced clinician seeks out the advice of a more experienced clinician or when a person defers important clinical decisions because of fatigue. Good decision making is based on realization of personal limitations.

Leadership is the ability to direct and coordinate the activities of other crew members and to encourage the crew to work together as a team. Analysis refers to the ability to develop short-term, long-term, and contingency plans, as well as to coordinate, allocate, and monitor crew and operating room resources.

The last, and most important, principle is situational awareness; that is, the accuracy with which a person’s perception of the current environment reflects reality. In the operating room, lack of situational awareness can cost precious minutes, as when readings from a monitor (eg, capnograph or arterial line) suddenly change and the operator focuses on the monitor rather than on the patient, who may have had an embolism. One must decide whether the monitor is correct and the patient is critically ill or the monitor is incorrect and the patient is fine. The problem-solving method utilized should consider both possibilities.
but quickly eliminate one. In this scenario, tunnel vision can result in catastrophic mistakes. Furthermore, if the sampling line has become dislodged and the capnograph indicates low end-tidal CO$_2$, this finding does not exclude the possibility that at the same time a pulmonary embolus may occur, resulting in decreased end-tidal CO$_2$.

If all members of the operating room team apply these seven principles, problems arising from human factors can almost entirely be eliminated. A culture of safety must also exist if the operating room is to be made a safer place. These seven principles serve no purpose when applied in a suppressive operating room environment. Anyone with a concern must be able speak up without fear of repercussion. Chapter 59 provides further discussion of these and other issues relating to patient safety.

**ROLES OF ACCREDITATION AGENCIES & REGULATORY BODIES**

In the United States, the Centers for Medicare and Medicaid Services (CMS) drive many of the mandated policies and procedures carried out by facilities. Efforts to reduce fraudulent claims and disparities in levels of care include the requirement of certification of an accrediting agency such as the Joint Commission, Det Norske Veritas/Germanischer Lloyd (DNV GL), and others.

These accreditation agencies examine processes and procedures and also ensure facilities have appropriate policies in place and that these policies are actually followed. The process may involve a self study submitted by a facility and also a site visit carried out by a team of various medical professionals who inspect a facility, observe operations, and compare observations to the policies and self studies.

Accreditors use laws, codes, and standards to determine if a facility is carrying out care in alignment with current best practices. Anesthesia providers should be apprised that guidelines, recommendations, and advisories typically should not be used by accreditors to determine a best practice. Recommendations, advisories, and guidelines carry a lesser degree of evidence than a standard, and are often educated opinions. Many accreditation agencies maintain policies prohibiting the use of anything other than standards or codes to determine accreditation. Facilities should be cautioned that sometimes the site visitors may issue a citation incorrectly based upon these opinions. All accrediting agencies maintain an appeal process for citations, and if seemingly unwarranted citations are issued, facility administrators may wish to consider
this option.

Site visitors frequently cite anesthesiologists for unlocked anesthesia carts and wearing of certain attire deemed to be an infection risk. However, these citations are often issued without basis. With regard to the locked cart, a more appropriate assessment is whether an anesthesia cart is secure. Since most operating rooms are within an access-controlled suite, this is considered a secure area, and as long as the operating rooms are not left unattended, this scenario should be in compliance with security concerns regarding medications.

Regarding operating room attire, site visitors may reference the Association of Perioperative Registered Nurses (AORN) recommendation for operating room attire, which limits the wearing of personal scrubs and jackets and requires that surgical attire be laundered at the health care facility. However, such a recommendation is merely a professional opinion due to the lack of clinical evidence. If available studies showed a direct relation between hospital laundering and surgical site infection rates, then this would be a standard supported by evidence and not just a recommendation. Organizations such as the American Society of Anesthesiologists (ASA) and the American College of Surgeons (ACS) have position statements and focused committees to assist with clarification when accrediting citations conflict with clinical evidence (or lack thereof).

Codes and regulations are not subject to such opinions, and accreditation citations based upon conflict with a code or regulation are usually valid. However, codes and regulations regularly undergo review and revision, and site accreditation inspectors may not be using the latest version as a reference.

*Safety is best driven by culture*, and attempts to regulate safe behavior by merely creating policy should be avoided. Assuming that health care workers are not seeking to do harm, but rather help others, many errors or safety breaches are likely due to factors such as poor engineering, production pressure, inconsistent processes, or a combination of these. Design improvements and examination and remedy of system faults are far more effective in promoting patient and operating room team safety than creating a policy.

**FUTURE DESIGN OF OPERATING ROOMS**

**Safety Interlock Technology**

Despite heightened awareness of safety factors and increased educational efforts among operating room personnel, harm to patients still occurs at a rate that most
industries and the public deem unacceptably high. Similarly, despite threats of payment withholding, public scoring of medical personnel and hospital systems, provider rating web sites, and punitive legal consequences, the human factors resulting in medical errors have not been entirely eliminated. In the future, safety-engineered designs may assist in the reduction of medical errors. One developing area is the use of interlock devices in the operating room. An interlock device is simply a device that cannot be operated until a defined sequence of events occurs. Anesthesia personnel use interlock technology with anesthesia vaporizers that prevent the use of more than one vaporizer at a time. Expansion of this technology might prevent release of a drug from an automated dispensing device until a barcode is scanned from a patient’s hospital armband or, at a minimum, the patient’s drug allergies have been entered into the machine’s database. Other applications might include an electrosurgical device or laser that could not be used when the Fio₂ content is higher than 30%, thus minimizing the risk of fire. Similarly, computers, monitors, and other devices could be designed to be inoperable until patient identification is confirmed.

**Workflow Design**

Coordinating the activities of surgical personnel, anesthesia providers, and operating room nurses is essential to the day-to-day running of a surgical suite. Clinical directors in facilities ranging from one- or two-room suites to multiroom centers must accommodate surgical procedures of varying durations, requiring varying degrees of surgical skill and efficiency, while allowing for sudden, unplanned, or emergency operations. The need to monitor workflow and analyze data for optimizing scheduling and staffing prompted the development of software systems that anticipate and record the timing of surgical events; these systems are constantly being refined.

Surgical suites are also being designed to improve workflow by incorporating separate induction areas to decrease nonsurgical time spent in operating rooms. Several models exist for induction room design and staffing. Although uncommon in the United States, induction rooms have long been employed in the United Kingdom.

One induction room model uses rotating anesthesia teams. One team is assigned to the first patient of the day; a second team induces anesthesia for the next patient in an adjacent area while the operating room is being turned over. The second team continues caring for that patient after transfer to the operating room, leaving the first team available to induce anesthesia in the third patient as
the operating room is being turned over. The advantage of this model is continuity of care; the disadvantage is the need for two anesthesia teams for every operating room.

Another model uses separate induction and anesthesia teams. The induction team induces anesthesia for all patients on a given day and then transfers care to the anesthesia team, which is assigned to an individual operating room. The advantage of this model is the reduction in anesthesia personnel to staff induction rooms; disadvantages include failure to maintain continuity of care and staffing problems that occur when several patients must undergo induction concurrently. This model can utilize either a separate induction room adjacent to each operating room or one common induction room that services several operating rooms.

The final model uses several staffed operating rooms, one of which is kept open. After the first patient of the day is transferred to the initial room, subsequent patients always proceed to the open room, thus eliminating the wait for room turnover and readiness of personnel. All of these models assume that the increased overhead cost of maintaining additional anesthesia personnel can be justified by the increased surgical productivity.

**Lean Methodology**

Many hospitals are exploring methods of applying *lean methodology* to the surgical environment. Lean examination systems seek to find and eliminate waste and duplicate activity. The most notable company to apply lean methodology is Toyota, which has branded a lean system, the Toyota Production System (TPS), that many health care systems incorporate into their perioperative settings. TPS centers on three concepts: muda, muri, and mura. *Muda* (from the Japanese term for “waste”) is created by *muri* and *mura*. *Muri* is waste created by overburden and production pressure, and *mura* is the waste created by uneven work patterns or lack of load leveling.

TPS also incorporates a set of five processes, referred to as 5S, into improvement efforts. These key processes, which begin with the letter “S” in the original Japanese, have since been translated into synonymous S-words in English.

- **Sort**—Eliminate excess, remove items that are not in use, remove the unneeded or unwanted items.
- **Set in Order**—Arrange items in use for easy selection and in an organized manner. Make the workflow easier and natural.
• **Shine**—The workplace should be clean.
• **Standardize**—Workstations should be alike and variability should be reduced or eliminated. Every process should have a standard.
• **Sustain**—Work should be goal driven; no one should be told to work, but rather all should do the work without asking.

With the elimination of waste and application of the 5S methodology, daily operations should become safer, standardized, and more efficient.

**Radio Frequency Identification (RFID)**

Radio frequency identification (RFID) technology utilizes a chip with a small transmitter whose signal is read by a reader; each chip yields a unique signal. The technology has many potential applications in the perioperative environment. Using RFID in employee identification (ID) badges could enable surgical control rooms to keep track of nursing, surgical faculty, and anesthesia personnel, obviating the need for paging systems and telephony to establish the location of key personnel. Incorporating the technology in patient ID bands and hospital gurneys could allow a patient’s flow to be tracked through an entire facility. The ability to project an identifying signal to hospital systems would offer an additional degree of safety for patients unable to communicate with hospital personnel. Finally, RFID could be incorporated into surgical instruments and sponges, allowing surgical counts to be performed by identification of the objects as they are passed on and off the surgical field. In the event that counts are mismatched, a wand could then be placed over the patient to screen for retained objects.

**CASE DISCUSSION**

**Monitored Anesthesia Care with Oxygen Supplementation**

You are asked to provide monitored anesthesia care for a patient undergoing simple removal of a lesion on the cheek. The patient is morbidly obese and has a history of sleep apnea. He states, “It bothers me when people are working on my face,” and indicates that he does not want to remember anything about the surgery. The surgeon assures you the procedure will not last more than 5 minutes. The patient’s
partner mentions that they are from out of town and have made flight arrangements to return home soon after the procedure.

**What features of this case indicate a high risk for surgical fire?**

Patients with a clinical history of obstructive sleep apnea usually have a sensitivity to sedating medications, especially opioids. Administration of even small doses of opioids may lead to upper airway obstruction and hypoventilation, resulting in hypercapnia and hypoxemia. In obese patients, upper airway obstruction, hypoventilation, and decreased functional reserve capacity may result in rapid oxygen desaturation. Most anesthesia providers respond by increasing the amount of oxygen supplementation delivered via face mask or nasal cannula. Open delivery of oxygen in concentrations greater than 30% is one of the elements of the fire triad. Another consideration is the anatomical location of the procedure. A location above the xiphoid process in this patient would place an ignition source (if used) in close proximity to the open delivery of an oxidizer.

**What is the safest manner in which to proceed?**

There are three strategies that can be implemented to improve safety in this scenario: avoid oxygen supplementation, secure the airway with an endotracheal tube or supraglottic device, or avoid use of an ignition source.

**Are there any concerns relating to airway management or selection of the delivery device?**

As previously noted, the patient is likely to manifest airway changes associated with obstructive sleep apnea and obesity. Selection of a delivery device should take into consideration the need to prevent the open delivery of oxygen.

**How would the length of the procedure affect the management of anesthesia?**

Practically speaking, if the patient requires a lengthy procedure, local anesthetics may wear off; the cumulative dose of narcotics provided may exacerbate the patient’s obstructive sleep apnea and increase recovery time. Additionally, more complex surgical excision may result in bleeding requiring the use of cautery.

**Does the patient’s expectation of discharge soon after the**
**procedure affect your anesthesia plans?**

The expectation of an accelerated recovery period may not be feasible if the patient requires general anesthesia or significant amounts of opioids. The American Society of Anesthesiologists (ASA) has published a practice advisory providing direction for the safe postoperative assessment and discharge of patients with obstructive sleep apnea. See [www.asahq.org](http://www.asahq.org).

**What if the surgeon thinks your plans are “overkill”?**

The first and most effective means for conflict resolution is to communicate your specific concerns to the surgeon. If this fails, the procedure must not be allowed to proceed as long as any team member has a legitimate safety concern. Many ASA safety-related guidelines and advisories are also endorsed by professional societies such as the American College of Surgeons (ACS). The anesthesiologist should also gain familiarity with a facility’s methods of dispute resolution before an event occurs.

The Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) has created an educational program, the Fundamental Use of Surgical Energy (FUSE) which is an educational and certification program for all surgical personnel. The educational content is (as of 2018) available without charge, and the certification and continuing education process is available for a reasonable fee. The course covers all types of electrical surgical units in the operating room and makes recommendation for their correct use and safety
Breathing Systems

KEY CONCEPTS

1. Because insufflation avoids any direct patient contact, there is no rebreathing of exhaled gases if the flow is high enough. Ventilation cannot be controlled with this technique, however, and the inspired gas contains unpredictable amounts of entrained atmospheric air.

2. Long breathing tubes with high compliance increase the difference between the volume of gas delivered to a circuit by a reservoir bag or ventilator and the volume actually delivered to the patient.

3. The adjustable pressure-limiting (APL) valve should be fully open during spontaneous ventilation so that circuit pressure remains negligible throughout inspiration and expiration.

4. Because a fresh gas flow equal to minute ventilation is sufficient to prevent rebreathing, the Mapleson A design is the most efficient Mapleson circuit for spontaneous ventilation.

5. The Mapleson D circuit is efficient during controlled ventilation, because fresh gas flow forces alveolar air away from the patient and toward the APL valve.

6. Increasing the hardness of soda lime by adding silica minimizes the risk of inhalation of sodium hydroxide dust and also decreases resistance of gas flow.

7. Malfunction of either unidirectional valve in a circle system may allow rebreathing of carbon dioxide, resulting in hypercapnia.

8. With an absorber, the circle system prevents rebreathing of carbon dioxide at fresh gas flows that are considered low (fresh gas flow ≤1 L) or even fresh gas flows equal to the uptake of anesthetic gases and oxygen by the patient and the circuit itself (closed-system anesthesia).

9. Because of the unidirectional valves, apparatus dead space in a circle
Breathing systems provide the final conduit for the delivery of anesthetic gases to the patient. Breathing circuits link a patient to an anesthesia machine (Figure 3–1). Many different circuit designs have been developed, each with varying degrees of efficiency, convenience, and complexity. This chapter reviews the most important breathing systems: insufflation, draw-over, Mapleson circuits, the circle system, and resuscitation systems.

**FIGURE 3–1** The relationship between the patient, the breathing system, and the anesthesia machine.

Most classifications of breathing systems artificially consolidate functional characteristics (eg, the extent of rebreathing) with physical characteristics (eg, the presence of unidirectional valves). Because these seemingly contradictory classifications (eg, open, closed, semiopen, semiclosed) often tend to confuse rather than aid understanding, they are avoided in this discussion.
INSUFFLATION

The term *insufflation* usually denotes the blowing of anesthetic gases across a patient’s face. Although insufflation is categorized as a breathing system, it is perhaps better considered a technique that avoids direct connection between a breathing circuit and a patient’s airway. Because children often resist the placement of a face mask (or an intravenous line), insufflation is particularly valuable during inductions with inhalation anesthetics in children (Figure 3–2). It is useful in other situations as well. Carbon dioxide accumulation under head and neck draping is a hazard of ophthalmic surgery performed with local anesthesia. Insufflation of air across the patient’s face at a high flow rate (>10 L/min) avoids this problem, while not increasing the risk of fire from accumulation of oxygen (Figure 3–3). Because insufflation avoids any direct patient contact, there is no rebreathing of exhaled gases if the flow is high enough. Ventilation cannot be controlled with this technique, however, and the inspired gas contains unpredictable amounts of entrained atmospheric air.

**FIGURE 3–2** Insufflation of an anesthetic agent across a child’s face during induction.
Insufflation can also be used to maintain arterial oxygenation during brief periods of apnea (eg, during bronchoscopy). Instead of blowing gases across the face, oxygen is directed into the lungs through a device placed in the trachea.

OPEN-DROP ANESTHESIA

Although open-drop anesthesia is not used in modern medicine, its historic significance warrants a brief description here. A highly volatile anesthetic—historically, ether or chloroform—was dripped onto a gauze-covered mask (Schimmelbusch mask) applied to the patient’s face. As the patient inhales, air passes through the gauze, vaporizing the liquid agent, and carrying high concentrations of anesthetic to the patient. The vaporization lowers mask temperature, resulting in moisture condensation and a drop in anesthetic vapor pressure (vapor pressure is proportional to temperature).

A modern derivative of open-drop anesthesia utilizes draw-over vaporizers that depend on the patient’s inspiratory efforts to draw ambient air through a vaporization chamber. This technique may be used in locations or situations in which compressed medical gases are unavailable (eg, battlefields).
DRAW-OVER ANESTHESIA

Draw-over devices have nonrebreathing circuits that use ambient air as the carrier gas, although supplemental oxygen can be used, if available. The devices can be fitted with connections and equipment that allow intermittent positive-pressure ventilation (IPPV) and passive scavenging, as well as continuous positive airway pressure (CPAP) and positive end-expiratory pressure (PEEP).

In its most basic application (Figure 3–4), air is drawn through a low-resistance vaporizer as the patient inspires. Patients spontaneously breathing room air and a potent halogenated agent often manifest an oxygen saturation (SpO₂) less than 90%, a situation treated with IPPV, supplemental oxygen, or both. The fraction of inspired oxygen (FiO₂) can be supplemented using an open-ended reservoir tube of about 400 mL, attached to a T-piece at the upstream side of the vaporizer. Across the clinical range of tidal volume and respiratory rate, an oxygen flow rate of 1 L/min gives an FiO₂ of 30% to 40%, or with 4 L/min, an FiO₂ of 60% to 80%. There are several commercial draw-over systems available that share common properties (Table 3–1).

The greatest advantage of draw-over systems is their simplicity and portability, making them useful in locations where compressed gases or ventilators are not available.

**MAPLESON CIRCUITS**

The insufflation and draw-over systems have several disadvantages: poor control of inspired gas concentration (and, therefore, poor control of depth of anesthesia), mechanical drawbacks during head and neck surgery, and pollution of the operating room with large volumes of waste gas. The Mapleson systems solve some of these problems by incorporating additional components (breathing tubes, fresh gas inlets, adjustable pressure-limiting [APL] valves, and reservoir bags) into the breathing circuit. The relative location of these components determines circuit performance and is the basis of the Mapleson classification (Table 3–2).

**TABLE 3–2** Classification and characteristics of Mapleson circuits.
Components of Mapleson Circuits

A. Breathing Tubes

Corrugated tubes—made of rubber (reusable) or plastic (disposable)—connect the components of the Mapleson circuit to the patient (Figure 3–5). The large diameter of the tubes (22 mm) creates a low-resistance pathway and a potential reservoir for anesthetic gases. To minimize fresh gas flow requirements, the volume of gas within the breathing tubes in most Mapleson circuits should be at least as great as the patient’s tidal volume.
Components of a Mapleson circuit. APL, adjustable pressure-limiting (valve).

The compliance of the breathing tubes largely determines the compliance of the circuit. (Compliance is defined as the change of volume produced by a change in pressure.) Long breathing tubes with high compliance increase the difference between the volume of gas delivered to a circuit by a reservoir bag or ventilator and the volume actually delivered to the patient. For example, if a breathing circuit with a compliance of 8 mL gas/cm H₂O is pressurized during delivery of a tidal volume to 20 cm H₂O, 160 mL of the tidal volume will be lost to the circuit. The 160 mL represent a combination of gas compression and breathing-tube expansion. This is an important consideration in any circuit delivering positive-pressure ventilation through breathing tubes (eg, circle systems).

B. Fresh Gas Inlet
Gases (anesthetics mixed with oxygen or air) from the anesthesia machine continuously enter the circuit through the fresh gas inlet. As discussed below, the relative position of the fresh gas inlet is a key differentiating factor among Mapleson circuits.

C. Adjustable Pressure-Limiting Valve (Pressure-Relief Valve, Pop-Off Valve)
As anesthetic gases enter the breathing circuit, pressure will rise if the gas inflow

FIGURE 3–5

[Diagram of a Mapleson circuit showing components including fresh gas inlet, breathing tube, reservoir, and APL valve.]
is greater than the combined uptake of the patient and the circuit. Gases may exit the circuit through an APL valve, controlling this pressure buildup. Exiting gases enter the operating room atmosphere or, preferably, a waste-gas scavenging system. All APL valves allow a variable pressure threshold for venting. The APL valve should be fully open during spontaneous ventilation so that circuit pressure remains negligible throughout inspiration and expiration. Assisted and controlled ventilation require positive pressure during inspiration to expand the lungs. Partial closure of the APL valve limits gas exit, permitting positive circuit pressures during reservoir bag compressions.

D. Reservoir Bag (Breathing Bag)
Reservoir bags function as a reservoir of anesthetic gas and a method of generating positive-pressure ventilation. They are designed to increase in compliance as their volume increases. Three distinct phases of reservoir bag filling are recognizable (Figure 3–6). After the nominal 3-L capacity of an adult reservoir bag is achieved (phase I), pressure rises rapidly to a peak (phase II). Further increases in volume result in a plateau or even a slight decrease in pressure (phase III). This ceiling effect provides some minimal protection of the patient’s lungs against high airway pressures, if the APL valve is unintentionally left in the closed position while fresh gas continues to flow into the circuit.
FIGURE 3–6 The increasing compliance and elasticity of breathing bags as demonstrated by three phases of filling (see text). (Reproduced with permission from Johnstone RE, Smith TC. Rebreathing bags as pressure limiting devices. Anesthesiology. 1973 Feb;38(2):192-194)

Performance Characteristics of Mapleson Circuits

Mapleson circuits are lightweight, inexpensive, and simple. Breathing-circuit efficiency is measured by the fresh gas flow required to reduce CO₂ rebreathing to a negligible value. Because there are no unidirectional valves or CO₂ absorption in Mapleson circuits, rebreathing is prevented by adequate fresh gas flow into the circuit and venting exhaled gas through the APL valve before inspiration. There is usually some rebreathing in any Mapleson circuit. The total fresh gas flow into the circuit controls the amount. To attenuate rebreathing, high fresh gas flows are required. The APL valve in Mapleson A, B, and C circuits is located near the face mask, and the reservoir bag is located at the opposite end of the circuit.

Reexamine the drawing of a Mapleson A circuit in Figure 3–5. During spontaneous ventilation, alveolar gas containing CO₂ will be exhaled into the
breathing tube or directly vented through an open APL valve. Before inhalation occurs, if the fresh gas flow exceeds alveolar minute ventilation, the inflow of fresh gas will force the alveolar gas remaining in the breathing tube to exit from the APL valve. If the breathing-tube volume is equal to or greater than the patient’s tidal volume, the next inspiration will contain only fresh gas. Because a fresh gas flow equal to minute ventilation is sufficient to prevent rebreathing, the Mapleson A design is the most efficient Mapleson circuit for spontaneous ventilation.

Positive pressure during controlled ventilation, however, requires a partially closed APL valve. Although some alveolar and fresh gas exits through the valve during inspiration, no gas is vented during expiration, since the exhaled gas stagnates during the expiratory phase of positive-pressure ventilation. As a result, very high fresh gas flows (greater than three times minute ventilation) are required to prevent rebreathing with a Mapleson A circuit during controlled ventilation. Fresh gas flows are conveniently available because the fresh gas inlet is in close proximity to the APL valve in a Mapleson B circuit.

Interchanging the position of the APL valve and the fresh gas inlet transforms a Mapleson A into a Mapleson D circuit (Table 3–2). The Mapleson D circuit is efficient during controlled ventilation, since fresh gas flow forces alveolar air away from the patient and toward the APL valve. Thus, simply moving components completely alters the fresh gas requirements of the Mapleson circuits.

The Bain circuit is a coaxial version of the Mapleson D system that incorporates the fresh gas inlet tubing inside the breathing tube (Figure 3–7). This modification decreases the circuit’s bulk and retains heat and humidity better than a conventional Mapleson D circuit as a result of partial warming of the inspiratory gas by countercurrent exchange with the warmer expired gases. A disadvantage of this coaxial circuit is the possibility of kinking or disconnection of the fresh gas inlet tubing. Periodic inspection of the inner tubing is mandatory to identify this complication; if unrecognized, either of these mishaps could result in significant rebreathing of exhaled gas.
**FIGURE 3–7** A Bain circuit is a Mapleson D circuit design with the fresh gas tubing inside the corrugated breathing tube. APL, adjustable pressure-limiting (valve). (Reproduced with permission from Bain JA, Spoerel WE. Flow requirements for a modified Mapleson D system during controlled ventilation. *Can Anaesth Soc J*. 1973 Sep;20(5):629-636.)

**THE CIRCLE SYSTEM**

Although Mapleson circuits overcome some of the disadvantages of the insufflation and draw-over systems, the high fresh gas flows required to prevent rebreathing of CO$_2$ result in waste of anesthetic agent, pollution of the operating room environment, and loss of patient heat and humidity (Table 3–3). In an attempt to avoid these problems, the circle system adds more components to the breathing system.

\(^1\)These properties depend on the rate of fresh gas flow.

The components of a circle system include: (1) a CO\(_2\) absorber containing CO\(_2\) absorbent; (2) a fresh gas inlet; (3) an inspiratory unidirectional valve and inspiratory breathing tube; (4) a Y-connector; (5) an expiratory unidirectional valve and expiratory breathing tube; (6) an APL valve; and (7) a reservoir (Figure 3–8).
Components of the Circle System

A. Carbon Dioxide Absorber and the Absorbent

Rebreathing alveolar gas conserves heat and humidity. However, the CO$_2$ in exhaled gas must be eliminated to prevent hypercapnia. CO$_2$ chemically combines with water to form carbonic acid. CO$_2$ absorbents (eg, soda lime or calcium hydroxide lime) contain hydroxide salts that are capable of neutralizing carbonic acid. Reaction end products include heat (the heat of neutralization), water, and calcium carbonate. **Soda lime** is an absorbent and is capable of absorbing up to 23 L of CO$_2$ per 100 g of absorbent. It consists primarily of calcium hydroxide (80%), along with sodium hydroxide, water, and a small amount of potassium hydroxide. Its reactions are as follows:

\[
\text{CO}_2 + \text{H}_2\text{O} \rightarrow \text{H}_2\text{CO}_3
\]

\[
\text{H}_2\text{CO}_3 + 2\text{NaOH} \rightarrow \text{Na}_2\text{CO}_3 + 2\text{H}_2\text{O} + \text{Heat}
\]

(a fast reaction)

\[
\text{Na}_2\text{CO}_3 + \text{Ca(OH)}_2 \rightarrow \text{CaCO}_3 + 2\text{NaOH}
\]
(a slow reaction)

Note that the water and sodium hydroxide initially required are regenerated. Another absorbent, barium hydroxide lime, is no longer used due to the possible increased hazard of fire in the breathing system.

A pH indicator dye (eg, ethyl violet) changes color from white to purple as a consequence of increasing hydrogen ion concentration and absorbent exhaustion. Absorbent should be replaced when 50% to 70% has changed color. Although exhausted granules may revert to their original color if rested, no significant recovery of absorptive capacity occurs. Granule size is a compromise between the higher absorptive surface area of small granules and the lower resistance to gas flow of larger granules. The granules commonly used as CO₂ absorbent are between 4 and 8 mesh; the mesh number corresponds to the number of holes per square inch of a screen. The hydroxide salts are irritating to the skin and mucous membranes. Increasing the hardness of soda lime by adding silica minimizes the risk of inhalation of sodium hydroxide dust and also decreases resistance of gas flow. Additional water is added to absorbent during packaging to provide optimal conditions for carbonic acid formation. Commercial soda lime has a water content of 14% to 19%.

Absorbent granules can absorb and later release medically active amounts of volatile anesthetic. This property can be responsible for modest delays of induction or emergence. The drier the soda lime, the more likely it will absorb and degrade volatile anesthetics. Volatile anesthetics can be broken down to carbon monoxide by dry absorbent (eg, sodium or potassium hydroxide) sufficiently to cause clinically measureable carboxyhemoglobin concentrations. The formation of carbon monoxide is greatest with desflurane; with sevoflurane, it occurs at a higher temperature.

Amsorb is a CO₂ absorbent consisting of calcium hydroxide and calcium chloride (with calcium sulfate and polyvinylpyrrolidone added to increase hardness). It possesses greater inertness than soda lime, resulting in less degradation of volatile anesthetics (eg, sevoflurane into compound A or desflurane into carbon monoxide).

Compound A is one of the byproducts of degradation of sevoflurane by absorbent. Higher concentrations of sevoflurane, prolonged exposure, and low-flow anesthetic technique seem to increase the formation of compound A. Compound A has been shown to produce nephrotoxicity in animals but has never been associated with ill effects in humans.

The granules of absorbent are contained within one or two canisters that fit
snugly between a head and base plate. Together, this unit is called an absorber (Figure 3–9). Although bulky, double canisters permit more complete CO₂ absorption, require less frequent absorbent changes, and lower gas flow resistance. To ensure complete absorption, a patient’s tidal volume should not exceed the air space between absorbent granules, which is roughly equal to 50% of the absorber’s capacity. Indicator dye color is monitored through the absorber’s transparent walls. Absorbent exhaustion typically occurs first where exhaled gas enters the absorber and along the canister’s smooth inner walls. Channeling through areas of loosely packed granules is minimized by a baffle system, which directs gas flow through the center, thereby allowing greater utilization of the absorbent. A trap at the base of the absorber collects dust and moisture.
FIGURE 3–9 A carbon dioxide absorber.

B. Unidirectional Valves
Unidirectional valves, which function as check valves, contain a ceramic or mica disk resting horizontally on an annular valve seat (Figure 3–10). Forward flow displaces the disk upward, permitting the gas to proceed through the circuit. Reverse flow pushes the disk against its seat, preventing reflux. Valve incompetence is usually due to a warped disk or seat irregularities. The expiratory valve is exposed to the humidity of alveolar gas. Condensation and resultant moisture formation may prevent upward displacement of the disks,
resulting in incomplete escape of expired gases and rebreathing.

**FIGURE 3–10** A unidirectional valve.

Inhalation opens the inspiratory valve, allowing the patient to breathe a mixture of fresh and exhaled gas that has passed through the CO$_2$ absorber. Simultaneously, the expiratory valve closes to prevent rebreathing of exhaled gas that still contains CO$_2$. The subsequent flow of gas away from the patient during exhalation opens the expiratory valve. This gas is vented through the APL valve or rebreathed by the patient after passing through the absorber. Closure of the inspiratory valve during exhalation prevents expiratory gas from mixing with fresh gas in the inspiratory limb. Malfunction of either unidirectional valve may allow rebreathing of CO$_2$, resulting in hypercapnia.

**Optimization of Circle System Design**

Although the major components of the circle system (unidirectional valves, fresh gas inlet, APL valve, CO$_2$ absorber, and a reservoir bag) can be placed in several configurations, the following arrangement is preferred (*Figure 3–8*):

- Unidirectional valves are relatively close to the patient to prevent backflow into the inspiratory limb if a circuit leak develops. However, unidirectional valves are not placed in the Y-piece, as that makes it difficult to confirm or
maintain proper orientation and intraoperative function.

- The fresh gas inlet is placed between the absorber and the inspiratory valve. Positioning it downstream from the inspiratory valve would allow fresh gas to bypass the patient during exhalation and be wasted. Fresh gas introduced between the expiratory valve and the absorber would be diluted by recirculating gas. Furthermore, inhalation anesthetics may be absorbed or released by soda lime granules, thus slowing induction and emergence.

- The APL valve is usually placed between the absorber and the expiratory valve and close to the reservoir bag (Figure 3–11). Positioning of the APL valve in this location (ie, before the absorber) helps to conserve absorption capacity and minimizes the venting of fresh gas. The APL valve regulates the flow of gas from the expiratory limb of the circuit into the gas scavenger system.

- Resistance to exhalation is decreased by locating the reservoir bag in the expiratory limb.
Performance Characteristics of the Circle System

A. Fresh Gas Requirement

With an absorber, the circle system prevents rebreathing of CO₂ at reduced fresh gas flows (≤1 L) or even fresh gas flows equal to the uptake of anesthetic gases and oxygen by the patient and the circuit itself (closed-system anesthesia). At fresh gas flows greater than 5 L/min, rebreathing is so minimal that a CO₂ absorber is usually unnecessary.

With low fresh gas flows, concentrations of oxygen and inhalation anesthetics can vary markedly between fresh gas (ie, gas in the fresh gas inlet) and inspired gas (ie, gas in the inspiratory limb of the breathing tubes). The latter is a mixture of fresh gas and exhaled gas that has passed through the absorber. The greater the fresh gas flow rate, the less time it will take for a change in fresh gas anesthetic concentration to be reflected in a change in inspired gas anesthetic concentration. Higher flows speed induction and recovery, compensate for leaks in the circuit, and decrease the risks of unanticipated gas mixtures.

B. Dead Space

That part of a tidal volume that does not undergo alveolar ventilation is referred to as dead space. Thus, any increase in dead space must be accompanied by a corresponding increase in tidal volume, if alveolar ventilation is to remain unchanged. Because of the unidirectional valves, apparatus dead space in a circle system is limited to the area distal to the point of inspiratory and expiratory gas mixing at the Y-piece. Unlike Mapleson circuits, the circle system tube length does not affect dead space. Like Mapleson circuits, length does affect circuit compliance and thus the amount of tidal volume lost to the circuit during positive-pressure ventilation. Pediatric circle systems may have both a septum dividing the inspiratory and expiratory gas in the Y-piece and low-compliance breathing tubes to further reduce dead space, and are lighter in weight.

C. Resistance

The unidirectional valves and absorber increase circle system resistance, especially at high respiratory rates and large tidal volumes. Nonetheless, even premature neonates can be successfully ventilated using a circle system.

D. Humidity and Heat Conservation

Medical gas delivery systems supply dehumidified gases to the anesthesia circuit
at room temperature. Exhaled gas, on the other hand, is saturated with water at body temperature. Therefore, the heat and humidity of inspired gas depend on the relative proportion of rebreathed gas to fresh gas. High flows are accompanied by low relative humidity, whereas low flows allow greater water saturation. Absorbent granules provide a significant source of heat and moisture in the circle system.

E. Bacterial Contamination
The minimal risk of microorganism retention in circle system components could theoretically lead to respiratory infections in subsequent patients. For this reason, bacterial filters are sometimes incorporated into the inspiratory or expiratory breathing tubes or at the Y-piece.

Disadvantages of the Circle System
Although most of the problems of Mapleson circuits are solved by the circle system, the improvements have led to other disadvantages: greater size and less portability; increased complexity, resulting in a higher risk of disconnection or malfunction; complications related to use of absorbent; and the difficulty of predicting inspired gas concentrations during low fresh gas flows.

RESUSCITATION BREATHING SYSTEMS
Resuscitation bags (AMBU bags or bag-mask units) are commonly used for emergency ventilation because of their simplicity, portability, and ability to deliver almost 100% oxygen (Figure 3–12). A resuscitator is unlike a Mapleson circuit or a circle system because it contains a nonrebreathing valve. (Remember that a Mapleson system is considered valveless even though it contains an APL valve, whereas a circle system contains unidirectional valves that direct flow through an absorber but allow rebreathing of exhaled gases.)
FIGURE 3–12  The Laerdal resuscitator. (Reproduced with permission from Laerdal Medical Corp.)

High concentrations of oxygen can be delivered to a mask or tracheal tube during spontaneous or controlled ventilation if a source of high fresh gas flow is connected to the inlet nipple. The patient valve opens during controlled or spontaneous inspiration to allow gas flow from the ventilation bag to the patient. Rebreathing is prevented by venting exhaled gas to the atmosphere through exhalation ports in this valve. The compressible, self-refilling ventilation bag also contains an intake valve. This valve closes during bag compression, permitting positive-pressure ventilation. The bag is refilled by flow through the fresh gas inlet and across the intake valve. Connecting a reservoir to the intake valve helps prevent the entrainment of room air. The reservoir valve assembly is really two unidirectional valves: the inlet valve and the outlet valve. The inlet valve allows ambient air to enter the ventilation bag if fresh gas flow is inadequate to maintain reservoir filling. Positive pressure in the reservoir bag opens the outlet valve, which vents oxygen if fresh gas flow is excessive.

There are several disadvantages to resuscitator breathing systems. First, they require high fresh gas flows to achieve a high FiO₂. FiO₂ is directly proportional to the oxygen concentration and flow rate of the gas mixture supplied to the resuscitator (usually 100% oxygen) and inversely proportional to the minute ventilation delivered to the patient. Finally, although a normally functioning patient valve has low resistance to inspiration and expiration, exhaled moisture can cause valve sticking.

CASE DISCUSSION

Unexplained Light Anesthesia
An extremely obese but otherwise healthy 5-year-old girl presents for inguinal hernia repair. After uneventful induction of general anesthesia and tracheal intubation, the patient is placed on a ventilator set to deliver a tidal volume of 6 mL/kg at a rate of 16 breaths/min. Despite delivery of high concentrations of sevoflurane in 50% nitrous oxide, tachycardia (145 beats/min) and mild hypertension (144/94 mm Hg) are noted. To increase anesthetic depth, fentanyl (3 mcg/kg) is administered. Heart rate and blood pressure continue to rise and are
accompanied by frequent premature ventricular contractions.

What should be considered in the differential diagnosis of this patient’s cardiovascular changes?

The combination of tachycardia and hypertension during general anesthesia should always alert the anesthesiologist to the possibility of hypercapnia or hypoxia, both of which produce signs of increased sympathetic activity. These life-threatening conditions should be quickly and immediately ruled out by end-tidal CO₂ monitoring, pulse oximetry, or arterial blood gas analysis.

A common cause of intraoperative tachycardia and hypertension is an inadequate level of anesthesia. Normally, this is confirmed by movement. If the patient is paralyzed, however, there are few reliable indicators of light anesthesia. The lack of a response to a dose of an opioid should alert the anesthesiologist to the possibility of other, perhaps more serious, causes.

Malignant hyperthermia is rare but must be considered in cases of unexplained tachycardia, especially if accompanied by premature atrial or ventricular contractions. Certain drugs used in anesthesia (eg, ketamine, ephedrine) stimulate the sympathetic nervous system and can produce or exacerbate tachycardia and hypertension. Diabetic patients who become hypoglycemic from administration of insulin or long-acting oral hypoglycemic agents can have similar cardiovascular changes. Other endocrine abnormalities (eg, pheochromocytoma, thyroid storm, carcinoid) should also be considered.

Could any of these problems be related to an equipment malfunction?

Gas analysis can confirm the delivery of anesthetic gases to the patient. A misconnection of the ventilator could result in hypoxia or hypercapnia. In addition, a malfunctioning unidirectional valve will increase circuit dead space and allow rebreathing of expired CO₂. Soda lime exhaustion could also lead to rebreathing in the presence of a low fresh gas flow. Rebreathing of CO₂ can be detected during the inspiratory phase on a capnograph. If rebreathing appears to be due to an equipment malfunction, the patient should be disconnected from the anesthesia machine and ventilated with a resuscitation bag until repairs are possible.

What are some other consequences of hypercapnia?
Hypercapnia has a multitude of effects, most of them masked by general anesthesia. Cerebral blood flow increases proportionately with arterial CO$_2$. This effect is dangerous in patients with increased intracranial pressure (eg, from brain tumor). Extremely high levels of CO$_2$ (>80 mm Hg) can cause unconsciousness related to a fall in cerebrospinal fluid pH. CO$_2$ depresses the myocardium, but this direct effect is usually overshadowed by activation of the sympathetic nervous system. During general anesthesia, hypercapnia usually results in an increased cardiac output, an elevation in arterial blood pressure, and a propensity toward arrhythmias.

Elevated serum CO$_2$ concentrations can overwhelm the blood’s buffering capacity, leading to respiratory acidosis. This causes other cations such as Ca$^{2+}$ and K$^+$ to shift extracellularly. Acidosis also shifts the oxyhemoglobin dissociation curve to the right.

Carbon dioxide is a powerful respiratory stimulant. In fact, for each mm Hg rise of Paco$_2$ above baseline, normal awake subjects increase their minute ventilation by about 2 to 3 L/min. General anesthesia markedly decreases this response, and paralysis eliminates it. Finally, severe hypercapnia can produce hypoxia by displacement of oxygen from alveoli.

SUGGESTED READINGS
The Anesthesia Workstation

KEY CONCEPTS

1. Equipment-related adverse outcomes are rarely due to device malfunction or failure; rather, misuse of anesthesia gas delivery systems is three times more prevalent among closed claims. An operator’s lack of familiarity with the equipment, an operator’s failure to verify machine function prior to use, or both are the most frequent causes. Such mishaps accounted for about 1% of cases in the ASA Closed Claims Project database from 1990 to 2011.

2. The anesthesia machine receives medical gases from a gas supply, controls the flow and reduces the pressure of desired gases to a safe level, vaporizes volatile anesthetics into the final gas mixture, and delivers the gases to a breathing circuit that is connected to the patient’s airway. A mechanical ventilator attaches to the breathing circuit but can be excluded with a switch during spontaneous or manual (bag) ventilation.

3. Whereas the oxygen supply can pass directly to its flow control valve, nitrous oxide, air, and other gases must first pass through safety devices before reaching their respective flow control valves. These devices permit the flow of other gases only if there is sufficient oxygen pressure in the safety device and help prevent accidental delivery of a hypoxic mixture in the event of oxygen supply failure.

4. Another safety feature of anesthesia machines is a linkage of the nitrous oxide gas flow to the oxygen gas flow; this arrangement helps ensure a minimum oxygen concentration of 25%.

5. All modern vaporizers are agent specific and temperature corrected, capable of delivering a constant concentration of agent regardless of temperature changes or flow through the vaporizer.

6. A rise in airway pressure may signal worsening pulmonary compliance,
an increase in tidal volume, or an obstruction in the breathing circuit, tracheal tube, or the patient’s airway. A drop in pressure may indicate an improvement in compliance, a decrease in tidal volume, or a leak in the circuit.

7 Traditionally ventilators on anesthesia machines have a double-circuit system design and are pneumatically powered and electronically controlled. Newer machines also incorporate microprocessor controls and sophisticated pressure and flow sensors. Some anesthesia machines have ventilators that use a single-circuit piston design.

8 The major advantage of a piston ventilator is its ability to deliver accurate tidal volumes to patients with very poor lung compliance and to very small patients.

9 Whenever a ventilator is used, “disconnect alarms” must be passively activated. Anesthesia workstations should have at least three disconnect alarms: low peak inspiratory pressure, low exhaled tidal volume, and low exhaled carbon dioxide.

10 Because the ventilator’s spill valve is closed during inspiration, fresh gas flow from the machine’s common gas outlet normally contributes to the tidal volume delivered to the patient.

11 Use of the oxygen flush valve during the inspiratory cycle of a ventilator must be avoided because the ventilator spill valve will be closed and the adjustable pressure-limiting (APL) valve is excluded; the surge of oxygen (600–1200 mL/s) and circuit pressure will be transferred to the patient’s lungs.

12 Large discrepancies between the set and actual tidal volume are often observed in the operating room during volume-controlled ventilation. Causes include breathing circuit compliance, gas compression, ventilator–fresh gas flow coupling, and leaks in the anesthesia machine, the breathing circuit, or the patient’s airway.

13 Waste-gas scavengers dispose of gases that have been vented from the breathing circuit by the APL valve and ventilator spill valve. Pollution of the operating room environment with anesthetic gases may pose a health hazard to surgical personnel.

14 A routine inspection of anesthesia equipment before each use increases operator familiarity and confirms proper functioning. The U.S. Food and Drug Administration has made available a generic checkout procedure for anesthesia gas machines and breathing systems.
No piece of equipment is more intimately associated with the practice of anesthesiology than the anesthesia machine (Figure 4–1). On the most basic level, the anesthesiologist uses the anesthesia machine to control the patient’s ventilation, ensure oxygen delivery, and administer inhalation anesthetics. Proper functioning of the machine is crucial for patient safety. Modern anesthesia machines have become very sophisticated, incorporating many built-in safety features and devices, monitors, and multiple microprocessors that can integrate and monitor all components. Moreover, modular machine designs allow a variety of configurations and features within the same product line. The term anesthesia workstation is therefore often used for modern anesthesia machines. While two manufacturers of anesthesia machines in the United States, GE Healthcare (Datex-Ohmeda) and Dräger Medical, have the largest market share, other manufacturers (eg, Mindray, Maquet, Spacelabs) also produce anesthesia delivery systems. Anesthesia providers should be familiar with the operations manuals of all varieties of machines present in their clinical practice.

Much progress has been made in reducing the number of adverse outcomes arising from anesthetic gas delivery. Equipment-related adverse outcomes are rarely due to device malfunction or failure; rather, misuse of anesthesia gas
delivery systems is three times more prevalent among closed claims. Equipment misuse includes errors in preparation, maintenance, or deployment of a device. Preventable anesthetic mishaps are frequently traced to an operator’s lack of familiarity with the equipment, an operator’s failure to verify machine function prior to use, or both. Such mishaps accounted for about 1% of cases in the American Society of Anesthesiologists’ (ASA) Closed Claims Project database from 1990 to 2011. Severe injury was found to be related to provider errors involving, in particular, improvised oxygen delivery systems and breathing circuit failures, supplemental oxygen supply problems outside of the operating room, and problems with an anesthesia ventilator. In 35% of claims an appropriate preanesthetic machine check (see the ASA’s 2008 Recommendations for Pre-Anesthesia Checkout) would likely have prevented any adverse event. Fortunately, patient injuries secondary to anesthesia equipment have decreased both in number and in severity over the past two decades. However, claims for awareness during general anesthesia have increased.

The American National Standards Institute and subsequently the ASTM International (formerly the American Society for Testing and Materials, F1850–00) published standard specifications for anesthesia machines and their components. Table 4–1 lists essential features of a modern anesthesia workstation.

**TABLE 4–1 Essential safety features on a modern anesthesia workstation.**
In its most basic form, the anesthesia machine receives medical gases from a gas supply, controls the flow and reduces the pressure of desired gases to a safe level, vaporizes volatile anesthetics into the final gas mixture, and delivers the gases at the common gas outlet to the breathing circuit connected to the patient’s airway (Figures 4–2 and 4–3).
FIGURE 4–2 Functional schematic of an anesthesia machine/workstation.

A mechanical ventilator attaches to the breathing circuit but can be excluded with a switch during spontaneous or manual (bag) ventilation. An auxiliary oxygen supply and suction regulator are also usually built into the workstation. In addition to standard safety features (Table 4–1) top-of-the-line anesthesia machines have additional safety features and built-in computer processors that integrate and monitor all components, perform automated machine checkouts, and provide options such as automated record-keeping and networking interfaces to external monitors and hospital information systems. Some machines are designed specifically for mobility, magnetic resonance imaging (MRI) compatibility, or compactness.

GAS SUPPLY
Most machines have gas inlets for oxygen, nitrous oxide, and air. Compact models often lack air inlets, whereas other machines may have a fourth inlet for helium, heliox, carbon dioxide, or nitric oxide. Separate inlets are provided for the primary pipeline gas supply that passes through the walls of health care facilities and the secondary cylinder gas supply. Machines therefore have two gas inlet pressure gauges for each gas: one for pipeline pressure and another for cylinder pressure.

**Pipeline Inlets**

Oxygen and nitrous oxide (and often air) are delivered from their central supply source to the operating room through a piping network. The tubing is color coded and connects to the anesthesia machine through a noninterchangeable **diameter-index safety system (DISS)** fitting that prevents incorrect hose attachment. Noninterchangeability is achieved by making the bore diameter of the body and that of the connection nipple specific for each supplied gas. A filter helps trap debris from the wall supply and a one-way check valve prevents retrograde flow of gases into the pipeline supplies. It should be noted that most modern machines have an oxygen (pneumatic) power outlet that may be used to drive the ventilator or provide an auxiliary oxygen flowmeter. The DISS fittings for the oxygen inlet and the oxygen power outlet are identical and should not be mistakenly interchanged. The approximate pipeline pressure of gases delivered to the anesthesia machine is 50 psig.

**Cylinder Inlets**

Cylinders attach to the machine via hanger-yoke assemblies that utilize a **pin index safety system** to prevent accidental connection of a wrong gas cylinder. The yoke assembly includes index pins, a washer, a gas filter, and a check valve that prevents retrograde gas flow. The gas cylinders are also color-coded for specific gases to allow for easy identification. In North America, the following color-coding scheme is used: oxygen = green, nitrous oxide = blue, carbon dioxide = gray, air = yellow, helium = brown, nitrogen = black. In the United Kingdom, white is used for oxygen and black and white for air. The E-cylinders attached to the anesthesia machine are a high-pressure source of medical gases and are generally used only as a backup supply in case of pipeline failure. Pressure of gas supplied from the cylinder to the anesthesia machine is 45 psig. Some machines have two oxygen cylinders so that one cylinder can be used while the other is changed. At 20°C, a full E-cylinder contains 600 L of oxygen.
FLOW CONTROL CIRCUITS

Pressure Regulators

Unlike the relatively constant pressure of the pipeline gas supply, the high and variable gas pressure in cylinders makes flow control difficult and potentially dangerous. To enhance safety and ensure optimal use of cylinder gases, machines utilize a pressure regulator to reduce the cylinder gas pressure to 45 to 47 psig. This pressure, which is slightly lower than the pipeline supply, allows preferential use of the pipeline supply if a cylinder is left open (unless pipeline pressure drops below 45 psig). After passing through pressure gauges and check valves, the pipeline gases share a common pathway with the cylinder gases. A high-pressure relief valve provided for each gas is set to open when the supply pressure exceeds the machine’s maximum safety limit (95–110 psig), as might happen with a regulator failure on a cylinder. Some machines also use a second regulator to drop both pipeline and cylinder pressure further (two-stage pressure regulation). A second-stage pressure reduction may also be needed for an auxiliary oxygen flowmeter, the oxygen flush mechanism, or the drive gas to power a pneumatic ventilator.

Oxygen Supply Failure Protection Devices

Whereas the oxygen supply can pass directly to its flow control valve, nitrous oxide, air (in some machines), and other gases must first pass through safety devices before reaching their respective flow control valves. In other machines, air passes directly to its flow control valve; this allows administration of air even in the absence of oxygen. These devices permit the flow of other gases only if there is sufficient oxygen pressure in the safety device and help prevent accidental delivery of a hypoxic mixture in the event of oxygen supply failure. Thus, in addition to supplying the oxygen flow control valve, oxygen from the common inlet pathway is used to pressurize safety devices, oxygen flush valves, and ventilator power outlets (in some models). Safety devices sense oxygen pressure via a small “piloting pressure” line that may be derived from the gas inlet or secondary regulator. In some anesthesia machine designs (eg, Datex-Ohmeda Excel), if the piloting pressure line falls below a threshold (eg, 20 psig), the shut-off valves close, preventing the administration of any other gases. The terms fail-safe and nitrous cut-off were previously used for the nitrous oxide.
shut-off valve.

Most modern machines use a proportioning safety device instead of a threshold shut-off valve. These devices, called either an oxygen failure protection device (Dräger) or a balance regulator (Datex-Ohmeda), proportionately reduce the pressure of nitrous oxide and other gases except for air. (They completely shut off nitrous oxide and other gas flow only below a set minimum oxygen pressure [eg, 0.5 psig for nitrous oxide and 10 psig for other gases]).

All machines also have an oxygen supply low-pressure sensor that activates alarm sounds when inlet gas pressure drops below a threshold value (usually 20–30 psig). It must be emphasized that these safety devices do not protect against other possible causes of hypoxic accidents (eg, gas line misconnections), in which threshold pressure may be maintained by gases containing inadequate or no oxygen.

### Flow Valves & Meters

Once the pressure has been reduced to a safe level, each gas must pass through flow control valves and is measured by flowmeters before mixing with other gases, entering the active vaporizer, and exiting the machine’s common gas outlet. **Gas lines proximal to flow valves are considered to be in the high-pressure circuit, whereas those between the flow valves and the common gas outlet are considered part of the low-pressure circuit of the machine.** Touch- and color-coded control knobs make it more difficult to turn the wrong gas off or on. As a safety feature the oxygen knob is usually fluted, larger, and protrudes farther than the other knobs. The oxygen flowmeter is positioned furthest to the right, downstream to the other gases; this arrangement helps to prevent hypoxia if there is leakage from a flowmeter positioned upstream.

Flow control knobs control gas entry into the flowmeters by adjustment via a needle valve. Flowmeters on anesthesia machines are classified as either constant-pressure variable-orifice (rotameter) or electronic. In constant-pressure variable-orifice flowmeters, an indicator ball, bobbin, or float is supported by the flow of gas through a tube (Thorpe tube) whose bore (orifice) is tapered. Near the bottom of the tube, where the diameter is small, a low flow of gas will create sufficient pressure under the float to raise it in the tube. As the float rises, the (variable) orifice of the tube widens, allowing more gas to pass around the float. The float will stop rising when its weight is just supported by the difference in pressure above and below it. If flow is increased, the pressure under the float
increases, raising it higher in the tube until the pressure drop again just supports the float’s weight. This pressure drop is constant regardless of the flow rate or the position in the tube and depends on the float weight and tube cross-sectional area.

Flowmeters are calibrated for specific gases, as the flow rate across a constriction depends on the gas’s viscosity at low laminar flows (Poiseuille’s law) and its density at high turbulent flows. To minimize the effect of friction with the tube’s wall, floats are designed to rotate constantly, which keeps them centered in the tube. Coating the tube’s interior with a conductive substance grounds the system and reduces the effect of static electricity. Some flowmeters have two glass tubes, one for low flows and another for high flows (Figure 4–4A); the two tubes are in series and are still controlled by one valve. A dual taper design can allow a single flowmeter to read both high and low flows (Figure 4–4B). Causes of flowmeter malfunction include debris in the flow tube, vertical tube misalignment, and sticking or concealment of a float at the top of a tube.

**FIGURE 4–3.** The anesthesia machine reduces the pressure from the gas supply, vaporizes anesthetic agents, and delivers the gas mixture to the common

Should a leak develop within or downstream from an oxygen flowmeter, a hypoxic gas mixture can be delivered to the patient (Figure 4–5). To reduce this risk, oxygen flowmeters are always positioned downstream to all other flowmeters (nearest to the vaporizer).

Some anesthesia machines have electronic flow control and measurement. In such instances, a backup conventional (Thorpe) auxiliary oxygen flowmeter is provided. Other models have conventional flowmeters but electronic measurement of gas flow along with Thorpe tubes and digital or digital/graphic displays. The amount of pressure drop caused by a flow restrictor is the basis for measurement of gas flow rate in these systems. In these machines oxygen, nitrous oxide, and air each have a separate electronic flow measurement device in the flow control section before they are mixed together. Electronic flowmeters are required if gas flow rate data will be acquired automatically by computerized anesthesia recording systems.

A. Minimum Oxygen Flow
The oxygen flow valves are usually designed to deliver a minimum oxygen flow when the anesthesia machine is turned on. One method involves the use of a minimum flow resistor. This safety feature helps ensure that some oxygen enters the breathing circuit even if the operator forgets to turn on the oxygen flow.

B. Oxygen/Nitrous Oxide Ratio Controller
Another safety feature of anesthesia machines is a linkage of the nitrous oxide gas flow to the oxygen gas flow; this arrangement helps ensure a minimum oxygen concentration of 25%. The oxygen/nitrous oxide ratio controller links the two flow valves either pneumatically or mechanically. To maintain the minimum oxygen concentration, the system (Link-25) in Datex-Ohmeda machines increases the flow of oxygen, whereas the oxygen ratio monitor controller (ORMC) in Dräger machines reduces the concentration of nitrous oxide. It should be noted that this safety device does not affect the flow of a third gas (eg, air, helium, or carbon dioxide).

Vaporizers
Volatile anesthetics (eg, halothane, isoflurane, desflurane, sevoflurane) must be
vaporized before being delivered to the patient. Vaporizers have concentration-calibrated dials that precisely add volatile anesthetic agents to the combined gas flow from all flowmeters. They must be located between the flowmeters and the common gas outlet. Moreover, unless the machine accepts only one vaporizer at a time, all anesthesia machines should have an interlocking or exclusion device that prevents the concurrent use of more than one vaporizer.

A. Physics of Vaporization

At temperatures encountered in the operating room, the molecules of a volatile anesthetic in a closed container are distributed between the liquid and gaseous phases. The gas molecules bombard the walls of the container, creating the saturated vapor pressure of that agent. Vapor pressure depends on the characteristics of the volatile agent and the temperature. The greater the temperature, the greater the tendency for the liquid molecules to escape into the gaseous phase and the greater the vapor pressure (Figure 4–6). Vaporization requires energy (the latent heat of vaporization), which results in a loss of heat from the liquid. As vaporization proceeds, temperature of the remaining liquid anesthetic drops and vapor pressure decreases unless heat is readily available to enter the system. Vaporizers contain a chamber in which a carrier gas becomes saturated with the volatile agent.

**FIGURE 4–4** Constant-pressure variable-orifice flowmeters (Thorpe type). A:
Two tube design. **B**: Dual taper design.

A liquid’s boiling point is the temperature at which its vapor pressure is equal to the atmospheric pressure. As the atmospheric pressure decreases (as in higher altitudes), the boiling point also decreases. Anesthetic agents with low boiling points are more susceptible to variations in barometric pressure than agents with higher boiling points. Among the commonly used agents, desflurane has the lowest boiling point (22.8°C at 760 mm Hg).

**B. Copper Kettle**
The copper kettle vaporizer is no longer used in clinical anesthesia; however, understanding how it works provides invaluable insight into the delivery of volatile anesthetics (Figure 4–7). It is classified as a measured-flow vaporizer (or flowmeter-controlled vaporizer). In a copper kettle, the amount of carrier gas bubbled through the volatile anesthetic is controlled by a dedicated flowmeter. This valve is turned off when the vaporizer circuit is not in use. Copper is used as the construction metal because its relatively high specific heat (the quantity of heat required to raise the temperature of 1 g of substance by 1°C) and high thermal conductivity (the speed of heat conductance through a substance) enhance the vaporizer’s ability to maintain a constant temperature. All the gas entering the vaporizer passes through the anesthetic liquid and becomes saturated with vapor. One milliliter of liquid anesthetic yields approximately 200 mL of anesthetic vapor. Because the vapor pressure of volatile anesthetics is greater than the partial pressure required for anesthesia, the saturated gas leaving a copper kettle has to be diluted before it reaches the patient.

![Diagram of flowmeters](image)

**FIGURE 4–5** Sequence of flowmeters in a three-gas machine. **A**: An unsafe sequence. **B**: Typical Datex-Ohmeda sequence. **C**: Typical Dräger sequence. Note that regardless of sequence a leak in the oxygen tube or further downstream can result in delivery of a hypoxic mixture.

For example, the vapor pressure of halothane is 243 mm Hg at 20°C, so the concentration of halothane exiting a copper kettle at 1 atmosphere would be
243/760, or 32%. If 100 mL of oxygen enters the kettle, roughly 150 mL of gas exits (the initial 100 mL of oxygen plus 50 mL of saturated halothane vapor), one-third of which would be saturated halothane vapor. To deliver a 1% concentration of halothane (MAC 0.75%), the 50 mL of halothane vapor and 100 mL of carrier gas that left the copper kettle have to be diluted within a total of 5000 mL of fresh gas flow. Thus, every 100 mL of oxygen passing through a halothane vaporizer translates into a 1% increase in concentration if total gas flow into the breathing circuit is 5 L/min. Therefore, when total flow is fixed, flow through the vaporizer determines the ultimate concentration of anesthetic. Isoflurane has an almost identical vapor pressure, so the same relationship between copper kettle flow, total gas flow, and anesthetic concentration exists. However, if total gas flow decreases without an adjustment in copper kettle flow (eg, exhaustion of a nitrous oxide cylinder), the delivered volatile anesthetic concentration rises rapidly to potentially dangerous levels.

C. Modern Conventional Vaporizers

All modern vaporizers are agent specific and temperature corrected, capable of delivering a constant concentration of agent regardless of temperature changes or flow through the vaporizer. Turning a single calibrated control knob counterclockwise to the desired percentage diverts an appropriate small fraction of the total gas flow into the carrier gas, which flows over the liquid anesthetic in a vaporizing chamber, leaving the balance to exit the vaporizer unchanged (Figure 4–8). Because some of the entering gas is never exposed to anesthetic liquid, this type of agent-specific vaporizer is also known as a variable-bypass vaporizer.
FIGURE 4–6 The vapor pressure of anesthetic gases.

FIGURE 4–7 Schematic of a copper kettle vaporizer. Note that 50 mL/min of halothane vapor is added for each 100 mL/min oxygen flow that passes through the vaporizer.
FIGURE 4–8 Schematic of agent-specific variable-bypass vaporizers. A:
Temperature compensation is achieved by a strip composed of two different metals welded together. The metal strips expand and contract differently in response to temperature changes. When the temperature decreases, differential contraction causes the strip to bend, allowing more gas to pass through the vaporizer. Such bimetallic strips are also used in home thermostats. As the temperature rises differential expansion causes the strip to bend the other way restricting gas flow into the vaporizer. Altering total fresh gas flow rates within a wide range does not significantly affect anesthetic concentration because the same proportion of gas is exposed to the liquid. However, the real output of an agent would be lower than the dial setting at extremely high flow (>15 L/min); the converse is true when the flow rate is less than 250 mL/min. Changing the gas composition from 100% oxygen to 70% nitrous oxide may transiently decrease volatile anesthetic concentration due to the greater solubility of nitrous oxide in volatile agents.

Given that these vaporizers are agent specific, filling them with the incorrect anesthetic must be avoided. For example, unintentionally filling a sevoflurane-specific vaporizer with halothane could lead to an anesthetic overdose. First, halothane’s higher vapor pressure (243 mm Hg versus 157 mm Hg) will cause a 40% greater amount of anesthetic vapor to be released. Second, halothane is more than twice as potent as sevoflurane (MAC 0.75 versus 2.0). Conversely, filling a halothane vaporizer with sevoflurane will cause an anesthetic underdosage. Modern vaporizers offer agent-specific, keyed, filling ports to prevent filling with an incorrect agent.

Excessive tilting of older vaporizers (Tec 4, Tec 5, and Vapor 19.n) during transport may flood the bypass area and lead to dangerously high anesthetic concentrations. In the event of tilting and spillage, high flow of oxygen with the vaporizer turned off should be used to vaporize and flush the liquid anesthetic from the bypass area. Fluctuations in pressure from positive-pressure ventilation in older anesthesia machines may cause a transient reversal of flow through the vaporizer, unpredictably changing agent delivery. This “pumping effect” is more pronounced with low gas flows. A one-way check valve between the vaporizers and the oxygen flush valve (Datex-Ohmeda) together with some design modifications in newer units limit the occurrence of some of these problems. Variable-bypass vaporizers compensate for changes in ambient pressures (ie, altitude changes maintaining relative anesthetic gas partial pressure). It is the partial pressure of the anesthetic agent that determines its concentration-dependent physiological effects. Thus, there is no need to increase the selected
anesthetic concentration when using a variable-bypass vaporizer at altitude because the partial pressure of the anesthetic agent will be largely unchanged. Although at lower ambient pressures gas passing through the vaporizer is exposed to increased vaporizer output, because of Dalton’s law of partial pressure the partial pressure of the anesthetic vapor will remain largely unaffected compared with partial pressures obtained at sea level.

D. Electronic Vaporizers

Electronically controlled vaporizers must be utilized for desflurane and are used for all volatile anesthetics in some sophisticated anesthesia machines.

1. Desflurane vaporizer—Desflurane’s vapor pressure is so high that at sea level it almost boils at room temperature (Figure 4–6). This high volatility, coupled with a potency only one-fifth that of other volatile agents, presents unique delivery problems. First, the vaporization required for general anesthesia produces a cooling effect that would overwhelm the ability of conventional vaporizers to maintain a constant temperature. Second, because it vaporizes so extensively, a tremendously high fresh gas flow would be necessary to dilute the carrier gas to clinically relevant concentrations. These problems have been addressed by the development of special desflurane vaporizers. A reservoir containing desflurane (desflurane sump) is electrically heated to 39°C (significantly higher than its boiling point) creating a vapor pressure of 2 atmospheres. Unlike a variable-bypass vaporizer, no fresh gas flows through the desflurane sump. Rather, pure desflurane vapor joins the fresh gas mixture before exiting the vaporizer. The amount of desflurane vapor released from the sump depends on the concentration selected by turning the control dial and the fresh gas flow rate. Although the Tec 6 Plus maintains a constant desflurane concentration over a wide range of fresh gas flow rates, it cannot automatically compensate for changes in elevation as do the variable-bypass vaporizers. Decreased ambient pressure (eg, high elevation) does not affect the concentration of agent delivered, but decreases the partial pressure of the agent. Thus, at high elevations one must manually increase the desflurane concentration control.

2. Aladin (GE) cassette vaporizer—Gas flow from the flow control is divided into bypass flow and liquid chamber flow. The latter is conducted into an agent-specific, color-coded, cassette (Aladin cassette) in which the volatile anesthetic is vaporized. The machine accepts only one cassette at a time and recognizes the cassette through magnetic labeling. The cassette does not contain any bypass
flow channels; therefore, unlike traditional vaporizers, liquid anesthetic cannot escape during handling and the cassette can be carried in any position. After leaving the cassette, the now anesthetic-saturated liquid chamber flow reunites with the bypass flow before exiting the fresh gas outlet. A flow restrictor valve near the bypass flow helps to adjust the amount of fresh gas that flows to the cassette. Adjusting the ratio between the bypass flow and liquid chamber flow changes the concentration of volatile anesthetic agent delivered to the patient. Sensors in the cassette measure pressure and temperature, thus determining agent concentration in the gas leaving the cassette. Correct liquid chamber flow is calculated based on desired fresh gas concentration and determined cassette gas concentration.

**Common (Fresh) Gas Outlet**

In contrast to the multiple gas inlets, the anesthesia machine has only one common gas outlet that supplies gas to the breathing circuit. The term *fresh gas outlet* is also often used because of its critical role in adding new gas of fixed and known composition to the circle system. Unlike older models, some newer anesthesia machines measure and report common outlet gas flows. An antidisconnect retaining device is used to prevent accidental detachment of the gas outlet hose that connects the machine to the breathing circuit.

The oxygen flush valve provides a high flow (35–75 L/min) of oxygen directly to the common gas outlet, bypassing the flowmeters and vaporizers. It is used to rapidly refill or flush the breathing circuit, but because the oxygen may be supplied at a line pressure of 45 to 55 psig, there is a real potential for lung barotrauma to occur. For this reason, the flush valve must be used cautiously whenever a patient is connected to the breathing circuit. Moreover, inappropriate use of the flush valve (or a situation of stuck valve) may result in backflow of gases into the low-pressure circuit, causing dilution of inhaled anesthetic concentration. Some machines use a second-stage regulator to drop the oxygen flush pressure to a lower level. A protective rim around the flush button limits the possibility of unintentional activation.

**THE BREATHING CIRCUIT**

In adults, the breathing system most commonly used with anesthesia machines is the circle system (**Figure 4–9**); a Bain circuit is occasionally used. The components and use of the circle system were previously discussed (see Chapter 3). It is important to note that gas composition at the common gas outlet can be
controlled precisely and rapidly by adjustments in flowmeters and vaporizers. In contrast, gas composition, especially volatile anesthetic concentration, in the breathing circuit is significantly affected by other factors, including anesthetic uptake in the patient’s lungs, minute ventilation, total fresh gas flow, volume of the breathing circuit, and the presence of gas leaks. Use of high gas flow rates during induction and emergence decreases the effects of such variables and can diminish the magnitude of discrepancies between fresh gas outlet and circle system anesthetic concentrations. Measurement of inspired and expired anesthetic gas concentration also greatly facilitates anesthetic management.
FIGURE 4–9 Diagram of a typical breathing circuit (Dräger Narkomed). Note gas flow during A: spontaneous inspiration, B: manual inspiration (“bagging”), and C: exhalation (spontaneous or bag ventilation).

In most machines, the common gas outlet is attached to the breathing circuit just past the exhalation valve to prevent artificially high exhaled tidal volume measurements. When spirometry measurements are made at the Y-connector, fresh gas flow can enter the circuit on the patient side of the inspiratory valve. The latter enhances CO₂ elimination and may help reduce desiccation of the CO₂ absorbent.

Newer anesthesia machines have integrated internalized breathing circuit components (Figure 4–10). The advantages of these designs include reduced probability of breathing circuit misconnects, disconnects, kinks, and leaks. The smaller volume of compact machines can also help conserve gas flow and volatile anesthetics and allow faster changes in breathing circuit gas concentration. Internal heating of manifolds can reduce precipitation of moisture.
FIGURE 4–10 Breathing circuit design. A: Conventional external components. B: Compact design that reduces external connections and circuit volume (Dräger Fabius GS).

**Oxygen Analyzers**

General anesthesia must not be administered without an oxygen analyzer in the breathing circuit. Three types of oxygen analyzers are available: polarographic (Clark electrode), galvanic (fuel cell), and paramagnetic. The first two techniques utilize electrochemical sensors that contain cathode and anode electrodes embedded in an electrolyte gel separated from the sample gas by an oxygen-permeable membrane (usually Teflon). As oxygen reacts with the electrodes, a current is generated that is proportional to the oxygen partial pressure in the sample gas. The galvanic and polarographic sensors differ in the composition of their electrodes and electrolyte gels. The components of the galvanic cell are capable of providing enough chemical energy so that the reaction does not require an external power source.

Although the initial cost of paramagnetic sensors is greater than that of electrochemical sensors, paramagnetic devices are self-calibrating and have no consumable parts. In addition, their response time is fast enough to differentiate between inspired and expired oxygen concentrations.

All oxygen analyzers should have a low-level alarm that is automatically activated by turning on the anesthesia machine. The sensor should be placed into the inspiratory or expiratory limb of the circle system’s breathing circuit—but
not into the fresh gas line. As a result of the patient’s oxygen consumption, the expiratory limb has a slightly lower oxygen partial pressure than the inspiratory limb, particularly at low fresh gas flows. The increased humidity of expired gas does not significantly affect most modern sensors.

**Spirometers**

Spirometers, also called respirometers, are used to measure exhaled tidal volume in the breathing circuit on all anesthesia machines, typically near the exhalation valve. Some anesthesia machines also measure the inspiratory tidal volume just past the inspiratory valve or the actual delivered and exhaled tidal volumes at the Y-connector that attaches to the patient’s airway.

A common method employs a rotating vane of low mass in the expiratory limb in front of the expiratory valve of the circle system (vane anemometer or Wright respirometer, [Figure 4–11A](#)).

The flow of gas across vanes within the respirometer causes their rotation, which is measured electronically, photoelectrically, or mechanically. In another variation using this turbine principle, the volumeter or displacement meter is
designed to measure the movement of discrete quantities of gas over time (Figure 4–11B).

During positive-pressure ventilation, changes in exhaled tidal volumes usually represent changes in ventilator settings, but can also be due to circuit leaks, disconnections, or ventilator malfunction. These spirometers are prone to errors caused by inertia, friction, and water condensation. For example, Wright respirometers under-read at low flow rates and over-read at high flow rates. Furthermore, the measurement of exhaled tidal volumes at this location in the expiratory limb includes gas that had been lost to the circuit (and not delivered to the patient; discussed below). The difference between the volume of gas delivered to the circuit and the volume of gas actually reaching the patient becomes very significant with long, compliant breathing tubes; rapid respiratory rates; and increased airway pressures. These problems are at least partially overcome by measuring the tidal volume at the Y-connector to the patient’s airway.

A hot-wire anemometer utilizes a fine platinum wire, electrically heated at a constant temperature, inside the gas flow. The cooling effect of increasing gas flow on the wire electrode causes a change in electrical resistance. In a constant-resistance anemometer, gas flow is determined from the current needed to maintain a constant wire temperature (and resistance). Disadvantages include an inability to detect reverse flow, less accuracy at higher flow rates, and the possibility that the heated wire may be a potential ignition source for fire in the breathing manifold.

Ultrasonic flow sensors rely on discontinuities in gas flow generated by turbulent eddies in the flow stream. Upstream and downstream ultrasonic beams, generated from piezoelectric crystals, are transmitted at an angle to the gas stream. The Doppler frequency shift in the beams is proportional to the flow velocities in the breathing circuit. Major advantages include the absence of moving parts and greater accuracy due to the device’s independence from gas density.

Machines with variable-orifice flowmeters usually employ two sensors (Figure 4–11C). One measures flow at the inspiratory port of the breathing system, and the other measures flow at the expiratory port. These sensors use a change in internal diameter to generate a pressure drop that is proportional to the flow through the sensor. The changes in gas flows during the inspiratory and expiratory phases help the ventilator to adjust and provide a constant tidal volume. However, due to excessive condensation, sensors can fail when used with heated humidified circuits.
A pneumotachograph is a fixed-orifice flowmeter that can function as a spirometer. A parallel bundle of small-diameter tubes in chamber (Fleisch pneumotachograph) or mesh screen provides a slight resistance to airflow. The pressure drop across this resistance is sensed by a differential pressure transducer and is proportional to the flow rate. Integration of flow rate over time yields tidal volume. Moreover, analysis of pressure, volume, and time relationships can yield potentially valuable information about airway and lung mechanics. Modifications have been required to overcome inaccuracies due to water condensation and temperature changes. One modification employs two pressure-sensing lines in a Pitot tube at the Y-connection (Figure 4–11D). Gas flowing through the Pitot tube (flow sensor tube) creates a pressure difference between the flow sensor lines. This pressure differential is used to measure flow, flow direction, and airway pressure. Respiratory gases are continuously sampled to correct the flow reading for changes in density and viscosity.

**Circuit Pressure**

A pressure gauge or electronic sensor is always used to measure breathing-circuit pressure somewhere between the expiratory and inspiratory unidirectional valves; the exact location depends on the model of anesthesia machine. Breathing-circuit pressure usually reflects airway pressure if it is measured as close to the patient’s airway as possible. The most accurate measurements of both inspiratory and expiratory pressures can be obtained from the Y-connection. A rise in airway pressure may signal worsening pulmonary compliance, an increase in tidal volume, or an obstruction in the breathing circuit, tracheal tube, or the patient’s airway. A drop in pressure may indicate an improvement in compliance, a decrease in tidal volume, or a leak in the circuit. If circuit pressure is being measured at the CO₂ absorber, however, it will not always mirror the pressure in the patient’s airway. For example, clamping the expiratory limb of the breathing tubes during exhalation will prevent the patient’s breath from exiting the lungs. Despite this buildup in airway pressure, a pressure gauge at the absorber will read zero because of the intervening one-way valve.

Some machines have incorporated auditory feedback for pressure changes during ventilator use.

**Adjustable Pressure-Limiting Valve**

The adjustable pressure-limiting (APL) valve, sometimes referred to as the
pressure relief or pop-off valve, is usually fully open during spontaneous ventilation but must be partially closed during manual or assisted bag ventilation. The APL valve often requires fine adjustments. If it is not closed sufficiently excessive loss of circuit volume due to leaks prevents manual ventilation. At the same time, if it is closed too much or is fully closed, a progressive rise in pressure could result in pulmonary barotrauma (eg, pneumothorax) or hemodynamic compromise, or both. As an added safety feature, the APL valves on modern machines act as true pressure-limiting devices that can never be completely closed; the upper limit is usually 70 to 80 cm H$_2$O.

**Humidifiers**

Absolute humidity is defined as the weight of water vapor in 1 L of gas (ie, mg/L). Relative humidity is the ratio of the actual mass of water present in a volume of gas to the maximum amount of water possible at a particular temperature. At 37°C and 100% relative humidity, absolute humidity is 44 mg/L, whereas at room temperature (21°C and 100% humidity) it is 18 mg/L. Inhaled gases in the operating room are normally administered at room temperature with little or no humidification. Gases must therefore be warmed to body temperature and saturated with water by the upper respiratory tract. Tracheal intubation and high fresh gas flows bypass this normal humidification system and expose the lower airways to dry (<10 mg H$_2$O/L), room temperature gases.

Prolonged humidification of gases by the lower respiratory tract leads to dehydration of mucosa, altered ciliary function, and, if excessively prolonged, could potentially lead to inspissation of secretions, atelectasis, and even ventilation/perfusion mismatching, particularly in patients with underlying lung disease. Body heat is also lost as gases are warmed, and even more importantly, as water is vaporized to humidify the dry gases. The heat of vaporization for water is 560 cal/g of water vaporized. Fortunately, this heat loss accounts for about only 5% to 10% of total intraoperative heat loss, is not significant for a short procedure (<1 h), and usually can easily be compensated for with a forced-air warming blanket. Humidification and heating of inspiratory gases may be most important for small pediatric patients and older patients with severe underlying lung pathology, eg, cystic fibrosis.

**A. Passive Humidifiers**

Humidifiers added to the breathing circuit minimize water and heat loss. The
simplest designs are condenser humidifiers or heat and moisture exchanger (HME) units (Figure 4–12). These passive devices do not add heat or vapor but rather contain a hygroscopic material that traps exhaled humidification and heat, which is released upon subsequent inhalation. Depending on the design, they may substantially increase apparatus dead space (more than 60 mL$^3$), which can cause significant rebreathing in pediatric patients. They can also increase breathing-circuit resistance and the work of breathing during spontaneous respirations. Excessive saturation of an HME with water or secretions can obstruct the breathing circuit. Some condenser humidifiers also act as effective filters that may protect the breathing circuit and anesthesia machine from bacterial or viral cross-contamination. This may be particularly important when ventilating patients with respiratory infections or compromised immune systems.
FIGURE 4–12 Heat and moisture exchanger (HME) functions as an “artificial nose” that attaches between the tracheal tube and the right-angle connector of the breathing circuit.

B. Active Humidifiers
Active humidifiers are more effective than passive ones in preserving moisture and heat. Active humidifiers add water to gas by passing the gas over a water chamber (passover humidifier) or through a saturated wick (wick humidifier), bubbling it through water (bubble-through humidifier), or mixing it with vaporized water (vapor-phase humidifier). Because increasing temperature increases the capacity of a gas to hold water vapor, heated humidifiers with
thermostatically controlled elements are most effective.

The hazards of heated humidifiers include thermal lung injury (inhaled gas temperature should be monitored and should not exceed 41°C), nosocomial infection, increased airway resistance from excess water condensation in the breathing circuit, interference with flowmeter function, and an increased likelihood of circuit disconnection. Use of these humidifiers is particularly valuable in children as they help prevent both hypothermia and the plugging of small tracheal tubes by dried secretions. Of course, any design that increases airway dead space should be avoided in pediatric patients. Unlike passive humidifiers, active humidifiers do not filter respiratory gases.

VENTILATORS

All modern anesthesia machines are equipped with a ventilator. Historically ventilators used in the operating room (OR) were simpler and more compact than their intensive care unit (ICU) counterparts. This distinction has become blurred due to advances in technology together with an increasing need for “ICU-type” ventilators as more critically ill patients come to the OR. The ventilators on some modern machines have almost the same capabilities as those in the ICU. A more complete discussion of mechanical ventilation in relation to ICU practice is contained in Chapter 57.

Overview

Ventilators generate gas flow by creating a pressure gradient between the proximal airway and the alveoli. Ventilator function is best described in relation to the four phases of the ventilatory cycle: inspiration, the transition from inspiration to expiration, expiration, and the transition from expiration to inspiration. Although several classification schemes exist, the most common is based on inspiratory phase characteristics and the method of cycling from inspiration to expiration.

A. Inspiratory Phase

During inspiration, ventilators generate tidal volumes by producing gas flow along a pressure gradient. The machine generates either a constant pressure (constant-pressure generators) or constant gas flow rate (constant-flow generators) during inspiration, regardless of changes in lung mechanics (Figure 4–13). Nonconstant generators produce pressures or gas flow rates that vary
during the cycle but remain consistent from breath to breath. For instance, a ventilator that generates a flow pattern resembling a half cycle of a sine wave (eg, rotary piston ventilator) would be classified as a nonconstant-flow generator. An increase in airway resistance or a decrease in lung compliance would increase peak inspiratory pressure but would not alter the flow rate generated by this type of ventilator (Figure 4–14).

![Figure 4–13](image)

**FIGURE 4–13** Pressure, volume, and flow profiles of different types of ventilators. **A**: Constant pressure. **B**: Constant flow. **C**: Nonconstant generator.
B. Transition Phase from Inspiration toExpiration
Termination of the inspiratory phase can be triggered by a preset limit of time (fixed duration), a set inspiratory pressure that must be reached, or a predetermined tidal volume that must be delivered. Time-cycled ventilators allow tidal volume and peak inspiratory pressure to vary depending on lung compliance. Tidal volume is adjusted by setting inspiratory duration and inspiratory flow rate. Pressure-cycled ventilators will not cycle from the inspiratory phase to the expiratory phase until a preset pressure is reached. If a large circuit leak decreases peak pressures significantly, a pressure-cycled ventilator may remain in the inspiratory phase indefinitely. On the other hand, a small leak may not markedly decrease tidal volume, because cycling will be delayed until the pressure limit is met. Volume-cycled ventilators vary inspiratory duration and pressure to deliver a preset volume. In reality, modern ventilators overcome the many shortcomings of classic ventilator designs by incorporating secondary cycling parameters or other limiting mechanisms. For example, time-cycled and volume-cycled ventilators usually incorporate a pressure-limiting feature that terminates inspiration when a preset, adjustable safety pressure limit is reached. Similarly, a volume-preset control that limits the excursion of the bellows allows a time-cycled ventilator to function somewhat
like a volume-cycled ventilator, depending on the selected ventilator rate and inspiratory flow rate.

C. Expiratory Phase
The expiratory phase of ventilators normally reduces airway pressure to atmospheric levels or some preset value of positive end-expiratory pressure (PEEP). Exhalation is therefore passive. Flow out of the lungs is determined primarily by airway resistance and lung compliance. Expired gases fill up the bellows; they are then relieved to the scavenging system.

D. Transition Phase from Expiration to Inspiration
Transition into the next inspiratory phase may be based on a preset time interval or a change in pressure. The behavior of the ventilator during this phase together with the type of cycling from inspiration to expiration determines ventilator mode. During controlled ventilation, the most basic mode of all ventilators, the next breath always occurs after a preset time interval. Thus tidal volume and rate are fixed in volume-controlled ventilation, whereas peak inspiratory pressure and rate are fixed in pressure-controlled ventilation (Figure 4–15).

Ventilator Circuit Design

Traditionally ventilators on anesthesia machines have a double-circuit system.
design and are pneumatically powered and electronically controlled (Figure 4–16). Newer machines also incorporate microprocessor controls and sophisticated and precise pressure and flow sensors to achieve multiple ventilatory modes, PEEP, accurate tidal volumes, and enhanced safety features. Some anesthesia machines have ventilators that use a single-circuit piston design.

![Figure 4–16 Double-circuit pneumatic ventilator design. A: Datex-Ohmeda. B: Dräger.](image)

**A. Double-Circuit System Ventilators**

In a double-circuit system design, tidal volume is delivered from a bellows assembly that consists of a bellows in a clear rigid plastic enclosure (Figure 4–16). A standing (ascending) bellows is preferred as it readily draws attention to a circuit disconnection by collapsing. Hanging (descending) bellows are rarely used and must not be weighted; older ventilators with weighted hanging bellows continue to fill by gravity despite a disconnection in the breathing circuit.

The bellows in a double-circuit design ventilator takes the place of the breathing bag in the anesthesia circuit. Pressurized oxygen or air from the
ventilator power outlet (45–50 psig) is routed to the space between the inside wall of the plastic enclosure and the outside wall of the bellows. Pressurization of the plastic enclosure compresses the pleated bellows inside, forcing the gas inside into the breathing circuit and patient. In contrast, during exhalation, the bellows ascend as pressure inside the plastic enclosure drops and the bellows fill up with the exhaled gas. A ventilator flow control valve regulates drive gas flow into the pressurizing chamber. This valve is controlled by ventilator settings in the control box (Figure 4–16). Ventilators with microprocessors also utilize feedback from flow and pressure sensors. If oxygen is used for pneumatic power it will be consumed at a rate at least equal to minute ventilation. Thus, if oxygen fresh gas flow is 2 L/min and a ventilator is delivering 6 L/min to the circuit, a total of at least 8 L/min of oxygen is being consumed. This should be kept in mind if the hospital’s medical gas system fails and cylinder oxygen is required. Some anesthesia machines reduce oxygen consumption by incorporating a Venturi device that draws in room air to provide air/oxygen pneumatic power. Newer machines may offer the option of using compressed air for pneumatic power. A leak in the ventilator bellows can transmit high gas pressure to the patient’s airway, potentially resulting in pulmonary barotrauma. This may be indicated by a higher than expected rise in inspired oxygen concentration (if oxygen is the sole pressurizing gas). Some machine ventilators have a built-in drive gas regulator that reduces the drive pressure (eg, to 25 psig) for added safety.

Double-circuit design ventilators also incorporate a free breathing valve that allows outside air to enter the rigid drive chamber and the bellows to collapse if the patient generates negative pressure by taking spontaneous breaths during mechanical ventilation.

**B. Piston Ventilators**

In a piston design, the ventilator substitutes an electrically driven piston for the bellows, and the ventilator requires either minimal or no pneumatic power. The major advantage of a piston ventilator is its ability to deliver accurate tidal volumes to patients with very poor lung compliance and to very small patients.

**C. Spill Valve**

Whenever a ventilator is used on an anesthesia machine, the circle system’s APL valve must be functionally removed or isolated from the circuit. A bag/ventilator switch typically accomplishes this. When the switch is turned to “bag” the
ventilator is excluded and spontaneous/manual (bag) ventilation is possible. When it is turned to “ventilator,” the breathing bag and the APL are excluded from the breathing circuit. The APL valve may be automatically excluded in some newer anesthesia machines when the ventilator is turned on. The ventilator contains its own pressure-relief (pop-off) valve, called the spill valve, which is pneumatically closed during inspiration so that positive pressure can be generated (Figure 4–16). During exhalation, the pressurizing gas is vented out and the ventilator spill valve is no longer closed. The ventilator bellows or piston refill during expiration; when the bellows is completely filled, the increase in circle system pressure causes the excess gas to be directed to the scavenging system through the spill valve. Sticking of this valve can result in abnormally elevated airway pressure during exhalation.

**Pressure & Volume Monitoring**

**Peak inspiratory pressure** is the highest circuit pressure generated during an inspiratory cycle, and provides an indication of dynamic compliance. **Plateau pressure** is the pressure measured during an inspiratory pause (a time of no gas flow), and mirrors static compliance. During normal ventilation of a patient without lung disease, peak inspiratory pressure is equal to or only slightly greater than plateau pressure. An increase in both peak inspiratory pressure and plateau pressure implies an increase in tidal volume or a decrease in pulmonary compliance. An increase in peak inspiratory pressure without any change in plateau pressure signals an increase in airway resistance or inspiratory gas flow rate (Table 4–2). Thus, the shape of the breathing-circuit pressure waveform can provide important airway information. Many anesthesia machines graphically display breathing-circuit pressure (Figure 4–17). Airway secretions or kinking of the tracheal tube can be easily ruled out with the use of a suction catheter. Flexible fiberoptic bronchoscopy usually provides a definitive diagnosis.
FIGURE 4–17 Airway pressures (Paw) can be diagrammatically presented as a function of time. A: In normal persons, the peak inspiratory pressure is equal to or slightly greater than the plateau pressure. B: An increase in peak inspiratory pressure and plateau pressure (the difference between the two remains almost constant) can be due to an increase in tidal volume or a decrease in pulmonary compliance. C: An increase in peak inspiratory pressure with little change in plateau pressure signals an increase in inspiratory flow rate or an increase in airway resistance.

TABLE 4–2 Causes of increased peak inspiratory pressure (PIP), with or without an increased plateau pressure (PP).

Ventilator Alarms
Alarms are an integral part of all modern anesthesia ventilators. Whenever a ventilator is used “disconnect alarms” must be passively activated. Anesthesia workstations should have at least three disconnect alarms: low peak inspiratory pressure, low exhaled tidal volume, and low exhaled carbon dioxide. The first is always built into the ventilator whereas the latter two may be in separate modules. A small leak or partial breathing-circuit disconnection may be detected by subtle decreases in peak inspiratory pressure, exhaled volume, or end-tidal carbon dioxide before alarm thresholds are reached. Other built-in ventilator alarms include high peak inspiratory pressure, high PEEP, sustained high airway pressure, negative pressure, and low oxygen-supply pressure. Most modern anesthesia ventilators also have integrated spirometers and oxygen analyzers that provide additional alarms.

### Problems Associated with Anesthesia Ventilators

#### A. Ventilator–Fresh Gas Flow Coupling

From the previous discussion, it is important to appreciate that because the ventilator’s spill valve is closed during inspiration, fresh gas flow from the machine’s common gas outlet normally contributes to the tidal volume delivered to the patient. For example, if the fresh gas flow is 6 L/min, the inspiratory-expiratory (I:E) ratio is 1:2, and the respiratory rate is 10 breaths/min, each tidal volume will include an extra 200 mL in addition to the ventilator’s output:

\[
\frac{(6000 \text{ mL/min})(33\%)}{10 \text{ breaths/min}} \approx 200 \text{ mL/breath}
\]

Thus, increasing fresh gas flow increases tidal volume, minute ventilation, and peak inspiratory pressure. To avoid problems with ventilator–fresh gas flow coupling, airway pressure and exhaled tidal volume must be monitored closely and excessive fresh gas flows must be avoided. Current ventilators automatically compensate for fresh gas flow coupling. Piston style ventilators redirect fresh gas flow to the reservoir bag during inspiration thus preventing augmentation of the tidal volume secondary to fresh gas flow.

#### B. Excessive Positive Pressure

Intermittent or sustained high inspiratory pressures (>30 mm Hg) during positive-pressure ventilation increase the risk of pulmonary barotrauma (eg, pneumothorax) or hemodynamic compromise, or both, during anesthesia.
Excessively high pressures may arise from incorrect settings on the ventilator, ventilator malfunction, fresh gas flow coupling (discussed above), or activation of the oxygen flush during the inspiratory phase of the ventilator. Use of the oxygen flush valve during the inspiratory cycle of a ventilator must be avoided because the ventilator spill valve will be closed and the APL valve is excluded; the surge of oxygen (600–1200 mL/s) and circuit pressure will be transferred to the patient’s lungs.

In addition to a high-pressure alarm, all ventilators have a built-in automatic or APL valve. The mechanism of pressure limiting may be as simple as a threshold valve that opens at a certain pressure or electronic sensing that abruptly terminates the ventilator inspiratory phase.

C. Tidal Volume Discrepancies

Large discrepancies between the set and actual tidal volume that the patient receives are often observed in the operating room during volume-controlled ventilation. Causes include breathing-circuit compliance, gas compression, ventilator–fresh gas flow coupling (described above), and leaks in the anesthesia machine, the breathing circuit, or the patient’s airway.

The compliance for standard adult breathing circuits is about 5 mL/cm H$_2$O. Thus, if peak inspiratory pressure is 20 cm H$_2$O, about 100 mL of set tidal volume is lost to expanding the circuit. For this reason, breathing circuits for pediatric patients are designed to be much stiffer, with compliances as small as 1.5 to 2.5 mL/cm H$_2$O.

Compression losses, normally about 3%, are due to gas compression within the ventilator bellows and may be dependent on breathing-circuit volume. Thus, if tidal volume is 500 mL another 15 mL of the set tidal gas may be lost. Gas sampling for capnography and anesthetic gas measurements represent additional losses unless the sampled gas is returned to the breathing circuit.

Accurate detection of tidal volume discrepancies is dependent on where the spirometer is placed. Sophisticated ventilators measure both inspiratory and expiratory tidal volumes. It is important to note that unless the spirometer is placed at the Y-connector in the breathing circuit, compliance and compression losses will not be apparent.

Several mechanisms have been built into newer anesthesia machines to reduce tidal volume discrepancies. During the initial electronic self-checkout, some machines measure total system compliance and subsequently use this measurement to adjust the excursion of the ventilator bellows or piston; leaks
may also be measured but are usually not compensated. The actual method of tidal volume compensation or modulation varies according to manufacturer and model. In one design a flow sensor measures the tidal volume delivered at the inspiratory valve for the first few breaths and adjusts subsequent metered drive gas flow volumes to compensate for tidal volume losses (feedback adjustment). Another design continually measures fresh gas and vaporizer flow and subtracts this amount from the metered drive gas flow (preemptive adjustment). Alternately, machines that use electronic control of gas flow can decouple fresh gas flow from the tidal volume by delivery of fresh gas flow only during exhalation. Lastly, the inspiratory phase of the ventilator–fresh gas flow may be diverted through a decoupling valve into the breathing bag, which is excluded from the circle system during ventilation. During exhalation the decoupling valve opens, allowing the fresh gas that was temporarily stored in the bag to enter the breathing circuit.

**WASTE-GAS SCAVENGERS**

Waste-gas scavengers dispose of gases that have been vented from the breathing circuit by the APL valve and ventilator spill valve. Pollution of the operating room environment with anesthetic gases may pose a health hazard to surgical personnel. Although it is difficult to define safe levels of exposure, the National Institute for Occupational Safety and Health (NIOSH) recommends limiting the room concentration of nitrous oxide to 25 ppm and halogenated agents to 2 ppm (0.5 ppm if nitrous oxide is also being used) in time-integrated samples. Reduction to these trace levels is possible only with properly functioning waste-gas scavenging systems.

To avoid the buildup of pressure, excess gas volume is vented through the APL valve in the breathing circuit and the ventilator spill valve. Both valves should be connected to hoses (transfer tubing) leading to the scavenging interface, which may be inside the machine or an external attachment. The pressure immediately downstream to the interface should be kept between 0.5 and +3.5 cm H$_2$O during normal operating conditions. The scavenging interface may be described as either open or closed.

An open interface is open to the outside atmosphere and usually requires no pressure relief valves (Figure 4–18). In contrast, a closed interface is closed to the outside atmosphere and requires negative- and positive-pressure relief valves that protect the patient from the negative pressure of the vacuum system and positive pressure from an obstruction in the disposal tubing, respectively. The
outlet of the scavenging system may be a direct line to the outside via a ventilation duct beyond any point of recirculation (passive scavenging) or a connection to the hospital’s vacuum system (active scavenging). A chamber or reservoir bag accepts waste-gas overflow when the capacity of the vacuum is exceeded. The vacuum control valve on an active system should be adjusted to allow the evacuation of 10 to 15 L of waste gas per minute. This rate is adequate for periods of high fresh gas flow (i.e., induction and emergence) yet minimizes the risk of transmitting negative pressure to the breathing circuit during lower flow conditions (maintenance). Unless used correctly the risk of occupational exposure for health care providers is higher with an open interface. Some machines may come with both active and passive scavenger systems.

ANESTHESIA MACHINE CHECKOUT LIST
Misuse or malfunction of anesthesia gas delivery equipment can cause major morbidity or mortality. A routine inspection of anesthesia equipment before each use increases operator familiarity and confirms proper functioning. The
U.S. Food and Drug Administration (FDA) has made available a generic checkout procedure for anesthesia gas machines and breathing systems (Table 4–3). This procedure should be modified as necessary, depending on the specific equipment being used and the manufacturer’s recommendations. Note that although the entire checkout does not need to be repeated between cases on the same day, the conscientious use of a checkout list is mandatory before each anesthetic procedure. A mandatory check-off procedure increases the likelihood of detecting anesthesia machine faults. Some anesthesia machines provide an automated system check that requires a variable amount of human intervention. These system checks may include nitrous oxide delivery (hypoxic mixture prevention), agent delivery, mechanical and manual ventilation, pipeline pressures, scavenging, breathing circuit compliance, and gas leakage.

**TABLE 4–3  Anesthesia apparatus checkout recommendations.**

1,2
This checkout, or a reasonable equivalent, should be conducted before administration of anesthesia. These recommendations are valid only for an anesthesia system that conforms to current and relevant standards and includes an asynchronizing bellows ventilator and at least the following monitors: capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer), and breathing-system pressure monitor with high- and low-pressure alarms. Users are encouraged to modify this guideline to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should follow appropriate peer review. Users should refer to the appropriate operator manuals for specific procedures and precautions.

**Emergency Ventilation Equipment**

*1. Verify backup ventilation equipment is available and functioning*

**High-Pressure System**

*2. Check O₂ cylinder supply*
   a. Open O₂ cylinder and verify at least half full (about 1000 psi).
   b. Close cylinder.

*3. Check central pipeline supplies; check that hoses are connected and pipeline gauges read about 50 psi.

**Low-Pressure System**

*4. Check initial status of low-pressure system*
   a. Close flow control valves and turn ventilators off.
   b. Check fill level and tighten vaporizers/filler caps.

*5. Perform leak check of machine low-pressure system*
   a. Verify that the machine master switch and flow control valves are off.
   b. Attach suction bulb to common gas outlet.
   c. Squeeze bulb repeatedly until fully collapsed.
   d. Verify bulb stays fully collapsed for at least 10 seconds.
   e. Open one vaporizer at a time and repeat steps c and d.
   f. Remove suction bulb, and reconnect fresh gas hose.

*6. Turn on machine master switch and all other necessary electrical equipment.

*7. Test flowmeters*
   a. Adjust flow of all gases through their full range, checking for smooth operation of flows and undamaged flowmeters.
   b. Attempt to create a hypoxic O₂/N₂/O₂ mixture and verify correct changes in flow and/or alarm.

**Scavenging System**

*8. Adjust and check scavenging system*
   a. Ensure proper connections between the scavenging system and both APL (pop-off) valves and ventilator relief valve.
   b. Adjust waste-gas vacuum (if possible).
   c. Fully open APL valve and obscure Y-piece.
   d. With minimum O₂ flow, allow scavenger reservoir bag to collapse completely and verify that absorber pressure gauge reads about zero.
   e. With the O₂ flush activated, allow scavenger reservoir bag to distend fully, and then verify that absorber pressure gauge reads <10 cm H₂O.

**Monitors**

*9. Calibrate O₂ monitor*
   a. Ensure monitor reads 21% in room air.
   b. Verify low O₂ alarm is enabled and functioning.
   c. Reinstall sensor in circuit and flush breathing system with O₂.
   d. Verify that monitor now reads greater than 90%.

*10. Check initial status breathing system*
   a. Set selector switch to Bag mode.
   b. Check that breathing circuit is complete, undamaged, and unobstructed.
   c. Verify that CO₂ absorbent is adequate.
   d. Install breathing-circuit accessory equipment (e.g., humidifier, PEEP valve) to be used during the case.

*11. Perform leak check of the breathing system*
   a. Set all gas flows to zero (or minimum).
   b. Close APL (pop-off) valve and obscure Y-piece.
   c. Insulate breathing system to about 30 cm H₂O with O₂ flush.
   d. Ensure that pressure remains fixed for at least 10 seconds.
   e. Open APL (pop-off) valve and ensure that pressure decreases.

**Manual and Automatic Ventilator Systems**

*12. Test ventilation systems and unidirectional valves*
   a. Place a second breathing bag on Y-piece.
   b. Set appropriate ventilator parameters for next patient.
   c. Switch to automatic-ventilation (ventilator) mode.
   d. Turn ventilator on and fill both and breathing bag with O₂ flush.
   e. Set O₂ flow to minimum, other gas flows to zero.
   f. Verify that during inspiration bellows deliver appropriate tidal volume and that during expiration bellows fill completely.
   g. Set fresh gas flow to about 5 L/min.
   h. Verify that the ventilator bellows and simulated lungs fill and empty appropriately without sustained pressure at end inspiration.
   i. Check for proper action of unidirectional valves.
   j. Exercise breathing circuit accessories to ensure proper function.
   k. Turn ventilator off and switch to manual ventilation (Bag/PLV) mode.
   l. Ventilate manually and ensure inflation and deflation of artificial lungs and appropriate feel of system resistance and compliance.
   m. Remove second breathing bag from Y-piece.

**Final Position**

*13. Check, calibrate and/or set alarm limits of all monitors: capnograph, pulse oximeter, O₂ analyzer, respiratory volume monitor (spirometer), pressure monitor with high and low alarm-pressure alarms.

*14. Check final status of machine*
   a. Ventilators off.
   b. APL valve open.
   c. Selector switch to Bag mode.
   d. All flowmeters to zero (or minimum).
   e. Patient suction valve adequate.
   f. Breathing system ready to use.

*Data from US Food and Drug Administration. US Department of Health and Human Services.

1APL, adjustable pressure-limiter; PEEP, positive-end-expiratory pressure.

*If an anesthesia provider uses the same machine in successive cases, these steps need not be repeated; or they can be abbreviated after the initial checkout.
Detection of a Leak

After induction of general anesthesia and intubation of a 70-kg man for elective surgery, a standing bellows ventilator is set to deliver a tidal volume of 500 mL at a rate of 10 breaths/min. Within a few minutes, the anesthesiologist notices that the bellows fails to rise to the top of its clear plastic enclosure during expiration. Shortly thereafter, the disconnect alarm is triggered.

Why has the ventilator bellows fallen and the disconnect alarm sounded?

Fresh gas flow into the breathing circuit is inadequate to maintain the circuit volume required for positive-pressure ventilation. In a situation in which there is no fresh gas flow, the volume in the breathing circuit will slowly fall because of the constant uptake of oxygen by the patient (metabolic oxygen consumption) and absorption of expired CO₂. An absence of fresh gas flow could be due to exhaustion of the hospital’s oxygen supply (remember the function of the fail-safe valve) or failure to turn on the anesthesia machine’s flow control valves. These possibilities can be ruled out by examining the oxygen Bourdon pressure gauge and the flowmeters. A more likely explanation is a gas leak that exceeds the rate of fresh gas flow. Leaks are particularly important in closed-circuit anesthesia.

How can the size of the leak be estimated?

When the rate of fresh gas inflow equals the rate of gas outflow, the circuit’s volume will be maintained. Therefore, the size of the leak can be estimated by increasing fresh gas flows until there is no change in the height of the bellows from one expiration to the next. If the bellows collapse despite a high rate of fresh gas inflow, a complete circuit disconnection should be considered. The site of the disconnection must be determined immediately and repaired to prevent hypoxia and hypercapnia. A resuscitation bag must be immediately available and can be used to ventilate the patient if there is a delay in correcting the situation.

Where are the most likely locations of a breathing-circuit disconnection or leak?

Frank disconnections occur most frequently between the right-angle connector and the tracheal tube, whereas leaks are most commonly traced to
the base plate of the CO₂ absorber. In the intubated patient, leaks often occur in the trachea around an uncuffed tracheal tube or an inadequately filled cuff. There are numerous potential sites of disconnection or leak within the anesthesia machine and the breathing circuit, however. Every addition to the breathing circuit, such as a humidifier, provides another potential location for a leak.

**How can these leaks be detected?**

Leaks usually occur before the fresh gas outlet (ie, within the anesthesia machine) or after the fresh gas inlet (ie, within the breathing circuit). Large leaks within the anesthesia machine are less common and can be ruled out by a simple test. Pinching the tubing that connects the machine’s fresh gas outlet to the circuit’s fresh gas inlet creates a back pressure that obstructs the forward flow of fresh gas from the anesthesia machine. This is indicated by a drop in the height of the flowmeter floats. When the fresh gas tubing is released, the floats should briskly rebound and settle at their original height. If there is a substantial leak within the machine, obstructing the fresh gas tubing will not result in any back pressure, and the floats will not drop. A more sensitive test for detecting small leaks that occur before the fresh gas outlet involves attaching a suction bulb at the outlet as described in step 5 of Table 4–3. Correcting a leak within the machine usually requires removing it from service.

Leaks within a breathing circuit not connected to a patient are readily detected by closing the APL valve, occluding the Y-piece, and activating the oxygen flush until the circuit reaches a pressure of 20 to 30 cm H₂O. A gradual decline in circuit pressure indicates a leak within the breathing circuit (Table 4–3, step 11).

**How are leaks in the breathing circuit located?**

Any connection within the breathing circuit is a potential site of a gas leak. A quick survey of the circuit may reveal a loosely attached breathing tube or a cracked oxygen analyzer adaptor. Less obvious causes include detachment of the tubing used by the disconnect alarm to monitor circuit pressures, an open APL valve, or an improperly adjusted scavenging unit. Leaks can usually be identified audibly or by applying a soap solution to suspect connections and looking for bubble formation.

Leaks within the anesthesia machine and breathing circuit are usually detectable if the machine and circuit have undergone an established
checkout procedure. For example, steps 5 and 11 of the FDA recommendations (Table 4–3) will reveal most significant leaks.

1 Pressure unit conversions: 1 kiloPascal (kP) = kg/m · s^2 = 1000 N/m^2 = 0.01 bar = 0.1013 atmospheres = 0.145 psig = 10.2 cm H_2O = 7.5 mm Hg.
Cardiovascular Monitoring

KEY CONCEPTS

1. The tip of the central venous pressure catheter should not be allowed to migrate into the heart chambers.
2. Although the PA catheter can be used to guide goal-directed hemodynamic therapy to ensure organ perfusion in shock states, other less invasive methods to determine hemodynamic performance are available, including transpulmonary thermodilution CO measurements, pulse contour analyses of the arterial pressure waveform, and methods based on bioimpedance measurements across the chest.
3. Relative contraindications to pulmonary artery catheterization include left bundle-branch block (because of the concern about complete heart block) and conditions associated with greatly increased risk of arrhythmias.
4. Pulmonary artery pressure should be continuously monitored to detect an overwedged position indicative of catheter migration.
5. Accurate measurements of cardiac output depend on rapid and smooth injection, precisely known injectant temperature and volume, correct entry of the calibration factors for the specific type of pulmonary artery catheter into the cardiac output computer, and avoidance of measurements during electrocautery.

Vigilant perioperative monitoring of the cardiovascular system is one of the primary duties of anesthesia providers. The American Society of Anesthesiologists has established standards for basic anesthesia monitoring. This chapter focuses on the specific monitoring devices and techniques used to monitor cardiac function and circulation in healthy and nonhealthy patients alike.
ARTERIAL BLOOD PRESSURE

The rhythmic contraction of the left ventricle, ejecting blood into the vascular system, results in pulsatile arterial pressures. The peak left ventricular end-systolic pressure (in the absence of aortic valve stenosis) approximates the systolic arterial blood pressure (SBP); the lowest arterial pressure during diastolic relaxation is the diastolic blood pressure (DBP). Pulse pressure is the difference between the systolic and diastolic pressures. The time-weighted average of arterial pressures during a pulse cycle is the mean arterial pressure (MAP). MAP can be estimated by application of the following formula:

\[
\text{MAP} = \frac{\text{SBP} + 2 \times \text{DBP}}{3}
\]

Arterial blood pressure varies depending upon where within the vasculature the pressure is measured. As a pulse moves peripherally through the arterial tree, wave reflection distorts the pressure waveform, leading to an exaggeration of systolic and pulse pressures (Figure 5–1). For example, radial artery systolic pressure is usually greater than aortic systolic pressure because of its more distal location. In contrast, radial artery systolic pressures often underestimate more “central” pressures following hypothermic cardiopulmonary bypass because of changes in hand vascular resistance. Vasodilating drugs may accentuate this discrepancy. The level of the sampling site relative to the heart affects the measurement of blood pressure because of the effect of gravity (Figure 5–2). In patients with severe peripheral vascular disease, there may be significant differences in blood pressure measurements among the extremities. The greater value should be used in these patients.

\[
(20 \text{ cm } H_2O) \left( \frac{0.74 \text{ mm Hg}}{\text{cm } H_2O} \right) = 14.7 \text{ mm Hg}
\]

FIGURE 5–2 The difference in blood pressure (mm Hg) at two different sites of measurement equals the height of an interposed column of water (cm H_2O) multiplied by a conversion factor (1 cm H_2O = 0.74 mm Hg).
Because noninvasive (palpation, Doppler, auscultation, oscillometry, plethysmography) and invasive (arterial cannulation) methods of blood pressure determination differ greatly, they are discussed separately.

1. Noninvasive Arterial Blood Pressure Monitoring

Indications

The use of any anesthetic is an indication for arterial blood pressure measurement. The techniques and frequency of pressure determination will depend on the patient’s condition and the type of surgical procedure. A noninvasive blood pressure measurement every 3 to 5 min is adequate in most cases.

Contraindications

Although some method of blood pressure measurement is mandatory, techniques that rely on a blood pressure cuff are best avoided in extremities with vascular abnormalities (eg, dialysis shunts) or with intravenous lines. It rarely may prove impossible to monitor blood pressure in patients (eg, those who have burns) who have no accessible site from which the blood pressure can be safely recorded.

Techniques & Complications

A. Palpation

SBP can be determined by (1) locating a palpable peripheral pulse, (2) inflating a blood pressure cuff proximal to the pulse until flow is occluded, (3) releasing cuff pressure by 2 or 3 mm Hg per heartbeat, and (4) measuring the cuff pressure at which pulsations are again palpable. This method tends to underestimate systolic pressure, however, because of the insensitivity of touch and the delay between flow under the cuff and distal pulsations. Palpation does not provide a diastolic pressure or MAP. The equipment required is simple and inexpensive.

B. Doppler Probe

When a Doppler probe is substituted for the anesthesiologist’s finger, arterial blood pressure measurement becomes sensitive enough to be useful in obese patients, pediatric patients, and patients in shock (Figure 5–3). The Doppler effect is the shift in the frequency of sound waves when their source moves relative to the observer. For example, the pitch of a train’s whistle increases as a
train approaches and decreases as it departs. Similarly, the reflection of sound waves off of a moving object causes a frequency shift. A Doppler probe transmits an ultrasonic signal that is reflected by underlying tissue. As red blood cells move through an artery, a Doppler frequency shift will be detected by the probe. The difference between transmitted and received frequency causes the characteristic swishing sound, which indicates blood flow. Because air reflects ultrasound, a coupling gel (but not corrosive electrode jelly) is applied between the probe and the skin. Positioning the probe directly above an artery is crucial, since the beam must pass through the vessel wall. Interference from probe movement or electrocautery is an annoying distraction. Note that only systolic pressures can be reliably determined with the Doppler technique.

![A Doppler probe secured over the radial artery will sense red blood cell movement as long as the blood pressure cuff is below systolic pressure.](image)

**FIGURE 5–3** A Doppler probe secured over the radial artery will sense red blood cell movement as long as the blood pressure cuff is below systolic pressure. (Reproduced with permission from Parks Medical Electronics.)

A variation of Doppler technology uses a piezoelectric crystal to detect lateral arterial wall movement to the intermittent opening and closing of vessels between systolic and diastolic pressure. This instrument thus detects both systolic and diastolic pressures. The Doppler effect is routinely employed by
perioperative echocardiographers to discern both the directionality and velocity of both blood flow within the heart and the movement of the heart’s muscle tissue (tissue Doppler).

C. Auscultation
Inflation of a blood pressure cuff to a pressure between systolic and diastolic pressures will partially collapse an underlying artery, producing turbulent flow and the characteristic Korotkoff sounds. These sounds are audible through a stethoscope placed under—or just distal to—the distal third of the blood pressure cuff. The clinician measures pressure with an aneroid or mercury manometer.

Occasionally, Korotkoff sounds cannot be heard through part of the range from systolic to diastolic pressure. This auscultatory gap is most common in hypertensive patients and can lead to an inaccurate diastolic pressure measurement. Korotkoff sounds are often difficult to auscultate in noisy patient care environments and during episodes of hypotension or marked peripheral vasoconstriction. In these situations, the subsonic frequencies associated with the sounds can be detected by a microphone and amplified to indicate systolic and diastolic pressures. Motion artifact and electrocautery interference limit the usefulness of this method.

D. Oscillometry
Arterial pulsations cause oscillations in cuff pressure. These oscillations are small if the cuff is inflated above systolic pressure. When the cuff pressure decreases to systolic pressure, the pulsations are transmitted to the entire cuff, and the oscillations markedly increase. Maximal oscillation occurs at the MAP, after which oscillations decrease. Because some oscillations are present above and below arterial blood pressure, a mercury or aneroid manometer provides an inaccurate and unreliable measurement. Automated blood pressure monitors electronically measure the pressures at which the oscillation amplitudes change (Figure 5–4). A microprocessor derives systolic, mean, and diastolic pressures using an algorithm. Machines that require identical consecutive pulse waves for measurement confirmation may be unreliable during arrhythmias (eg, atrial fibrillation). Oscillometric monitors should not be used on patients on cardiopulmonary bypass. Nonetheless, the speed, accuracy, and versatility of oscillometric devices have greatly improved, and they have become the preferred noninvasive blood pressure monitors in the United States and worldwide.
E. Arterial Tonometry
Arterial tonometry measures beat-to-beat arterial blood pressure by sensing the pressure required to partially flatten a superficial artery that is supported by a bony structure (e.g., radial artery). A tonometer consisting of several independent pressure transducers is applied to the skin overlying the artery (Figure 5–5). The contact stress between the transducer directly over the artery and the skin reflects intraluminal pressure. Continuous pulse recordings produce a tracing very similar to an invasive arterial blood pressure waveform. Limitations to this technology include sensitivity to movement artifact and the need for frequent calibration.
pressure determination. The sensors must be positioned directly over the artery.

**Clinical Considerations**

Adequate oxygen delivery to vital organs must be maintained during anesthesia. Unfortunately, instruments to monitor specific organ perfusion and oxygenation are complex, expensive, and often unreliable, and, for that reason, an adequate arterial blood pressure is assumed to predict adequate organ blood flow. However, flow also depends on vascular resistance:

\[
\text{Flow} = \frac{\text{Pressure}}{\text{Resistance}}
\]

Even if the pressure is high, when the resistance is also high, flow can be low. Thus, arterial blood pressure should be viewed as an indicator—but not a measure—of organ perfusion.

The accuracy of any method of blood pressure measurement that involves a blood pressure cuff depends on proper cuff size (Figure 5–6). The cuff’s bladder should extend at least halfway around the extremity, and the width of the cuff should be 20% to 50% greater than the diameter of the extremity.
Blood pressure cuff width influences the pressure readings. The narrowest cuff (A) will require more pressure, and the widest cuff (C) less pressure, to occlude the brachial artery for determination of systolic pressure. Too narrow a cuff may produce a large overestimation of systolic pressure. Whereas the wider cuff may underestimate the systolic pressure, the error with a cuff 20% too wide is not as significant as the error with a cuff 20% too narrow. (Reproduced with permission from Gravenstein JS, Paulus DA. Clinical Monitoring Practice. 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1987.)

Automated blood pressure monitors, using one or a combination of the methods described above, are frequently used in anesthesiology. A self-contained air pump inflates the cuff at set intervals. Incorrect placement or too-frequent cycling of these automated devices has resulted in nerve palsies and extensive extravasation of intravenously administered fluids. In case of equipment failure, an alternative method of blood pressure determination must be immediately available.

2. Invasive Arterial Blood Pressure Monitoring
Indications

Indications for invasive arterial blood pressure monitoring by catheterization of an artery include induced current or anticipated hypotension or wide blood pressure deviations, end-organ disease necessitating precise beat-to-beat blood pressure regulation, and the need for multiple arterial blood gas or other blood analyses.

Contraindications

If possible, catheterization should be avoided in smaller end arteries lacking collateral blood flow or in extremities where there is a suspicion of preexisting vascular insufficiency.

A. Selection of Artery for Cannulation

Several arteries are available for percutaneous catheterization.

1. The radial artery is commonly cannulated because of its superficial location and substantial collateral flow (in most patients the ulnar artery is larger than the radial and there are connections between the two via the palmar arches). Five percent of patients have incomplete palmar arches and lack adequate collateral blood flow. Allen’s test is a simple, but not reliable, method for assessing the safety of radial artery cannulation. In this test, the patient exsanguinates his or her hand by making a fist. While the operator occludes the radial and ulnar arteries with fingertip pressure, the patient relaxes the blanched hand. Collateral flow through the palmar arterial arch is confirmed by flushing of the thumb within 5 s after pressure on the ulnar artery is released. Delayed return of normal color (5–10 s) indicates an equivocal test or insufficient collateral circulation (>10 s). The Allen’s test is of such questionable utility that many practitioners routinely avoid it. Alternatively, blood flow distal to the radial artery occlusion can be detected by palpation, Doppler probe, plethysmography, or pulse oximetry. Unlike Allen’s test, these methods of determining the adequacy of collateral circulation do not require patient cooperation.

2. Ulnar artery catheterization is usually more difficult than radial catheterization because of the ulnar artery’s deeper and more tortuous course. Because of the risk of compromising blood flow to the hand, ulnar catheterization would not normally be considered if the ipsilateral radial artery has been punctured but unsuccessfully cannulated.
3. The **brachial artery** is large and easily identifiable in the antecubital fossa. Its proximity to the aorta provides less waveform distortion. However, being near the elbow predisposes brachial artery catheters to kinking.

4. The **femoral artery** is prone to atheroma formation and pseudoaneurysm, but often provides excellent access. The femoral site has been associated with an increased incidence of infectious complications and arterial thrombosis. Aseptic necrosis of the head of the femur is a rare, but tragic, complication of femoral artery cannulation in children.

5. The **dorsalis pedis and posterior tibial arteries** are some distance from the aorta and therefore have the most distorted waveforms.

6. The **axillary artery** is surrounded by the axillary plexus, and nerve damage can result from a hematoma or traumatic cannulation. Air or thrombi can quickly gain access to the cerebral circulation during vigorous retrograde flushing of axillary artery catheters.

### B. Technique of Radial Artery Cannulation

One technique of radial artery cannulation is illustrated in **Figure 5–7**. Supination and extension of the wrist optimally position the radial artery. The pressure–tubing–transducer system should be nearby and already flushed with saline to ensure easy and quick connection after cannulation. The radial pulse is palpated, and the artery’s course is determined by lightly pressing the *tips* of the index and middle fingers of the nondominant hand over the area of maximal impulse or by use of ultrasound. After skin cleansing with chlorhexidine (or other prep solution), and using aseptic technique 1% lidocaine is infiltrated in the skin of awake patients, directly above the artery, with a small gauge needle. A larger 18-gauge needle can then be used as a skin punch, facilitating entry of a 20- or 22-gauge catheter over a needle through the skin at a 45° angle, directing it toward the point of palpation. Upon blood flashback, a guidewire may be advanced through the catheter into the artery and the catheter advanced over the guidewire. Alternatively, the needle is lowered to a 30° angle and advanced another 1 to 2 mm to make certain that the tip of the catheter is well into the vessel lumen. The catheter is advanced off the needle into the arterial lumen, after which the needle is withdrawn. Applying firm pressure over the artery proximal to the catheter insertion site prevents blood from spurting from the catheter while the tubing is connected. Waterproof tape or suture can be used to hold the catheter in place, and a sterile dressing should be applied over the insertion site.
FIGURE 5–7  Cannulation of the radial artery. A: Proper positioning and palpation of the artery are crucial. After skin preparation, local anesthetic is infiltrated with a 25-gauge needle. B: A 20- or 22-gauge catheter is advanced through the skin at a 45° angle. C: Flashback of blood signals entry into the artery, and the catheter–needle assembly is lowered to a 30° angle and advanced 1–2 mm to ensure an intraluminal catheter position. D: The catheter is advanced over the needle, which is withdrawn. E: Proximal pressure with middle and ring fingers prevents blood loss, while the arterial tubing Luer-lock connector is secured to the intraarterial catheter.

C. Complications
Complications of intraarterial monitoring include hematoma, bleeding (particularly with catheter tubing disconnections), vasospasm, arterial thrombosis, embolization of air bubbles or thrombi, pseudoaneurysm formation,
necrosis of skin overlying the catheter, nerve damage, infection, necrosis of extremities or digits, and unintentional intraarterial drug injection. Factors associated with an increased rate of complications include prolonged cannulation, hyperlipidemia, repeated insertion attempts, female gender, extracorporeal circulation, the use of larger catheters in smaller vessels, and the use of vasopressors. The risks are reduced with good aseptic techniques, when the ratio of catheter to artery size is small, when saline is continuously infused through the catheter at a rate of 2 to 3 mL/h, and when flushing of the catheter is limited. Adequacy of perfusion can be continually monitored during radial artery cannulation by placing a pulse oximeter on the thumb or index finger.

**Clinical Considerations**

Because intraarterial cannulation allows continuous beat-to-beat blood pressure measurement, it is considered the optimal blood pressure monitoring technique. The quality of the transduced waveform, however, depends on the dynamic characteristics of the catheter–tubing–transducer system. False readings can lead to inappropriate therapeutic interventions.

A complex waveform, such as an arterial pulse wave, can be expressed as a summation of simple harmonic waves (according to the Fourier theorem). For accurate measurement of pressure, the catheter–tubing–transducer system must be capable of responding adequately to the highest frequency of the arterial waveform (Figure 5–8). Stated another way, the natural frequency of the measuring system must exceed the natural frequency of the arterial pulse (approximately 16–24 Hz).

**FIGURE 5–8** An original waveform overlays a four-harmonic reconstruction (left) and an eight-harmonic reconstruction (right). Note that the higher harmonic plot more closely resembles the original waveform. (Reproduced with permission from Saidman LS, Smith WT. *Monitoring in Anesthesia*. Philadelphia, PA: Butterworth-
Most transducers have frequencies of several hundred Hz (>200 Hz for disposable transducers). The addition of tubing, stopcocks, and air in the line all decrease the frequency of the system. If the frequency response is too low, the system will be overdamped and will not faithfully reproduce the arterial waveform, underestimating the systolic pressure. Underdamping is also a serious problem, leading to overshoot and a falsely high SBP.

Catheter–tubing–transducer systems must also prevent hyperresonance, an artifact caused by reverberation of pressure waves within the system. A damping coefficient ($\beta$) of 0.6 to 0.7 is optimal. The natural frequency and damping coefficient can be determined by examining tracing oscillations after a high-pressure flush.

Arterial blood pressure measurements are improved by minimizing tubing length, eliminating unnecessary stopcocks, removing air bubbles, and using low-compliance tubing. Although smaller diameter catheters lower natural frequency, they improve underdampened systems and are less apt to result in vascular complications. If a large catheter totally occludes an artery, reflected waves can distort pressure measurements.

Pressure transducers have evolved from bulky, reusable instruments to miniaturized, disposable devices. Transducers contain a diaphragm that is distorted by an arterial pressure wave. The mechanical energy of a pressure wave is converted into an electric signal. Most transducers are resistance types that are based on the strain gauge principle: stretching a wire or silicone crystal changes its electrical resistance. The sensing elements are arranged as a “Wheatstone bridge” circuit so that the voltage output is proportionate to the pressure applied to the diaphragm.

Transducer accuracy depends on correct calibration and zeroing procedures. A stopcock at the level of the desired point of measurement—usually the midaxillary line—is opened, and the zero trigger on the monitor is activated. If the patient’s position is altered by raising or lowering the operating table, the transducer must either be moved in tandem or zeroed to the new level of the midaxillary line. In a seated patient, the arterial pressure in the brain differs significantly from left ventricular pressure. In this circumstance, cerebral pressure is determined by setting the transducer to zero at the level of the ear, which approximates the circle of Willis. The transducer’s zero should be verified regularly, as some transducer measurements can “drift” over time.

External calibration of a transducer compares the transducer’s reading with a manometer, but modern transducers rarely require external calibration.
Digital readouts of systolic and diastolic pressures are a running average of the highest and lowest measurements within a certain time interval. Because motion or cautery artifacts can result in some very misleading numbers, the arterial waveform should always be monitored. The shape of the arterial wave provides clues to several hemodynamic variables. The rate of upstroke indicates contractility, the rate of downstroke indicates peripheral vascular resistance, and exaggerated variations in size during the respiratory cycle suggest hypovolemia. MAP is calculated by integrating the area under the pressure curve.

Intraarterial catheters also provide access for intermittent arterial blood gas sampling and analysis. The development of fiberoptic sensors that can be inserted through a 20-gauge arterial catheter enables continuous blood gas monitoring. Unfortunately, these sensors are quite expensive and are often inaccurate, so they are rarely used. Analysis of the arterial pressure waveform allows for estimation of cardiac output (CO) and other hemodynamic parameters. These devices are discussed in the section on CO monitoring.

**ELECTROCARDIOGRAPHY**

**Indications & Contraindications**

All patients should have intraoperative monitoring of their electrocardiogram (ECG). There are no contraindications.

**Techniques & Complications**

Lead selection determines the diagnostic sensitivity of the ECG. ECG leads are positioned on the chest and extremities to provide different perspectives of the electrical potentials generated by the heart. At the end of diastole, the atria contract, which provides the atrial contribution to CO, generating the “P” wave. Following atrial contraction, the ventricle is loaded awaiting systole. The QRS complex begins the electrical activity of systole following the 120 to 200 msec atrioventricular (AV) nodal delay. Depolarization of the ventricle proceeds from the AV node through the interventricular system via the His–Purkinje fibers. The normal QRS lasts approximately 120 msec, which can be prolonged in patients with cardiomyopathies and heart failure. The T wave represents repolarization as the heart prepares to contract again. Prolongation of the QT interval secondary to electrolyte imbalances or drug effects can potentially lead to life-threatening arrhythmias (torsades de pointes).

The electrical axis of lead II is approximately 60° from the right arm to the
left leg, which is parallel to the electrical axis of the atria, resulting in the largest P-wave voltages of any surface lead. This orientation enhances the diagnosis of arrhythmias and the detection of inferior wall ischemia. Lead V5 lies over the fifth intercostal space at the anterior axillary line; this position is a good compromise for detecting anterior and lateral wall ischemia. A true V5 lead is possible only on operating room ECGs with at least five lead wires, but a modified V5 can be monitored by rearranging the standard three-limb lead placement (Figure 5–9). Ideally, because each lead provides unique information, leads II and V5 should be monitored simultaneously. If only a single-channel machine is available, the preferred lead for monitoring depends on the location of any prior infarction or ischemia and whether arrhythmia or ischemia appears to be the greater concern.
FIGURE 5–9  Rearranged three-limb lead placement. Anterior and lateral ischemia can be detected by placing the left arm lead (LA) at the V₅ position. When lead I is selected on the monitor, a modified V₅ lead (CS₅) is displayed. Lead II allows detection of arrhythmias and inferior wall ischemia. RA, right arm; LL, left leg.

Electrodes are placed on the patient’s body to monitor the ECG (Figure 5–10). Conductive gel lowers the skin’s electrical resistance, which can be further decreased by cleansing the site with alcohol. Needle electrodes are used only if the disks are unsuitable (eg, with an extensively burned patient).
Clinical Considerations

The ECG is a recording of the electrical potentials generated by myocardial cells. Its routine use allows arrhythmias, myocardial ischemia, conduction abnormalities, pacemaker malfunction, and electrolyte disturbances to be detected (Figure 5–11). Because of the small voltage potentials being measured, artifacts remain a major problem. Patient or lead-wire movement, use of electrocautery, 60-Hz interference from nearby alternating current devices, and faulty electrodes can simulate arrhythmias. Monitoring filters incorporated into the amplifier to reduce “motion” artifacts will lead to distortion of the ST segment and may impede the diagnosis of ischemia. Digital readouts of the heart rate (HR) may be misleading because of monitor misinterpretation of artifacts or large T waves—often seen in pediatric patients—as QRS complexes.
Depending on equipment availability, a preinduction rhythm strip can be printed or frozen on the monitor’s screen to compare with intraoperative tracings. To interpret ST-segment changes properly, the ECG must be standardized so that a 1-mV signal results in a deflection of 10 mm on a standard strip monitor. Newer units continuously analyze ST segments for early detection of myocardial ischemia. Automated ST-segment analysis increases the sensitivity of ischemia detection, does not require additional physician skill or vigilance, and may help diagnose intraoperative myocardial ischemia.

Commonly accepted criteria for diagnosing myocardial ischemia require that the ECG be recorded in “diagnostic mode” and include a flat or downsloping ST-segment depression exceeding 1 mm, 80 msec after the J point (the end of the
QRS complex), particularly in conjunction with T-wave inversion. ST-segment elevation with peaked T waves can also represent ischemia. Wolff–Parkinson–White syndrome, bundle-branch blocks, extrinsic pacemaker capture, and digoxin therapy may preclude the use of ST-segment information. The audible beep associated with each QRS complex should be loud enough to detect rate and rhythm changes when the anesthesiologist’s visual attention is directed elsewhere. Some ECGs are capable of storing aberrant QRS complexes for further analysis, and some can even interpret and diagnose arrhythmias. The interference caused by electrocautery units limits the usefulness of automated arrhythmia analysis in the operating room.

CENTRAL VENOUS CATHETERIZATION

Indications

Central venous catheterization is indicated for monitoring central venous pressure (CVP), administration of fluid to treat hypovolemia and shock, infusion of caustic drugs and total parenteral nutrition, aspiration of air emboli, insertion of transcutaneous pacing leads, and gaining venous access in patients with poor peripheral veins. With specialized catheters, central venous catheterization can be used for continuous monitoring of central venous oxygen saturation (ScvO₂). ScvO₂ is used as a measure to assess adequacy of oxygen delivery. Decreased ScvO₂ (normal >65%) alerts to the possibility of inadequate delivery of oxygen to the tissues (eg, low cardiac output, low hemoglobin, low arterial oxygen saturation, increased oxygen consumption). An elevated ScvO₂ (>80%) may indicate arterial/venous shunting or impaired cellular oxygen utilization (eg, cyanide poisoning).

Contraindications

Relative contraindications include tumors, clots, or tricuspid valve vegetations that could be dislodged or embolized during cannulation. Other contraindications relate to the cannulation site. For example, subclavian vein cannulation is relatively contraindicated in patients who are receiving anticoagulants (due to the inability to provide direct compression in the event of an accidental arterial puncture). Based on tradition but not science, some clinicians avoid internal jugular vein cannulation on the side of a previous carotid endarterectomy due to concerns about unintentional carotid artery puncture. The presence of other
Central catheters or pacemaker leads may reduce the number of sites available for central line placement.

**Techniques & Complications**

Central venous cannulation involves introducing a catheter into a vein so that the catheter’s tip lies with the venous system within the thorax. Generally, the optimal location of the catheter tip is just superior to or at the junction of the superior vena cava and the right atrium. When the catheter tip is located within the thorax, inspiration will increase or decrease CVP, depending on whether ventilation is controlled or spontaneous. Measurement of CVP is made with a water column (cm H$_2$O) or, preferably, an electronic transducer (mm Hg). The pressure should be measured during end expiration.

Various sites can be used for cannulation (Figure 5–12). All cannulation sites have an increased risk of infection the longer the catheter remains in place. Compared with other sites, the subclavian vein is associated with a greater risk of pneumothorax during insertion, but a reduced risk of other complications during prolonged cannulations (eg, in critically ill patients). The right internal jugular vein provides a combination of accessibility and safety. Left-sided internal jugular vein catheterization has an increased risk of pleural effusion and chylothorax. The external jugular veins can also be used as entry sites, but due to the acute angle at which they join the great veins of the chest, are associated with a slightly increased likelihood of failure to gain access to the central circulation than the internal jugular veins. Femoral veins can also be cannulated, but are associated with an increased risk of line-related sepsis. There are at least three cannulation techniques: a catheter over a needle (similar to peripheral catheterization), a catheter through a needle (requiring a large-bore needle stick), and a catheter over a guidewire (Seldinger technique; Figure 5–13). The overwhelming majority of central lines are placed using Seldinger technique.
FIGURE 5–12 The subclavian and internal jugular veins are both used for central access perioperatively with the sternal notch and ipsilateral nipple in the direction of needle passage for each, respectively. (Reproduced with permission from Wasnick J, Hillel Z, Kramer D, et al. Cardiac Anesthesia & Transesophageal Echocardiography. New York, NY: McGraw-Hill; 2011.)
The following scenario describes the placement of an internal jugular venous line. The patient is placed in the Trendelenburg position to decrease the risk of air embolism and to distend the internal jugular (or subclavian) vein. Central venous catheterization requires full aseptic technique, including hand scrub, sterile gloves, gown, mask, hat, bactericidal skin preparation (alcohol-based solutions are preferred), and sterile drapes. The two heads of the sternocleidomastoid muscle and the clavicle form the three sides of a triangle (Figure 5–13A). A 25-gauge needle is used to infiltrate the apex of the triangle with local anesthetic. The internal jugular vein can be located using ultrasound, and we strongly recommend that it be used whenever possible (Figure 5–14). Many institutions mandate the use of ultrasound whenever internal jugular vein cannulation is performed. Alternatively, the vein may be located by advancing the 25-gauge needle—or a 23-gauge needle in heavier patients—along the medial border of the lateral head of the sternocleidomastoid, toward the ipsilateral nipple, at an angle of 30° to the skin, aiming just lateral to the carotid artery pulse. Aspiration of venous blood confirms the vein’s location. It is
essential that the vein (and not the artery) be cannulated. Cannulation of the carotid artery can lead to hematoma, stroke, airway compromise, and possibly death. An 18-gauge thin-wall needle or an 18-gauge catheter over needle is advanced along the same path as the locator needle (Figure 5–13B), and, with the latter apparatus, the needle is removed from the catheter once the catheter has been advanced into the vein. After free blood flow is achieved we usually confirm central venous versus arterial pressure (using intravenous extension tubing) before introducing a guidewire. (Figure 5–13C). We recommend that correct placement of the guidewire be confirmed using ultrasound. The needle (or catheter) is removed, and a dilator is advanced over the wire. The catheter is prepared for insertion by flushing all ports with saline, and all distal ports are “capped” or clamped, except the one through which the wire must pass. Next, the dilator is removed, and the final catheter is advanced over the wire (Figure 5–13D). Do not lose control of the proximal tip of the guidewire. The guidewire is removed, with a thumb placed over the catheter hub to prevent aspiration of air until the intravenous catheter tubing is connected to it. The catheter is then secured, and a sterile dressing is applied. Correct location is confirmed with a chest radiograph. The tip of the catheter should not be allowed to migrate into the heart chambers. Fluid-administration sets should be changed frequently, per your medical center protocol.
As mentioned, the likelihood of accidental placement of the vein dilator or catheter into the carotid artery can be decreased by transducing the vessel’s pressure from the introducer needle (or catheter, if a catheter over needle has been used) before passing the wire (most simply accomplished by using a sterile intravenous extension tubing as a manometer). Alternatively, one may compare the color or PaO$_2$ of the blood with that of an arterial sample. Blood color and pulsatility can be misleading or inconclusive, and more than one confirmation method should be used. In cases where either surface ultrasound or transesophageal echocardiography (TEE) are used, the guidewire can be seen in the jugular vein or right atrium, confirming venous entry (Figure 5–15).
The risks of central venous cannulation include line infection, bloodstream infection, air or thrombus embolism, arrhythmias (indicating that the catheter tip is in the right atrium or ventricle), hematoma, pneumothorax, hemothorax, hydrothorax, chylothorax, cardiac perforation, cardiac tamponade, trauma to nearby nerves and arteries, and thrombosis.

**Clinical Considerations**

Normal cardiac function requires adequate ventricular filling. CVP approximates right atrial pressure. Ventricular volumes are related to pressures through compliance. Highly compliant ventricles accommodate volume with minimal changes in pressure. Noncompliant systems have larger swings in pressure with less volume changes. Consequently, any one CVP measurement will reveal only limited information about ventricular volumes and filling. Although a very low CVP may indicate a volume-depleted patient, a moderate to high pressure reading may reflect volume overload, poor ventricular compliance, or both. Changes in CVP associated with volume administration coupled with other measures of hemodynamic performance (eg, stroke volume, cardiac output, blood pressure, HR, urine output) may be a better indicator of the patient’s volume responsiveness.
The shape of the central venous waveform corresponds to the events of cardiac contraction (Figure 5–16): a waves from atrial contraction are absent in atrial fibrillation and are exaggerated in junctional rhythms (“cannon” a waves); c waves are due to tricuspid valve elevation during early ventricular contraction; v waves reflect venous return against a closed tricuspid valve; and the x and y descents are probably caused by the downward displacement of the tricuspid valve during systole and tricuspid valve opening during diastole.

![Graph of ECG and central venous tracing](image)

**FIGURE 5–16** The upward waves (a, c, v) and the downward descents (x, y) of a central venous tracing in relation to the electrocardiogram (ECG).

**PULMONARY ARTERY CATHETERIZATION**

**Indications**

The pulmonary artery (PA) catheter (or Swan-Ganz catheter) was introduced into routine practice in operating rooms and in coronary and critical care units in the 1970s. It quickly became common for sicker patients undergoing major surgery to be managed with PA catheterization. The catheter provides measurements of both CO and PA occlusion pressures and was used to guide hemodynamic therapy, especially when patients became unstable. Determination of the PA occlusion or wedge pressure permitted (in the absence of mitral stenosis) an
estimation of the left ventricular end-diastolic pressure (LVEDP), and, depending upon ventricular compliance, an estimate of ventricular volume. Through its ability to perform measurements of CO, the patient’s stroke volume (SV) was also determined.

\[ \text{CO} = \text{SV} \times \text{HR} \]

\[ \text{SV} = \frac{\text{CO}}{\text{HR}} \]

Blood pressure = CO \times \text{systemic vascular resistance (SVR)}

Consequently, hemodynamic monitoring with the PA catheter attempted to discern why a patient was unstable so that therapy could be directed at the underlying problem.

If the SVR is diminished, such as in states of vasodilatory shock (sepsis), the SV may increase. Conversely, a reduction in SV may be secondary to poor cardiac performance or hypovolemia. Determination of the “wedge” or pulmonary capillary occlusion pressure (PCOP) by inflating the catheter balloon estimates the LVEDP. A decreased SV in the setting of a low PCOP/LVEDP indicates hypovolemia and the need for volume administration. A “full” heart, reflected by a high PCOP/LVEDP and low SV, indicates the need for a positive inotropic drug. Conversely, a normal or increased SV in the setting of hypotension could be treated with the administration of vasoconstrictor drugs to restore SVR in a vasodilated patient.

Although patients can present concurrently with hypovolemia, sepsis, and heart failure, this basic treatment approach and the use of the PA catheter to guide therapy became more or less synonymous with perioperative intensive care and cardiac anesthesia. However, several large observational studies have shown that patients managed with PA catheters had worse outcomes than similar patients who were managed without PA catheters. Other studies seem to indicate that although PA catheter-guided patient management may do no harm, it offers no specific benefits. Although the PA catheter can be used to guide goal-directed hemodynamic therapy to ensure organ perfusion in shock states, other less invasive methods to determine hemodynamic performance are available, including transpulmonary thermodilution CO measurements, pulse contour analyses of the arterial pressure waveform, and methods based on bioimpedance measurements across the chest. All these methods permit calculation of the SV as a guide for hemodynamic management. Moreover, right atrial blood oxygen saturation, as opposed to mixed venous saturation (normal is 75%), can be used
as an alternative measure to discern tissue oxygen extraction and the adequacy of tissue oxygen delivery.

Despite numerous reports of its questionable utility and the increasing number of alternative methods to determine hemodynamic parameters, the PA catheter is still employed perioperatively more often in the United States than elsewhere. Although echocardiography can readily determine if the heart is full, compressed, contracting, or empty, a trained individual is required to obtain and interpret the images. Alternative hemodynamic monitors have gained wide acceptance in Europe and are increasingly used in the United States, further decreasing the use of PA catheters.

PA catheterization should be considered whenever cardiac index, preload, volume status, or the degree of mixed venous blood oxygenation need to be known. These measurements might prove particularly important in surgical patients at greatest risk for hemodynamic instability or during surgical procedures associated with a greatly increased incidence of hemodynamic complications (eg, thoracic aortic aneurysm repair).

**Contraindications**

Relative contraindications to pulmonary artery catheterization include left bundle-branch block (because of the concern about complete heart block) and conditions associated with a greatly increased risk of arrhythmias. A catheter with pacing capability is better suited to these situations. A PA catheter may serve as a nidus of infection in bacteremic patients or thrombus formation in patients prone to hypercoagulation.

**Techniques & Complications**

Although various PA catheters are available, the most popular design integrates five lumens into a 7.5 FR catheter, 110-cm long, with a polyvinylchloride body (Figure 5–17). The lumens house the following: wiring to connect the thermistor near the catheter tip to a thermodilution CO computer; an air channel for inflation of the balloon; a proximal port 30 cm from the tip for infusions, CO injections, and measurements of right atrial pressures; a ventricular port at 20 cm for infusion of drugs; and a distal port for aspiration of mixed venous blood samples and measurements of PA pressure.
Insertion of a PA catheter requires central venous access, which can be accomplished using Seldinger’s technique, described earlier. Instead of a central venous catheter, a dilator and sheath are threaded over the guidewire. The sheath lumen accommodates the PA catheter after removal of the dilator and guidewire (Figure 5–18).
Prior to insertion, the PA catheter is checked by inflating and deflating its balloon and filling all three lumens with intravenous fluid. The distal port is connected to a transducer that is zeroed to the patient’s midaxillary line.

The PA catheter is advanced through the introducer and into the internal jugular vein. At approximately 15 cm, the distal tip should enter the right atrium, and a central venous tracing that varies with respiration confirms an intrathoracic position. The balloon is then inflated with air according to the manufacturer’s recommendations (usually 1.5 mL) to protect the endocardium from the catheter tip and to allow flow through the right ventricle to direct the catheter forward. The balloon is always deflated during withdrawal. During catheter advancement, the ECG should be monitored for arrhythmias. Transient ectopy from irritation of the right ventricle by the balloon and catheter tip is common and rarely requires treatment. A sudden increase in the systolic pressure on the distal

**FIGURE 5–18** A percutaneous introducer consisting of a vessel dilator and sheath is passed over the guidewire.
tracing indicates a right ventricular location of the catheter tip (Figure 5–19). Entry into the pulmonary artery normally occurs by 35 to 45 cm and is heralded by a sudden increase in *diastolic* pressure.

**FIGURE 5–19** Although their utility is increasingly questioned, pulmonary artery (PA) catheters continue to be a part of perioperative management of the cardiac surgery patient. Following placement of a sheath introducer in the central circulation (panels 1 and 2), the PA catheter is floated. Central line placement should always be completed using rigorous sterile technique, full body draping, and only after multiple, redundant confirmations of the correct localization of the venous circulation. Pressure guidance is used to ascertain the localization of the PA catheter in the venous circulation and the heart. Upon entry into the right atrium (RA; panels 3 and 4), the central venous pressure tracing is noted. Passing through the tricuspid valve (panels 5 and 6) right ventricular pressures are detected. At 35 to 50 cm depending upon patient size, the catheter will pass from the right ventricle (RV) through the pulmonic valve into the pulmonary artery (panels 7 and 8). This is noted by the measurement of diastolic pressure once the pulmonic valve is passed. Lastly, when indicated the balloon-tipped
catheter will wedge or occlude a pulmonary artery branch (panels 9, 10, and 11). When this occurs, the pulmonary artery pressure equilibrates with that of the left atrium (LA) which, barring any mitral valve pathology, should be a reflection of left ventricular end-diastolic pressure. IVC, inferior vena cava; SVC, superior vena cava. (Reproduced with permission from Soni N. Practical Procedures in Anaesthesia and Intensive Care. Philadelphia, PA: Butterworth Heinemann; 1994.)

To prevent catheter knotting, the balloon should be deflated and the catheter withdrawn if pressure changes do not occur at the expected distances. Occasionally, the insertion may require fluoroscopy or TEE for guidance.

After the catheter tip enters the PA, minimal additional advancement results in a pulmonary artery occlusion pressure (PAOP) waveform. The PA tracing should reappear when the balloon is deflated. Wedging before maximal balloon inflation signals an overwedged position, and the catheter should be slightly withdrawn (with the balloon down, of course). Because PA rupture from balloon overinflation may cause hemorrhage and mortality, wedge readings should be obtained infrequently. PA pressure should be continuously monitored to detect an overwedged position indicative of catheter migration. Correct PA catheter position is confirmed by a chest radiograph.

The numerous complications of PA catheterization include all those associated with central venous cannulation plus endocarditis, thrombogenesis, pulmonary infarction, PA rupture, and hemorrhage (particularly in patients taking anticoagulants, elderly or female patients, or patients with pulmonary hypertension), catheter knotting, arrhythmias, conduction abnormalities, and pulmonary valvular damage (Table 5–1). Even trace hemoptysis should not be ignored, as it may herald PA rupture. If the latter is suspected, prompt placement of a double-lumen tracheal tube may maintain adequate oxygenation by the unaffected lung. The risk of complications increases with the duration of catheterization, which usually should not exceed 72 h.

**Clinical Considerations**
The introduction of PA catheters into the operating room revolutionized the intraoperative management of critically ill patients. PA catheters allow more precise estimation of left ventricular preload than either CVP or physical examination (but not as precise as TEE), as well as the sampling of mixed venous blood. Catheters with self-contained thermistors (discussed later in this chapter) can be used to measure CO, from which a multitude of hemodynamic values can be derived (Table 5–2). Some catheter designs incorporate electrodes that allow intracavitary ECG recording and pacing. Optional fiberoptic bundles allow continuous measurement of the oxygen saturation of mixed venous blood.

Starling demonstrated the relationship between left ventricular function and left ventricular end-diastolic muscle fiber length, which is usually proportionate to end-diastolic volume (see Chapter 20). If compliance is not abnormally decreased (eg, by myocardial ischemia, overload, ventricular hypertrophy, or pericardial tamponade). LVEDP should reflect fiber length. In the presence of a normal mitral valve, left atrial pressure approaches left ventricular pressure during diastolic filling. The left atrium connects with the right side of the heart through the pulmonary vasculature. The distal lumen of a correctly wedged PA catheter is isolated from right-sided pressures by balloon inflation. Its distal opening is exposed only to capillary pressure, which—in the absence of high airway pressures or pulmonary vascular disease—equals left atrial pressure. In fact, aspiration through the distal port during balloon inflation samples arterialized blood. PAOP is an indirect measure of LVEDP which, depending
upon ventricular compliance, approximates left ventricular end diastolic volume.

Whereas CVP may reflect right ventricular function, a PA catheter may be indicated if either ventricle is markedly depressed, causing disassociation of right- and left-sided hemodynamics. CVP is poorly predictive of pulmonary capillary pressures, especially in patients with abnormal left ventricular function. Even the PAOP does not always predict LVEDP. The relationship between left ventricular end-diastolic volume (actual preload) and PAOP (estimated preload) can become unreliable during conditions associated with changing left atrial or ventricular compliance, mitral valve function, or pulmonary vein resistance. These conditions are common immediately following major cardiac or vascular surgery and in critically ill patients who are receiving inotropic agents or are suffering from septic shock.

Ultimately, the value of the information provided by the PA catheter is dependent upon its correct interpretation by the patient’s caregivers. Thus, the PA catheter is only a tool to assist in goal-directed perioperative therapy. Given the increasing number of less invasive methods now available to obtain similar information, we anticipate that PA catheterization will become mostly of historic interest.

**CARDIAC OUTPUT**

**Indications**

CO measurement to permit calculation of the SV is one of the primary reasons for PA catheterization. Currently, there are a number of alternative, less invasive methods to estimate ventricular function to assist in goal-directed therapy.

**Techniques & Complications**

A. **Thermodilution**

The injection of a quantity (2.5, 5, or 10 mL) of fluid that is below body temperature (usually room temperature or iced) into the right atrium changes the temperature of blood in contact with the thermistor at the tip of the PA catheter. The degree of change is inversely proportional to CO: Temperature change is minimal if there is a high blood flow, whereas temperature change is greater when flow is reduced. After injection, one can plot the temperature as a function of time to produce a **thermodilution curve** (Figure 5–20). CO is determined by a computer program that integrates the area under the curve. ❖ Accurate
measurements of CO depend on rapid and smooth injection, precisely known injectant temperature and volume, correct entry of the calibration factors for the specific type of PA catheter into the CO computer, and avoidance of measurements during electrocautery. Tricuspid regurgitation and cardiac shunts invalidate results because only right ventricular output into the PA is actually being measured. Rapid infusion of the iced injectant has rarely resulted in cardiac arrhythmias.

**FIGURE 5–20** Comparison of thermodilution curves after injection of cold saline into the superior vena cava. The peak temperature change arrives earlier when measured in the pulmonary artery (a) than if measured in the femoral artery (b). Thereafter, both curves soon reapproximate baseline. (Reproduced with permission from Reuter D, Huang C, Edrich T, et al. Cardiac output monitoring using indicator dilution techniques: Basics, limits and perspectives. Anesth Analg. 2010 Mar 1;110(3):799-811.)

A modification of the thermodilution technique allows continuous CO measurement with a special catheter and monitor system. The catheter contains a thermal filament that introduces small pulses of heat into the blood proximal to the pulmonic valve and a thermistor that measures changes in PA blood temperature. A computer in the monitor determines CO by cross-correlating the amount of heat input with the changes in blood temperature.

Transpulmonary thermodilution (PiCCO® system) relies upon the same principles of thermodilution, but does not require PA catheterization. A central line and a thermistor-equipped arterial catheter (usually placed in the femoral artery) are necessary to perform transpulmonary thermodilution. Thermal measurements from radial artery catheters have been found to be invalid.
Transpulmonary thermodilution measurements involve injection of cold indicator into the superior vena cava via a central line (Figure 5–21). A thermistor notes the change in temperature in the arterial system following the cold indicator’s transit through the heart and lungs and estimates the CO.

Transpulmonary thermodilution also permits the calculation of both the global end-diastolic volume (GEDV) and the extravascular lung water (EVLW). Through mathematical analysis and extrapolation of the thermodilution curve, it is possible for the transpulmonary thermodilution computer to calculate both the mean transit time of the indicator and its exponential decay time (Figure 5–22). The intrathoracic thermal volume (ITTV) is the product of the CO and the mean
transit time (MTT). The ITTV includes the pulmonary blood volume (PBV), EVLW, and the blood contained within the heart. The pulmonary thermal volume (PTV) includes both the EVLW and the PBV and is obtained by multiplying the CO by the exponential decay time (EDT). Subtracting the PTV from the ITTV gives the GEDV (Figure 5–23). The GEDV is a hypothetical volume that assumes that all of the heart’s chambers are simultaneously full in diastole. With a normal index between 640 and 800 mL/m², the GEDV can assist in determining volume status. An extravascular lung water index of less than 10 mL/kg is normative. The EVLW is the ITTV minus the intrathoracic blood volume (ITBV). The ITBV = GEDV × 1.25.

**FIGURE 5–22** The upper curve represents the classic thermodilution curve, showing the concentration of an indicator over time at the site of detection. By extrapolation of the curve (dashed line), potential recirculation phenomena are excluded. Logarithmic illustration (lower curve) allows defining the mean transit time (MTT) and the exponential decay time (EDT) of the indicator. (Reproduced with permission from Reuter D, Huang C, Edrich T, et al. Cardiac output monitoring using indicator dilution techniques: Basics, limits and perspectives. *Anesth Analg.* 2010 Mar 1;110(3):799-811.)
FIGURE 5–23 Assessment of global end-diastolic volume (GEDV) by transcardiopulmonary thermodilution. Upper row: The intrathoracic thermal volume (ITTV) is the complete volume of distribution of the thermal indicator, including the right atrium end-diastolic volume (RAEDV), the right ventricle (RVEDV), the left atrium (LAEDV), the left ventricle (LVEDV), the pulmonary blood volume (PBV), and the extravascular lung water (EVLW). It is calculated by multiplying cardiac output ($F_T$) with the mean transit time ($MTT_T$) of the indicator. Middle row: The pulmonary thermal volume (PTV) represents the largest mixing chamber in this system and includes the PBV and the EVLW and is assessed by multiplying $F_T$ with the exponential decay time ($EDT_T$) of the thermal indicator. Bottom row: The GEDV, including the volumes of the right and the left heart, now is calculated by subtracting PTV from ITTV. (Reproduced with permission from Reuter D, Huang C, Edrich T, et al. Cardiac output monitoring using indicator dilution techniques: Basics, limits and perspectives. *Anesth Analg.* 2010 Mar 1;110(3):799-811.)

Thus, $EVLW = ITTV – ITBV$. An increased EVLW can be indicative of fluid overload. Through mathematical analysis of the transpulmonary thermodilution curve, it is therefore possible to obtain volumetric indices to guide fluid
replacement therapy. Moreover, the PiCCO® system calculates SV variation and pulse pressure variation through pulse contour analysis, both of which can be used to determine fluid responsiveness. Both SV and pulse pressure are decreased during positive-pressure ventilation. The greater the variations over the course of positive-pressure inspiration and expiration, the more likely the patient is to improve hemodynamic measures following volume administration. Figure 5–24 demonstrates that patients located on the steeper portion of the curve will be more responsive to volume administration compared with those whose volume status is already adequate. Dynamic measures such as SV and pulse pressure variation assist in the identification of individuals likely to respond to volume administration (Figures 5-25 and 5-26).

**FIGURE 5–24** The fluid responder located on the steep portion of the right atrial pressure (RAP)/cardiac output (CO) curve will augment CO with minimal change in RAP when administered a fluid challenge. Conversely, the nonresponder will see little change in CO; however, RAP will likely increase. (Reproduced with permission from Cherpanath T, Aarts L, Groeneveld J, Geerts B. Defining fluid responsiveness: A guide to patient tailored volume titration. *J Cardiothorac Vasc Anesth*. 2014 Jun;28(3):745-754.)
Pulse pressure variation is the change in pulse pressure that occurs throughout the respiratory cycle in patients supported by positive-pressure ventilation.

As volume is administered, pulse pressure variation decreases. Variation greater than 12% to 13% is suggestive of fluid responsiveness. Dynamic measures such as pulse pressure variation and stroke volume variation become
less reliable when arrhythmias are present. Unfortunately, many of the validation studies using these dynamic measures were performed prior to the routine use of low tidal volume (6 mL/kg) lung protective ventilation strategies during positive-pressure ventilation.

**B. Dye Dilution**

If indocyanine green dye (or another indicator such as lithium) is injected through a central venous catheter, its appearance in the systemic arterial circulation can be measured by analyzing arterial samples with an appropriate detector (eg, a densitometer for indocyanine green). The area under the resulting **dye indicator curve** is related to CO. By analyzing arterial blood pressure and integrating it with CO, systems that use lithium (LiDCO™) also calculate beat-to-beat SV. In the LiDCO™ system, a small bolus of lithium chloride is injected into the circulation. A lithium-sensitive electrode in an arterial catheter measures the decay in lithium concentration over time. Integrating the concentration over time graph permits the machine to calculate the CO. The LiDCO™ device, like the PiCCO® thermodilution device, employs pulse contour analysis of the arterial wave form to provide ongoing beat-to-beat determinations of CO and other calculated parameters. Lithium dilution determinations can be made in patients who have only peripheral venous access. Lithium should not be administered to patients in the first trimester of pregnancy. The dye dilution technique, however, introduces the problems of indicator recirculation, arterial blood sampling, and background tracer buildup, potentially limiting the use of such approaches perioperatively. Nondepolarizing neuromuscular blockers may affect the lithium sensor.

**C. Pulse Contour Devices**

Pulse contour devices use the arterial pressure tracing to estimate the CO and other dynamic parameters, such as pulse pressure and SV variation with mechanical ventilation. These indices are used to help determine if hypotension is likely to respond to fluid therapy.

Pulse contour devices rely upon algorithms that measure the area of the systolic portion of the arterial pressure trace from end diastole to the end of ventricular ejection. The devices then incorporate a calibration factor for the patient’s vascular compliance, which is dynamic and not static. Some pulse contour devices rely first on transpulmonary thermodilution or lithium thermodilution to calibrate the machine for subsequent pulse contour measurements. The FloTrac (Edwards Life Sciences) does not require calibration
with another measure and relies upon a statistical analysis of its algorithm to account for changes in vascular compliance occurring as a consequence of changed vascular tone.

D. Esophageal Doppler

Esophageal Doppler relies upon the Doppler principle to measure the velocity of blood flow in the descending thoracic aorta. The Doppler principle is integral in perioperative echocardiography. The Doppler effect has been described previously in this chapter. Blood in the aorta is in relative motion compared with the Doppler probe in the esophagus. As red blood cells travel, they reflect a frequency shift, depending upon both the direction and velocity of their movement. When blood flows toward the transducer, its reflected frequency is higher than that which was transmitted by the probe. When blood cells move away from the transducer, the frequency is lower than that which was initially sent by the probe. By using the Doppler equation, it is possible to determine the velocity of blood flow in the aorta. The equation is:

\[
\text{Velocity of blood flow} = \left\{ \frac{\text{frequency change}}{\text{cosine of angle of incidence between Doppler beam and blood flow}} \right\} \times \left\{ \frac{\text{speed of sound in tissue}}{2 \times \text{source frequency}} \right\}
\]

For Doppler to provide a reliable estimate of velocity, the angle of incidence should be as close to zero as possible, since the cosine of 0 is 1. As the angle approaches 90°, the Doppler measure is unreliable, as the cosine of 90° is 0.

The esophageal Doppler device calculates the velocity of flow in the aorta. As the velocities of the cells in the aorta travel at different speeds over the cardiac cycle, the machine obtains a measure of all of the velocities of the cells moving over time. Mathematically integrating the velocities represents the distance that the blood travels. Next, using normograms, the monitor approximates the area of the descending aorta. The monitor thus calculates both the distance the blood travels, as well as the area: area × length = volume.

Consequently, the SV of blood in the descending aorta is calculated. Knowing the HR allows calculation of that portion of the CO flowing through the descending thoracic aorta, which is approximately 70% of total CO. Correcting for this 30% allows the monitor to estimate the patient’s total CO. Esophageal Doppler is dependent upon many assumptions and nomograms, which may hinder its ability to accurately reflect CO in a variety of clinical situations.
E. Thoracic Bioimpedance
Changes in thoracic volume cause changes in thoracic resistance (bioimpedance) to low amplitude, high frequency currents. If thoracic changes in bioimpedance are measured following ventricular depolarization, SV can be continuously determined. This noninvasive technique requires six electrodes to inject microcurrents and to sense bioimpedance on both sides of the chest. Increasing fluid in the chest results in less electrical bioimpedance. Mathematical assumptions and correlations are then made to calculate CO from changes in bioimpedance. Disadvantages of thoracic bioimpedance include susceptibility to electrical interference and reliance upon correct electrode positioning. The accuracy of this technique is questionable in several groups of patients, including those with aortic valve disease, previous heart surgery, or acute changes in thoracic sympathetic nervous function (eg, those undergoing spinal anesthesia).

F. Fick Principle
The amount of oxygen consumed by an individual ($V_{O_2}$) equals the difference between arterial and venous (a–v) oxygen content (C) ($C_{aO_2}$ and $C_{vO_2}$) multiplied by CO. Therefore

$$ CO = \frac{\text{Oxygen consumption}}{\text{a–v O}_2 \text{ content difference}} = \frac{\dot{V}_{O_2}}{C_{aO_2} - C_{vO_2}} $$

Mixed venous and arterial oxygen content are easily determined if a PA catheter and an arterial line are in place. Oxygen consumption can also be calculated from the difference between the oxygen content in inspired and expired gas. Variations of the Fick principle are the basis of all indicator–dilution methods of determining CO.

G. Echocardiography
There are no more powerful tools to diagnose and assess cardiac function perioperatively than transthoracic (TTE) and transesophageal echocardiography (TEE). Both TTE and TEE can be employed preoperatively and postoperatively. TTE has the advantage of being completely noninvasive; however, acquiring the “windows” to view the heart can be difficult. In the operating rooms, limited access to the chest makes TEE an ideal option to visualize the heart. Disposable TEE probes are now available that can remain in position in critically ill patients for days, during which intermittent TEE examinations can be performed.
Echocardiography can be employed by anesthesia staff in two ways, depending upon degrees of training and certification. Basic (or hemodynamic) TEE permits the anesthesiologist to discern the primary source of a patient’s hemodynamic instability. Whereas in past decades the PA flotation catheter would be used to determine why the patient might be hypotensive, the anesthetist performing TEE is attempting to determine if the heart is adequately filled, contracting appropriately, not externally compressed, and devoid of any grossly obvious structural defects. At all times, information obtained from TEE may be correlated with other information as to the patient’s general condition.

Anesthesiologists performing advanced (diagnostic) TEE make therapeutic and surgical recommendations based upon their TEE interpretations. Various organizations and boards have been established worldwide to certify individuals in all levels of perioperative echocardiography. More importantly, individuals who perform echocardiography should be aware of the credentialing requirements of their respective institutions.

Echocardiography has many uses, including:

- Diagnosis of the source of hemodynamic instability, including myocardial ischemia, systolic and diastolic heart failure, valvular abnormalities, hypovolemia, and pericardial tamponade
- Estimation of hemodynamic parameters, such as SV, CO, and intracavitary pressures
- Diagnosis of structural diseases of the heart, such as valvular heart disease, shunts, aortic diseases
- Guiding surgical interventions, such as mitral valve repair

Various echocardiographic modalities are employed perioperatively by anesthesiologists, including TTE, TEE, epiaortic and epicardiac ultrasound, and three-dimensional echocardiography. Some advantages and disadvantages of the modalities are as follows:

- TTE has the advantage of being noninvasive and essentially risk free. Limited scope TTE exams are now increasingly common in the intensive care unit (Figure 5–27). Bedside TTE exams such as the FATE or FAST protocols can readily assist in hemodynamic diagnosis. Using pattern recognition, it is possible to identify various common cardiac pathologies perioperatively (Figures 5–28 and 5–29).
FIGURE 5–28 The FATE examination. AO, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Reproduced with permission from UltraSound Airway Breathing Circulation Dolor (USABCD) and Prof. Erik Sloth. http://usabcd.org/node/35.)
FIGURE 5–29 Important pathological conditions identified with the FATE examination. AO, aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (Reproduced with permission from UltraSound Airway Breathing Circulation Dolor (USABCD) and Prof. Erik Sloth. http://usabcd.org/node/35.)
Unlike TTE, TEE is an invasive procedure with the potential for life-threatening complications (esophageal rupture and mediastinitis) (Figure 5–30). The close proximity of the esophagus to the left atrium eliminates the problem of obtaining “windows” to view the heart and permits great detail. TEE has been used frequently in the cardiac surgical operating room over the past decades. Its use to guide therapy in general cases has been limited by both the cost of the equipment and the learning necessary to correctly interpret the images. Both TTE and TEE generate two-dimensional images of the three-dimensional heart. Consequently, it is necessary to view the heart through many two-dimensional image planes and windows to mentally recreate the three-dimensional anatomy. The ability to interpret these images at the advanced certification level requires much training.

FIGURE 5–30 The structures of the heart as seen on a midesophageal four-chamber view, including the right atrium (RA), tricuspid valve (TV), right ventricle (RV), left atrium (LA), mitral valve (MV), and left ventricle (LV). (Reproduced with permission from Wasnick J, Hillel Z, Kramer D, et al. Cardiac Anesthesia & Transesophageal Echocardiography. New York, NY: McGraw-Hill; 2011.)

Epiaortic and epicardiac ultrasound imaging techniques employ an echo probe wrapped in a sterile sheath and manipulated by thoracic surgeons intraoperatively to obtain views of the aorta and the heart. The air-filled trachea prevents TEE imaging of the ascending aorta. Because the aorta is manipulated during cardiac surgery, detection of atherosclerotic plaques permits the surgeon to potentially minimize the incidence of embolic stroke. Imaging of the heart with epicardial ultrasound permits intraoperative echocardiography when TEE is contraindicated because of esophageal or
gastric pathology.

- Three-dimensional echocardiography (TTE and TEE) has become available in recent years (Figure 5–31). These techniques provide a three-dimensional view of the heart’s structure. In particular, three-dimensional images can better quantify the heart’s volumes and can generate a surgeon’s view of the mitral valve to aid in guiding valve repair.

**FIGURE 5–31** Three-dimensional echocardiography of the mitral valve demonstrates the anterior leaflet (AML), the posterior leaflet (PML), the anterolateral commissure (ALC), and the posteromedial commissure (PMC). The aortic valve (AV) is also seen. (Reproduced with permission from Wasnick J, Hillel Z, Kramer D, et al. *Cardiac Anesthesia & Transesophageal Echocardiography*. New York, NY: McGraw-Hill; 2011.)

Echocardiography employs ultrasound (sound at frequencies greater than normal hearing) from 2 to 10 MHz. A piezoelectrode in the probe transducer converts electrical energy delivered to the probe into ultrasound waves. These waves then travel through the tissues, encountering the blood, the heart, and other structures. Sound waves pass readily through tissues of similar acoustic impedance; however, when they encounter different tissues, they are scattered, refracted, or reflected back toward the ultrasound probe. The echo wave then interacts with the ultrasound probe, generating an electrical signal that can be reconstructed as an image. The machine knows the time delay between the transmitted and the reflected sound wave. By knowing the time delay, the
location of the source of the reflected wave can be determined and the image generated. The TEE probe contains myriad crystals generating and processing waves, which then create the echo image. The TEE probe can generate images through multiple planes and can be physically manipulated in the stomach and esophagus, permitting visualization of heart structures (Figure 5–32). These views can be used to determine if the walls of the heart are receiving an adequate blood supply (Figure 5–33). Increasingly it is realized that myocardial blood supply is not demarcated as clearly as in traditional depictions (eg, in Figure 5–33). In the healthy heart, the walls thicken and move inwardly with each beat. Wall motion abnormalities, in which the heart walls fail to thicken during systole or move in a dyskinetic fashion, can be associated with myocardial ischemia.
FIGURE 5–32 The echo probe is manipulated by the examiner in multiple ways to create the standard images that constitute the comprehensive perioperative transesophageal echocardiography (TEE) examination. Never force the probe; if resistance is encountered abandon the examination. Echocardiographic information can be provided by intraoperative epicardial and epiaortic examination. Advancing the probe in the esophagus permits the upper, mid, and transgastric examinations (A). The probe can be turned in the esophagus from left to right to examine both left- and right-sided structures (A). Using the button located on the probe permits the echocardiographer to rotate the scan beam through 180°, thereby creating various two-dimensional imaging slices of the three-dimensional heart (B). Lastly, panels (C) and (D) demonstrate

**FIGURE 5–33** The midesophageal four-chamber view (A), the midesophageal two-chamber view (B), the midesophageal long-axis view (C), and the transgastric mid short-axis view (D) are depicted. The different views provide the opportunity to observe the myocardium supplied by each of the three main coronary vessels, the left circumflex (Cx), the left anterior descending (LAD) and the right coronary artery (RCA). Areas of impaired myocardial perfusion are
suggested by the inability of the myocardium to both thicken and move inwardly during systole. Image D is very useful for monitoring in the operating room because left ventricular myocardium supplied by each of the three vessels can be seen in one image. (Modified with permission from Shanewise JS, Cheung AT, Aronson S, et al. ASE/SCA guidelines for performing a comprehensive intraoperative multiplane transesophageal echocardiography examination; recommendations of the American Society of Echocardiography Council for Intraoperative Echocardiography and the Society for Cardiovascular Anesthesiologists Task Force for Certification in Perioperative Transesophageal Echocardiography. Anesth Analg. 1999 Oct;89(4):870-884.)

The Doppler effect is routinely used in echocardiographic examinations to determine both the direction and the velocity of blood flow and tissue movement. Blood flow in the heart follows the law of the conservation of mass. Therefore, the volume of blood that flows through one point (eg, the left ventricular outflow tract) must be the same volume that passes through the aortic valve. When the pathway through which the blood flows becomes narrowed (eg, aortic stenosis), the blood velocity must increase to permit the volume to pass. The increase in velocity as blood moves toward an esophageal echo probe is detected. The Bernoulli equation (pressure change = 4V^2) allows echocardiographers to determine the pressure gradient between areas of different velocity, where v represents the area of maximal velocity (Figure 5–34). Using continuous wave Doppler, it is possible to determine the maximal velocity as blood accelerates through a pathological heart structure. For example, a blood flow of 4 m/s reflects a pressure gradient of 64 mm Hg between an area of slow flow (the left ventricular outflow tract) and a region of high flow (a stenotic aortic valve).
The time-velocity interval (TVI) of the aortic valve is calculated using continuous wave Doppler, while pulse wave Doppler is useful for measurements at lower blood velocities. This continuous wave Doppler has been aligned parallel to that aortic valve flow as imaged using the deep transgastric view. Of note, the blood velocity across the aortic valve is greater than 4 m/s. (Reproduced with permission from Wasnick J, Hillel Z, Kramer D, et al. Cardiac Anesthesia & Transesophageal Echocardiography. New York, NY: McGraw-Hill; 2011.)

The Bernoulli equation permits echocardiographers to estimate PA and other intracavitary pressures.

Assume $P_1 > > P_2$

Blood flow proceeds from an area of high pressure $P_1$ to an area of low pressure $P_2$.

The pressure gradient $= 4V^2$, where $V$ is the maximal velocity measured in meters per second.

Thus,

$$4V^2 = P_1 - P_2$$

Thus, assuming that there is a jet of regurgitant blood flow from the left ventricle into the left atrium and that left ventricular systolic pressure ($P_1$) is the same as systemic blood pressure (eg, no aortic stenosis), it is possible to calculate left atrial pressure ($P_2$). In this manner, echocardiographers can estimate intracavitary pressures when there are pressure gradients, measurable flow velocities between areas of high and low pressure, and knowledge of either $P_1$ or $P_2$ (Figure 5–35).
FIGURE 5–35 Intracavity pressures can be calculated using known pressures and the Bernoulli equation when regurgitant jets are present. The pulmonary artery (PA) systolic pressure is obtained when tricuspid regurgitation is present and the right atrial pressure known. Assuming no pulmonic valve disease, the right ventricular systolic pressure (RVSP) and the pulmonary systolic pressure are the same. The left atrial pressure can be similarly calculated if mitral regurgitation is present. Again, assuming no valvular disease left ventricular systolic pressure (LVSP) should equal systemic systolic blood pressure. Subtracting $4V^2$ from the LVSP estimates the left atrial pressure (LAP).

Color flow Doppler is used by echocardiographers to identify areas of abnormal flow. Color flow Doppler creates a visual picture by assigning a color code to the blood velocities in the heart. Blood flow directed away from the echocardiographic transducer is blue, whereas that which is moving toward the probe is red. The higher the velocity of flow, the lighter the color hue (Figure 5–36). When the velocity of blood flow becomes greater than that which the machine can measure, flow toward the probe is misinterpreted as flow away from the probe, creating images of turbulent flow and “aliasing” of the image. Such changes in flow pattern are used by echocardiographers to identify areas of pathology.

Doppler can also be used to provide an estimate of SV and CO. Similar to esophageal Doppler probes previously described, TTE and TEE can be used to estimate CO. Assuming that the left ventricular outflow tract is a cylinder, it is possible to measure its diameter (Figure 5–37). Knowing this, it is possible to calculate the area through which blood flows using the following equation:
The midesophageal long-axis view is employed in this image to measure the diameter of the left ventricular outflow tract (LVOT). Knowing the diameter of the LVOT permits calculation of the LVOT area. (Reproduced with permission from Wasnick J, Hillel Z, Kramer D, et al. Cardiac Anesthesia & Transesophageal Echocardiography. New York, NY: McGraw-Hill; 2011.)

\[ \text{Area} = \pi r^2 = 0.785 \times \text{diameter}^2 \]

Next, the time velocity integral is determined. A Doppler beam is aligned in parallel with the left ventricular outflow tract (Figure 5–38). The velocities passing through the left ventricular outflow tract are recorded, and the machine integrates the velocity/time curve to determine the distance the blood traveled.
PW Doppler is employed in this deep transgastric view interrogation of the left ventricular outflow tract (LVOT). Blood is flowing in the LVOT away from the esophagus. Therefore, the flow velocities appear below the baseline. Flow velocity through the LVOT is 46.5 cm/s. This is as expected when there is no pathology noted as blood is ejected along the LVOT. Tracing the flow envelope (dotted lines) identifies the time-velocity interval (TVI). In this example the TVI is 14 cm. (Reproduced with permission from Wasnick J, Hillel Z, Kramer D, et al. Cardiac Anesthesia & Transesophageal Echocardiography New York, NY: McGraw-Hill; 2011.)

\[
\text{Area } \times \text{ length } = \text{ volume}
\]

In this instance, the SV is calculated:

\[
\text{SV } \times \text{ HR } = \text{ CO}
\]

Lastly, Doppler can be used to examine the movement of the myocardial tissue. Tissue velocity is normally 8 to 15 cm/s (much less than that of blood, which is 100 cm/s). Using the tissue Doppler function of the echo machine, it is possible to discern both the directionality and velocity of the heart’s movement. During diastolic filling, the lateral annulus myocardium will move toward a TEE probe. Reduced myocardial velocities (<8 cm/s) are associated with impaired diastolic function and higher left ventricular end-diastolic pressures.

Ultimately, echocardiography can provide comprehensive cardiovascular monitoring. Its routine use outside of the cardiac operating room has been hindered by both the costs of the equipment and the training required to correctly interpret the images. It is likely that anesthesia staff will perform an increasing number of echocardiographic examinations perioperatively. All anesthesiology trainees should acquire basic echocardiography skills. When questions arise beyond those related to hemodynamic guidance, interpretation by an individual credentialed in diagnostic echocardiography is warranted.

**CASE DISCUSSION**

**Hemodynamic Monitoring and Management of a Complicated Patient**

A 68-year-old man presents with a perforated colon secondary to diverticulitis. Vital signs are as follows: heart rate, 120 beats/min;
blood pressure, 80 mm Hg/55 mm Hg; respiratory rate, 28 breaths/min; and body temperature, 38 C°. He is scheduled for emergency exploratory laparotomy. His past history includes placement of a drug-eluting stent in the left anterior descending artery 2 weeks earlier. His medications include metoprolol and clopidogrel.

**What hemodynamic monitors should be employed?**

This patient presents with multiple medical issues that could lead to perioperative hemodynamic instability. He has a history of coronary artery disease for which he has been given stents. His previous and current ECGs should be reviewed for signs of new ST- and T-wave changes, heralding ischemia. He is both tachycardic and febrile, and, consequently, may be concurrently ischemic, vasodilated, and hypovolemic. All of these conditions could complicate perioperative management.

Arterial cannulation and monitoring will provide beat-to-beat blood pressure determinations intraoperatively and will also provide for blood gas measurements in a patient likely to be acidotic and hemodynamically unstable. Central venous access is obtained to permit volume resuscitation and to provide a port for delivery of fluid for transpulmonary measurements of CO and SV variation. Alternatively, pulse contour analysis can be employed from an arterial trace to determine volume responsiveness, should the patient become hemodynamically unstable. Echocardiography can be used to determine ventricular function, filling pressures, and CO and to provide surveillance for the development of ischemia-induced wall motion abnormalities.

PA catheters could also be placed to measure CO and pulmonary capillary occlusion pressure; however, we would use TEE if we were unable to manage the patient well with arterial line, CVP, and a noninvasive monitor of SV.

The choice of hemodynamic monitors remains with the individual physician and the availability of various monitoring techniques. It is important to also consider which monitors can be used postoperatively to ensure continuation of goal-directed therapy.

WEB SITE

The American Society of Anesthesiologists (ASA)’s standards for basic anesthesia monitoring can be found on the organization web site.
Noncardiovascular Monitoring

KEY CONCEPTS

1. Capnographs rapidly and reliably detect esophageal intubation—a cause of anesthetic catastrophe—but do not reliably detect mainstem bronchial intubation.
2. Postoperative residual paralysis remains a problem in postanesthesia care, producing potentially injurious airway and respiratory function compromise and increasing length of stay and cost in the postanesthesia care unit (PACU).

The previous chapter reviewed routine hemodynamic monitoring used by anesthesiologists. This chapter examines the vast array of techniques and devices used perioperatively to monitor neuromuscular transmission, neurological condition, respiratory gas exchange, and body temperature.

Respiratory Gas Exchange Monitors

PRECORDIAL & ESOPHAGEAL STETHOSCOPEs

Indications

Prior to the routine availability of gas exchange monitors, anesthesiologists used a precordial or esophageal stethoscope to ensure that the lungs were being ventilated, to monitor for circuit disconnections, and to auscultate heart tones to confirm a beating heart. Although largely supplanted by other modalities, the finger on the pulse and auscultation remain frontline monitors, especially when technology fails. Chest auscultation remains the primary method to confirm
bilateral lung ventilation in the operating room, even though detection of an end-tidal CO₂ waveform is definitive to exclude esophageal intubation.

**Contraindications**

Esophageal stethoscopes and esophageal temperature probes should be avoided in patients with esophageal varices or strictures.

**Techniques & Complications**

A precordial stethoscope (Wenger chestpiece) is a heavy, bell-shaped piece of metal placed over the chest or suprasternal notch. Although its weight tends to maintain its position, double-sided adhesive disks provide an acoustic seal to the patient’s skin. Various chestpieces are available, but the child size works well for most patients. The bell is connected to the anesthesiologist’s ear by extension tubing.

The esophageal stethoscope is a soft plastic catheter (8–24FR) with balloon-covered distal openings (Figure 6–1). Although the quality of breath and heart sounds is much better than with a precordial stethoscope, its use is limited to intubated patients. Temperature probes, electrocardiogram (ECG) leads, ultrasound probes, and even atrial pacemaker electrodes have been incorporated into esophageal stethoscopes. Placement through the mouth or nose can occasionally cause mucosal irritation and bleeding. Rarely, the stethoscope slides into the trachea instead of the esophagus, resulting in a gas leak around the tracheal tube cuff.

![Figure 6–1 Esophageal stethoscope.](image)
Clinical Considerations

The information provided by a precordial or esophageal stethoscope includes confirmation of ventilation, quality of breath sounds (eg, stridor, wheezing), regularity of heart rate, and quality of heart tones (muffled tones are associated with decreased cardiac output). The confirmation of bilateral breath sounds after tracheal intubation, however, is best made with a binaural stethoscope.

PULSE OXIMETRY

Indications & Contraindications

Pulse oximeters are mandatory monitors for any anesthetic, including cases of moderate sedation. There are no contraindications.

Techniques & Complications

Pulse oximeters combine the principles of oximetry and plethysmography to noninvasively measure oxygen saturation in arterial blood. A sensor containing light sources (two or three light-emitting diodes) and a light detector (a photodiode) is placed across a finger, toe, earlobe, or any other perfused tissue that can be transilluminated. When the light source and detector are opposite one another across the perfused tissue, transmittance oximetry is used. When the light source and detector are placed on the same side of the patient (eg, the forehead), the backscatter (reflectance) of light is recorded by the detector.

Oximetry depends on the observation that oxygenated and reduced hemoglobin differ in their absorption of red and infrared light (Lambert–Beer law). Specifically, oxyhemoglobin (HbO₂) absorbs more infrared light (940 nm), whereas deoxyhemoglobin absorbs more red light (660 nm) and thus appears blue, or cyanotic, to the naked eye. The change in light absorption during arterial pulsations is the basis of oximetric determinations (Figure 6–2). The ratio of the absorptions at the red and infrared wavelengths is analyzed by a microprocessor to provide the oxygen saturation (Spo₂) of arterial blood based on established norms. The greater the ratio of red to infrared absorption, the lower is the arterial hemoglobin oxygen saturation. Arterial pulsations are identified by plethysmography, allowing corrections for light absorption by nonpulsating venous blood and tissue. Heat from the light source or sensor pressure may, rarely, result in tissue damage if the monitor is not periodically moved. No user calibration is required.
FIGURE 6–2 Oxyhemoglobin and deoxyhemoglobin differ in their absorption of red and infrared light.

Clinical Considerations
In addition to $\text{SpO}_2$, pulse oximeters provide an indication of tissue perfusion (pulse amplitude) and measure heart rate. Depending on a particular patient’s oxygen–hemoglobin dissociation curve, a 90% saturation may indicate a $\text{PaO}_2$ of less than 65 mm Hg. Clinically detectable cyanosis requires 5 g of desaturated hemoglobin and usually corresponds to $\text{SpO}_2$ of less than 80%. Mainstem bronchial intubation will usually go undetected by pulse oximetry in the absence of lung disease or low fraction of inspired oxygen concentrations ($\text{FiO}_2$).

Because carboxyhemoglobin (COHb) and HbO$_2$ absorb light at 660 nm similarly, pulse oximeters that compare only two wavelengths of light will register a falsely high reading in patients with carbon monoxide poisoning. Methemoglobin has the same absorption coefficient at both red and infrared
wavelengths. The resulting 1:1 absorption ratio corresponds to a saturation reading of 85%. Thus, methemoglobinemia causes a falsely low saturation reading when $\text{SaO}_2$ is actually greater than 85% and a falsely high reading if $\text{SaO}_2$ is actually less than 85%.

Most pulse oximeters are inaccurate at low $\text{SpO}_2$, and all demonstrate a delay between changes in $\text{SaO}_2$ and $\text{SpO}_2$. Other causes of pulse oximetry artifact include excessive ambient light, motion, methylene blue dye, venous pulsations in a dependent limb, low perfusion (eg, low cardiac output, profound anemia, hypothermia, increased systemic vascular resistance), malpositioned sensor, and leakage of light from the light-emitting diode to the photodiode, bypassing the arterial bed (optical shunting). Nevertheless, pulse oximetry can be an invaluable aid to the rapid diagnosis of hypoxia, which may occur in unrecognized esophageal intubation, and it furthers the goal of monitoring oxygen delivery to vital organs. In the recovery room, pulse oximetry helps identify postoperative pulmonary problems, such as hypoventilation, bronchospasm, and atelectasis. Advanced examination of the photoplethysmographic waveform can aid assessment of volume responsiveness and vascular impedance in mechanically ventilated patients.

Two extensions of pulse oximetry technology are mixed venous blood oxygen saturation ($\text{SvO}_2$) and noninvasive brain oximetry. The former requires the placement of a pulmonary artery catheter containing fiberoptic sensors that continuously determine $\text{SvO}_2$ in a manner analogous to pulse oximetry. Because $\text{SvO}_2/\text{ScvO}_2$ varies with changes in hemoglobin concentration, cardiac output, arterial oxygen saturation, and whole-body oxygen consumption, its interpretation is somewhat complex. Impaired oxygen delivery to the tissues (reduced arterial oxygen saturation, reduced cardiac output, increased tissue oxygen demand) results in a lower venous oxygen saturation. Higher venous oxygen concentrations occur when tissue oxygen delivery exceeds tissue demand or arterial venous shunting occurs. Measurement of central vein oxygen saturation ($\text{ScvO}_2$) is frequently used as a surrogate for $\text{SvO}_2$. $\text{SvO}_2$ measures the saturation of venous blood returning from the upper body, the cardiac circulation, and the lower body. Normally the $\text{SvO}_2$ is approximately 70%. $\text{ScvO}_2$ is usually a few percentage points higher as it does not reflect venous return from the cardiac circulation.

Noninvasive brain oximetry monitors regional oxygen saturation ($\text{rSO}_2$) of hemoglobin in the brain. A sensor placed on the forehead emits light of specific wavelengths and measures the light reflected back to the sensor (near-infrared
optical spectroscopy). Unlike pulse oximetry, brain oximetry measures venous and capillary blood oxygen saturation in addition to arterial blood saturation. Thus, its oxygen saturation readings represent the average oxygen saturation of all regional microvascular hemoglobin (approximately 70%). Cardiac arrest, cerebral embolization, and severe hypoxia cause a dramatic decrease in rSO₂. Cerebral oximetry is routinely employed in the perioperative management of patients undergoing cardiopulmonary bypass. (See the section “Neurological System Monitors.”)

**CAPNOGRAPHY**

**Indications & Contraindications**

Determination of end-tidal CO₂ (ETCO₂) concentration to confirm adequate ventilation is mandatory during all anesthetic procedures, but particularly so for general anesthesia. Increases in alveolar dead space ventilation (eg, pulmonary thromboembolism, venous air embolism, decreased pulmonary perfusion) produce a decrease in ETCO₂ compared with arterial CO₂ concentration (Paco₂). Generally, ETCO₂ and Paco₂ increase or decrease depending upon the balance of CO₂ production and CO₂ elimination (ventilation). A rapid fall of ETCO₂ is a sensitive indicator of air embolism, in which both an increase in deadspace ventilation and a decrease in cardiac output may occur. There are no contraindications.

**Techniques & Complications**

Capnography is a valuable monitor of the pulmonary, cardiovascular, and anesthetic breathing systems. Capnographs in common use rely on the absorption of infrared light by CO₂. As with oximetry, absorption of infrared light by CO₂ is governed by the Beer–Lambert law.

**A. Nondiverting (Flowthrough)**

Nondiverting (mainstream) capnographs measure CO₂ passing through an adaptor placed in the breathing circuit (Figure 6–3). Infrared light transmission through the gas is measured and CO₂ concentration is determined by the monitor. Because of problems with drift, older flowthrough models self-zeroed during inspiration. Thus, they were incapable of detecting inspired CO₂, such as
would occur with a breathing circuit malfunction (eg, absorbent exhaustion, sticking unidirectional valves). The weight of the sensor caused traction on the tracheal tube, and its generation of radiant heat can cause skin burns. Newer designs avoid these problems.

FIGURE 6–3 A nondiverting sensor placed in-line analyzes CO\textsubscript{2} concentration at the sampling site.

**B. Diverting (Aspiration)**

Diverting (sidestream) capnographs continuously suction gas from the breathing circuit into a sample cell within the bedside monitor. CO\textsubscript{2} concentration is determined by comparing infrared light absorption in the sample cell with a chamber free of CO\textsubscript{2}. Continuous aspiration of anesthetic gas essentially represents a leak in the breathing circuit that will contaminate the operating room unless it is scavenged or returned to the breathing system. High aspiration rates (up to 250 mL/min) and low-dead-space sampling tubing usually increase sensitivity and decrease lag time. If tidal volumes (V\textsubscript{T}) are small (eg, pediatric patients), however, a high rate of aspiration may entrain fresh gas from the circuit and dilute ETCO\textsubscript{2} measurement. Low aspiration rates (<50 mL/min) can retard ETCO\textsubscript{2} measurement and underestimate it during rapid ventilation.
Diverting units are prone to water precipitation in the aspiration tube and sampling cell that can cause obstruction of the sampling line and erroneous readings. Expiratory valve malfunction is detected by the presence of CO$_2$ in inspired gas. Although inspiratory valve failure also results in rebreathing CO$_2$, this is not as readily apparent because part of the inspiratory volume will still be free of CO$_2$, causing the monitor to read zero during part of the inspiratory phase.

**Clinical Considerations**

1. Capnographs rapidly and reliably detect esophageal intubation—a cause of anesthetic catastrophe—but do not reliably detect mainstem bronchial intubation. Although there may be some CO$_2$ in the stomach from swallowed expired air, this should be washed out within a few breaths. Sudden cessation of CO$_2$ during the expiratory phase may indicate a circuit disconnection. The increased metabolic rate caused by malignant hyperthermia causes a marked rise in ET$_{CO_2}$.

   The gradient between Pa$_{CO_2}$ and ET$_{CO_2}$ (normally 2–5 mm Hg) reflects alveolar dead space (alveoli that are ventilated but not perfused). Any significant reduction in lung perfusion (eg, air embolism, decreased cardiac output, or decreased blood pressure) increases alveolar dead space, dilutes expired CO$_2$, and lessens ET$_{CO_2}$. True capnographs (as opposed to capnometers) display a waveform of CO$_2$ concentration that allows recognition of a variety of conditions (**Figure 6–4**).
FIGURE 6–4 A: A normal capnograph demonstrating the three phases of expiration: phase I—dead space; phase II—mixture of dead space and alveolar gas; phase III—alveolar gas plateau. B: Capnograph of a patient with severe chronic obstructive pulmonary disease. No plateau is reached before the next inspiration. The gradient between end-tidal CO₂ and arterial CO₂ is increased. C: Depression during phase III indicates spontaneous respiratory effort. D: Failure of the inspired CO₂ to return to zero may represent an incompetent expiratory valve or exhausted CO₂ absorbent. E: The persistence of exhaled gas during part of the inspiratory cycle signals the presence of an incompetent inspiratory valve.

ANESTHETIC GAS ANALYSIS

Indications

Analysis of anesthetic gases is essential during any procedure requiring inhalation anesthesia. There are no contraindications to analyzing these gases.

Techniques

Techniques for analyzing multiple anesthetic gases include mass spectrometry, Raman spectroscopy, infrared spectrophotometry, or piezoelectric crystal
(quartz) oscillation. Most of these methods are primarily of historical interest, as most anesthetic gases are now measured by infrared absorption analysis.

Infrared units use a variety of techniques similar to that described for capnography. These devices are all based on the Beer–Lambert law, which provides a formula for measuring an unknown gas within inspired gas because the absorption of infrared light passing through a solvent (inspired or expired gas) is proportional to the amount of the unknown gas. Oxygen and nitrogen do not absorb infrared light. There are a number of commercially available devices that use a single- or dual-beam infrared light source and positive or negative filtering. Because oxygen molecules do not absorb infrared light, their concentration cannot be measured with monitors that rely on infrared technology and, hence, it must be measured by other means (see below).

**Clinical Considerations**

**A. Oxygen Analysis**
To measure the $\text{FiO}_2$ of inhaled gas, manufacturers of anesthesia machines have relied on various technologies.

**B. Galvanic Cell**
Galvanic cell (fuel cell) contains a lead anode and gold cathode bathed in potassium chloride. At the gold terminal, hydroxyl ions are formed that react with the lead electrode (thereby gradually consuming it) to produce lead oxide, causing current, which is proportional to the amount of oxygen being measured, to flow. Because the lead electrode is consumed, monitor life can be prolonged by exposing it to room air when not in use. These are the oxygen monitors used on many anesthesia machines in the inspiratory limb.

**C. Paramagnetic Analysis**
Oxygen is a nonpolar gas, but it is paramagnetic, and when placed in a magnetic field, the gas will expand, contracting when the magnet is turned off. By switching the field on and off and comparing the resulting change in volume (or pressure or flow) to a known standard, the amount of oxygen can be measured.

**D. Polarographic Electrode**
A polarographic electrode has a gold (or platinum) cathode and a silver anode, both bathed in an electrolyte, separated from the gas to be measured by a
semipermeable membrane. Unlike the galvanic cell, a polarographic electrode works only if a small voltage is applied to two electrodes. When voltage is applied to the cathode, electrons combine with oxygen to form hydroxide ions. The amount of current that flows between the anode and the cathode is proportional to the amount of oxygen present.

**E. Spirometry and Pressure Measurements**
Contemporary anesthesia machines measure airway pressures, volume, and flow to calculate resistance and compliance. Measurements of flow and volume are made by mechanical devices that are usually fairly lightweight and are often placed in the inspiratory limb of the anesthesia circuit.

The most fundamental detected abnormalities include low peak inspiratory pressure and high peak inspiratory pressure, which indicate either a ventilator or circuit disconnect, or an airway obstruction, respectively. By measuring $V_T$ and breathing frequency $(f)$, exhaled minute ventilation $(V_E)$ can be calculated, providing some sense of security that ventilation requirements are being met.

Spirometric loops are usually displayed as flow versus volume and volume versus pressure (Figure 6–5). There are characteristic changes with obstruction, bronchial intubation, reactive airways disease, and so forth. If a normal loop is observed shortly after induction of anesthesia and a subsequent loop is different, the observant anesthesiologist is alerted to the fact that pulmonary or airway compliance, or both, may have changed. Mechanical ventilation and ventilators are discussed more completely in Chapter 57.
Neurological System Monitors

ELECTROENCEPHALOGRAPHY

Indications & Contraindications

The electroencephalogram (EEG) is occasionally used during cerebrovascular surgery to confirm the adequacy of cerebral oxygenation or during cardiovascular surgery to ensure that burst suppression or an isoelectric signal has been obtained before circulatory arrest. A full 16-lead, 8-channel EEG is not
necessary for these tasks, and simpler systems are available. There are no contraindications.

**Techniques & Complications**

The EEG is a recording of electrical potentials generated by cells in the cerebral cortex. Although standard ECG electrodes can be used, silver disks containing a conductive gel are preferred. Platinum or stainless steel needle electrodes traumatize the scalp and have high impedance (resistance); however, they can be sterilized and placed in a surgical field. Electrode position (montage) is governed by the international 10–20 system (Figure 6–6). Electric potential differences between combinations of electrodes are filtered, amplified, and displayed by an oscilloscope or pen recorder. EEG activity occurs mostly at frequencies between 1 and 30 cycles/sec (Hz). Alpha waves have a frequency of 8 to 13 Hz and are found often in a resting adult with eyes closed. Beta waves at 8 to 13 Hz are found in concentrating individuals, and at times, in individuals under anesthesia. Delta waves have a frequency of 0.5 to 4 Hz and are found in brain injury, deep sleep, and anesthesia. Theta waves (4–7 Hz) are also found in sleeping individuals and during anesthesia. EEG waves are also characterized by their amplitude, which is related to their potential (high amplitude, >50 microV; medium amplitude, 20–50 microV; and low amplitude, <20 microV). Lastly, the EEG is examined for symmetry between the left and right hemispheres.
Examination of a multichannel EEG is at times performed intraoperatively to detect areas of cerebral ischemia, such as during carotid endarterectomy. Likewise, it can be used to detect EEG isoelectricity and maximal cerebral protection during hypothermic arrest. The strip chart EEG is cumbersome in the operating room, and often the EEG is processed using power spectral analysis. Frequency analysis divides the EEG into a series of sine waves at different frequencies and then plots the power of the signal at each frequency, allowing for a presentation of EEG activity in a more easily interpreted form than the raw EEG (Figure 6–7).
FIGURE 6–7 Patient states, candidate depth of anesthesia devices or approaches, key features of different monitoring approaches, and possible readings at different depths of anesthesia. The readings shown represent examples of possible readings that may be seen in conjunction with each frontal electroencephalography trace. The electroencephalography traces show 3-s epochs (x-axis), and the scale (y-axis) is 50 μV. AAI, A-Line Autoregressive Index (a proprietary method of extracting the midlatency auditory evoked potential from the electroencephalogram); Amp, amplitude of an EEG wave; BIS, bispectral index scale; blinks, eye blink artifacts; BS, burst suppression; BSR, burst suppression ratio; EEG, electroencephalography; ETAG, end-tidal anesthetic gas concentration; f, frequency; γ, β, α, θ, δ, EEG waves in decreasing frequencies (γ, >30 hertz [Hz]; β, 12–30 Hz; α, 8–12 Hz; θ, 4–8 Hz; δ, 0–4 Hz); K, K complexes; lat, latency between an auditory stimulus and an evoked EEG waveform response; MAC, minimum alveolar concentration; NI, Narcotrend index; SEF₉₅, spectral edge frequency below which 95% of the EEG frequencies reside; Spindles, sleep spindles. (Reproduced with permission from Mashour GA, Orser BA, Avidan MS. Intraoperative awareness: From neurobiology to clinical practice. Anesthesiology. 2011 May;114(5):1218–1233.)

As inhalational anesthesia progressively deepens, initial beta activation is followed by slowing, burst suppression, and isoelectricity. Intravenous agents, depending on dose and drug used, can produce a variety of EEG patterns.
To reduce the incidence of awareness during general anesthesia, devices have been developed in recent years that process two-channel EEG signals and create a dimensionless variable to indicate level of wakefulness. The bispectral index (BIS) is most commonly used in this regard. BIS monitors examine four components within the EEG that are associated with the anesthetic state: (1) low frequency, as found during deep anesthesia; (2) high-frequency beta activation found during “light” anesthesia; (3) suppressed EEG waves; and (4) burst suppression.

Other devices attempt to include measures of spontaneous muscle activity, as influenced by the activity of subcortical structures not contributing to the EEG to further provide an assessment of anesthetic depth. Various devices, each with its own algorithm to process the EEG or incorporate other variables to ascertain patient wakefulness, may become available in the future (Table 6–1).

² EEG: electroencephalographic; ECG: electrocardiographic; AE: auxiliary electroencephalographic.

Controversy still exists as to the exact role of processed EEG devices in assessing anesthetic depth. Some studies have demonstrated a reduced incidence of awareness when these devices were used, whereas other studies have failed to reveal any advantage over the use of end-tidal inhalational gas measurements to ensure an adequate concentration of volatile anesthetic. Because individual EEG responsiveness to anesthetic agents and level of surgical stimulus are variable,
EEG monitoring to assess anesthesia depth or titrate anesthetic delivery may not always ensure absence of wakefulness. Moreover, many monitors have a delay, which might only indicate a risk for the patient being aware after he or she had already become conscious (Table 6–2).

TABLE 6–2  Checklist for preventing awareness.¹
✓ Check all equipment, drugs, and dosages; ensure that drugs are clearly labeled and that infusions are running into veins.
✓ Consider administering an amnesic premedication.
✓ Avoid or minimize the administration of muscle relaxants. Use a peripheral nerve stimulator to guide minimal required dose.
✓ Consider using the isolated forearm technique if intense paralysis is indicated.
✓ Choose potent inhalation agents rather than total intravenous anesthesia, if possible.
✓ Administer at least 0.5–0.7 minimum alveolar concentration (MAC) of the inhalation agent.
✓ Set an alarm for a low anesthetic gas concentration.
✓ Monitor anesthetic gas concentration during cardiopulmonary bypass from the bypass machine.
✓ Consider alternative treatments for hypotension other than decreasing anesthetic concentration.
✓ If it is thought that sufficient anesthesia cannot be administered because of concern about hemodynamic compromise, consider the administration of benzodiazepines or scopolamine for amnesia.
✓ Supplement hypnotic agents with analgesic agents such as opioids or local anesthetics, which may help decrease the experience of pain in the event of awareness.
✓ Consider using a brain monitor, such as a raw or processed electroencephalogram but do not try to minimize the anesthetic dose based on the brain monitor because there currently is insufficient evidence to support this practice.
✓ Monitor the brain routinely if using total intravenous anesthesia.
✓ Evaluate known risk factors for awareness, and if specific risk factors are identified consider increasing administered anesthetic concentration.
✓ Re-dose Intravenous anesthesia when delivery of inhalation anesthesia is difficult, such as during a long intubation attempt or during rigid bronchoscopy.

Clinical Considerations

To perform a bispectral analysis, data measured by EEG are taken through a number of steps (Figure 6–8) to calculate a single number that correlates with depth of anesthesia/hypnosis.

BIS values of 65 to 85 have been advocated as a measure of sedation, whereas values of 40 to 65 have been recommended for general anesthesia (Figure 6–9). Bispectral analysis may reduce patient awareness during
anesthesia, an issue that is important to the public.

FIGURE 6–9 The bispectral index (BIS versions 3.0 and higher) is a dimensionless scale from 0 (complete cortical electroencephalographic suppression) to 100 (awake). BIS values of 65–85 have been recommended for sedation, whereas values of 40–65 have been recommended for general anesthesia. At BIS values lower than 40, cortical suppression becomes discernible in a raw electroencephalogram as a burst suppression pattern. (Reproduced with permission from Johansen JW et al: Development and clinical application of electroencephalographic bispectrum monitoring. Anesthesiology. 2000 Nov;93(5):1337–1344.)

Many of the initial studies of BIS were not prospective, randomized, controlled trials, but were observational in nature. The monitor costs several thousand dollars and the single-use electrodes cost approximately $10 to $15 per anesthetic. Some patients with awareness have been identified as having a BIS of less than 65. However, in other patients with awareness, either there were
problems with the recordings, or awareness could not be related to any specific time or BIS value.

Detection of awareness often can minimize its consequences. Use of the Brice questions during postoperative visits can identify a potential awareness event. Ask patients to recall the following:

- What do you remember before going to sleep?
- What do you remember right when awakening?
- Do you remember anything in between going to sleep and awakening?
- Did you have any dreams while asleep?

Close follow-up and involvement of mental health experts may avoid the traumatic stress that can be associated with awareness events. Increasingly, patients undergoing such anesthetics should be made aware that they are not having general anesthesia and might recall perioperative events. Clarification of the techniques used may prevent patients so managed from the belief that they “were awake” during anesthesia.

Can BIS predict outcomes? Some investigators have suggested that both hospital stay and mortality are increased in patients experiencing the so called “triple low” of low mean arterial blood pressure, low bispectral index score, and low minimum alveolar concentration of volatile anesthetics. Other investigations have failed to identify such an association.

**EVOKED POTENTIALS**

**Indications**

Indications for intraoperative monitoring of evoked potentials (EPs) include surgical procedures associated with possible neurological injury: spinal fusion with instrumentation, spine and spinal cord tumor resection, brachial plexus repair, thoracoabdominal aortic aneurysm repair, epilepsy surgery, and cerebral tumor resection. Ischemia in the spinal cord or cerebral cortex can be detected by EPs. Auditory EPs have also been used to assess the effects of general anesthesia on the brain. The middle latency auditory EP may be a more sensitive indicator than BIS in regard to anesthetic depth. The amplitude and latency of this signal following an auditory stimulus is influenced by anesthetics.
**Contraindications**

Although there are no specific contraindications for somatosensory evoked potentials (SEPs), this modality is severely limited by the availability of monitoring sites, equipment, and trained personnel. Sensitivity to anesthetic agents can also be a limiting factor, particularly in children. Motor evoked potentials (MEPs) are contraindicated in patients with retained intracranial metal, skull defects, or implantable devices, as well as after seizures and any major cerebral insult. Brain injury secondary to repetitive stimulation of the cortex and inducement of seizures is a concern with MEPs.

**Techniques & Complications**

EP monitoring noninvasively assesses neural function by measuring electrophysiological responses to sensory or motor pathway stimulation. Commonly monitored EPs are brainstem auditory evoked responses (BAERs), SEPs, and increasingly, MEPs (Figure 6–10).

![Figure 6–10](image)

**FIGURE 6–10** Neuroanatomic pathways of somatosensory evoked potential (SEP) and motor evoked potential (MEP). The SEP is produced by stimulation of a peripheral nerve wherein a response can be measured. The electrical volley ascends the spinal cord by the posterior columns and can be recorded in the epidural space and over the posterior cervical spine. It crosses the mid-line after synapsing at the cervicomedullary junction and ascends the lemniscal pathways having a second synapse in the thalamus. From there, it travels to the primary sensory cortex where the cortical response is measured. The MEP is produced by stimulation of the motor cortex leading to an electrical volley that descends to
the anterior horn cells of the spinal cord via the corticospinal tract. After synapsing there it travels via a peripheral nerve and crosses the neuromuscular junction (NMJ) to produce a muscle response. The MEP can be measured in the epidural space as D and I waves produced by direct and indirect (via internuncial neurons) stimulation of the motor cortex, respectively. It can also be measured as a compound muscle action potential (CMAP) in the muscle. (Reproduced with permission from Sloan TB, Janik D, Jameson L. Multimodality monitoring of the central nervous system using motor-evoked potentials. Curr Opin Anaesthesiol. 2008 Oct;21(5):560–564.)

For SEPs, a brief electrical current is delivered to a sensory or mixed peripheral nerve by a pair of electrodes. If the intervening pathway is intact, a nerve action potential will be transmitted to the contralateral sensory cortex to produce an EP. This potential can be measured by cortical surface electrodes, but is usually measured by scalp electrodes. To distinguish the cortical response to a specific stimulus, multiple responses are averaged and background noise is eliminated. EPs are represented by a plot of voltage versus time. The resulting waveforms are analyzed for their poststimulus latency (the time between stimulation and potential detection) and peak amplitude. These are compared with baseline tracings. Technical and physiological causes of a change in an EP must be distinguished from changes due to neural damage. Complications of EP monitoring are rare, but include skin irritation and pressure ischemia at the sites of electrode application.

**Clinical Considerations**

EPs are altered by many variables other than neural damage. The effect of anesthetics is complex and not easily summarized. In general, intravenous anesthetic techniques (with or without nitrous oxide) cause minimal changes, whereas volatile agents (halothane, sevoflurane, desflurane, and isoflurane) are best avoided or used at a constant low concentration. Early-occurring (specific) EPs are less affected by anesthetics than are late-occurring (nonspecific) responses. Changes in BAERs may provide a measure of the depth of anesthesia. Physiological (eg, blood pressure, temperature, and oxygen saturation) and pharmacological factors should be kept as constant as possible.

Persistent obliteration of EPs is predictive of postoperative neurological deficit. Although SEPs usually identify spinal cord damage, because of their different anatomic pathways, sensory (dorsal spinal cord) EP preservation does not guarantee normal motor (ventral spinal cord) function (false negative). Furthermore, SEPs elicited from posterior tibial nerve stimulation cannot
distinguish between peripheral and central ischemia (false positive). Techniques that elicit MEPs by using transcranial magnetic or electrical stimulation of the cortex allow the detection of action potentials in the muscles if the neural pathway is intact. The advantage of using MEPs as opposed to SEPs for spinal cord monitoring is that MEPs monitor the ventral spinal cord, and if sensitive and specific enough, can be used to indicate which patients might develop a postoperative motor deficit. MEPs are more sensitive to spinal cord ischemia than are SEPs. The same considerations for SEPs are applicable to MEPs in that they are reduced in amplitude by volatile inhalational agents, high-dose benzodiazepines, and moderate hypothermia (temperatures <32°C). MEPs require monitoring of the level of neuromuscular blockade. Close communication with a neurophysiologist or monitoring technician is essential prior to the start of any case where these monitors are used to review the optimal anesthetic technique to ensure monitoring integrity.

**CEREBRAL OXIMETRY AND OTHER MONITORS OF THE BRAIN**

Cerebral oximetry uses near-infrared spectroscopy (NIRS). Using reflectance spectroscopy near-infrared light is emitted by a probe on the scalp (Figure 6–11). Receptors are likewise positioned to detect the reflected light from both deep and superficial structures. As with pulse oximetry, oxygenated and deoxygenated hemoglobin absorb light at different frequencies. Likewise, cytochrome absorbs infrared light in the mitochondria. The NIRS saturation largely reflects the absorption of venous hemoglobin, as it does not have the ability to identify the pulsatile arterial component. Regional saturations of less than 40% on NIRS measures, or changes of greater than 25% of baseline measures, may herald neurological events secondary to decreased cerebral oxygenation.
Reduced jugular venous bulb saturation can also provide an indication of increased cerebral tissue oxygen extraction or decreased cerebral oxygen delivery. Direct tissue oxygen monitoring of the brain is accomplished by placement of a probe to determine the oxygen tension in the brain tissue. In addition to maintaining a cerebral perfusion pressure that is greater than 60 mm Hg and an intracranial pressure that is less than 20 mm Hg, neuroanesthesiologists/intensivists attempt to preserve brain tissue oxygenation by intervening when oxygen tissue tension is less than 20 mm Hg. Such interventions center upon improving oxygen delivery by increasing FiO₂, augmenting hemoglobin, adjusting cardiac output, decreasing oxygen demand, or a combination of these methods.

**Other Monitors**

**TEMPERATURE**

**Indications**

The temperature of patients undergoing anesthesia should be monitored during use of all but the shortest anesthetics. Postoperative temperature is increasingly used as a quality anesthesia indicator. Hypothermia is associated with delayed drug metabolism, increased blood glucose, vasoconstriction, impaired coagulation, postoperative shivering accompanied by tachycardia and hypertension, and increased risk of surgical site infections. Hyperthermia can likewise have deleterious effects perioperatively, leading to tachycardia, vasodilation, and neurological injury. Consequently, temperature must be measured and recorded perioperatively.

**Contraindications**

There are no contraindications, although a particular monitoring site may be unsuitable in certain patients.
Techniques & Complications

Intraoperatively, temperature is usually measured using a thermistor or thermocouple. Thermistors are semiconductors whose resistance decreases predictably with warming. A thermocouple is a circuit of two dissimilar metals joined so that a potential difference is generated when the metals are at different temperatures. Disposable thermocouple and thermistor probes are available for monitoring the temperature of the tympanic membrane, nasopharynx, esophagus, bladder, rectum, and skin. Infrared sensors estimate temperature from the infrared energy that is produced. Tympanic membrane temperatures reflect core body temperature; however, the devices used may not reliably measure the temperature at the tympanic membrane. Complications of temperature monitoring are usually related to trauma caused by the probe (eg, rectal or tympanic membrane perforation).

Clinical Considerations

Each monitoring site has advantages and disadvantages. The tympanic membrane theoretically reflects brain temperature because the auditory canal’s blood supply is the external carotid artery. Trauma during insertion and cerumen insulation detract from the routine use of tympanic probes. Rectal temperature probes have a slow response to changes in core temperature. Nasopharyngeal probes are prone to cause epistaxis, but accurately measure core temperature if placed adjacent to the nasopharyngeal mucosa. The thermistor in a pulmonary artery catheter also measures core temperature. There is a variable correlation between axillary temperature and core temperature, depending on skin perfusion. Liquid crystal adhesive strips placed on the skin are inadequate indicators of core body temperature during surgery. Esophageal temperature sensors, often incorporated into esophageal stethoscopes, provide the best combination of economy, performance, and safety. To avoid measuring the temperature of tracheal gases, the temperature sensor should be positioned behind the heart in the lower third of the esophagus. Conveniently, heart sounds are most prominent at this location. For more on the clinical considerations of temperature control, see Chapter 52.

URINARY OUTPUT

Indications
Urinary bladder catheterization is the most reliable method of monitoring urinary output. Catheterization is routine in some complex and prolonged surgical procedures such as cardiac surgery, aortic or renal vascular surgery, craniotomy, major abdominal surgery, or procedures in which large fluid shifts are expected. Lengthy surgeries and intraoperative diuretic administration are other possible indications. Occasionally, postoperative bladder catheterization is indicated in patients who have difficulty voiding in the recovery room after general or regional anesthesia.

**Contraindications**

Foley catheters should be removed as soon as feasible to avoid the risk of catheter-associated urinary tract infections.

**Techniques & Complications**

Bladder catheterization is usually performed by surgical or nursing personnel. The urologist may be needed to catheterize patients with strictures and other abnormal urethral anatomy. A soft rubber Foley catheter is inserted into the bladder transurethrally and connected to a disposable calibrated collection chamber. To avoid urine reflux and minimize the risk of infection, the collection chamber should remain at a level below the bladder. Complications of catheterization include urethral trauma and urinary tract infections. Rapid decompression of a distended bladder can cause hypotension. Suprapubic drainage of the bladder with tubing inserted through a large-bore needle is an uncommon alternative.

**Clinical Considerations**

An additional advantage of placing a Foley catheter is the ability to include a thermistor in the catheter tip so that bladder temperature can be monitored. As long as urinary output is high, bladder temperature accurately reflects core temperature. An added value with more widespread use of urometers is the ability to electronically monitor and record urinary output and temperature.

Urinary output is an imperfect reflection of kidney perfusion and function and of renal, cardiovascular, and fluid volume status. Noninvasive monitors of cardiac function and output (including echocardiography) provide more reliable assessments of the adequacy of intravascular volume. Inadequate urinary output (oliguria) is often arbitrarily defined as urinary output of less than 0.5 mL/kg/h,
but actually is a function of the patient's concentrating ability and osmotic load. Urine electrolyte composition, osmolality, and specific gravity aid in the differential diagnosis of oliguria.

**PERIPHERAL NERVE STIMULATION**

**Indications**

Because of the variation in patient sensitivity to neuromuscular blocking agents, the neuromuscular function of all patients receiving intermediate- or long-acting neuromuscular blocking agents should be monitored. In addition, peripheral nerve stimulation is helpful in detecting the onset of paralysis during anesthesia inductions or the adequacy of block during continuous infusions with short-acting agents.

**Contraindications**

There are no contraindications to neuromuscular monitoring, although certain sites may be precluded by the surgical procedure. Additionally, atrophied muscles in areas of hemiplegia or nerve damage may appear refractory to neuromuscular blockade secondary to the proliferation of receptors. Determining the degree of neuromuscular blockade using such an extremity could lead to potential overdosing of competitive neuromuscular blocking agents.

**Techniques & Complications**

A peripheral nerve stimulator delivers current (60–80 mA) to a pair of either ECG silver chloride pads or subcutaneous needles placed over a peripheral motor nerve. The evoked mechanical or electrical response of the innervated muscle is observed. Although electromyography provides a fast, accurate, and quantitative measure of neuromuscular transmission, visual or tactile observation of muscle contraction is usually relied upon in clinical practice. Ulnar nerve stimulation of the adductor pollicis muscle and facial nerve stimulation of the orbicularis oculi are most commonly monitored (Figure 6–12). Because it is the inhibition of the neuromuscular receptor that needs to be monitored, direct stimulation of muscle should be avoided by placing electrodes over the course of the nerve and not over the muscle itself. To deliver a supramaximal stimulation to the underlying nerve, peripheral nerve stimulators must be capable of generating at least a 50-mA current across a 1000-Ω load. This current is
uncomfortable for a conscious patient. Complications of nerve stimulation are limited to skin irritation and abrasion at the site of electrode attachment.

**FIGURE 6–12**  
A: Stimulation of the ulnar nerve causes contraction of the adductor pollicis muscle. B: Stimulation of the facial nerve leads to orbicularis oculi contraction. The orbicularis oculi recovers from neuromuscular blockade before the adductor pollicis. (Reproduced with permission from Dorsch JA, Dorsch SE. Understanding Anesthesia Equipment. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

Because of concerns of residual neuromuscular blockade, increased attention has been focused on providing quantitative measures of the degree of neuromuscular blockade perioperatively. Acceleromyography uses a piezoelectric transducer on the muscle to be stimulated. Movement of the muscle
generates an electrical current that can be quantified and displayed. Indeed, acceleromyography can better predict residual paralysis, compared with routine tactile train-of-four monitoring used in most operating rooms, if calibrated from the beginning of the operative period to establish baselines prior to administration of neuromuscular blocking agents.

**Clinical Considerations**

The degree of neuromuscular blockade is monitored by applying various patterns of electrical stimulation ([Figure 6–13](#)). All stimuli are 200 μs in duration and of square-wave pattern and equal current intensity. A twitch is a single pulse that is delivered from every 1 to every 10 s (1–0.1 Hz). Increasing block results in decreased evoked response to stimulation.
Peripheral nerve stimulators can generate various patterns of electrical impulses.

Train-of-four stimulation denotes four successive 200-μs stimuli in 2 s (2 Hz).
The twitches in a train-of-four pattern progressively fade as nondepolarizing muscle relaxant block increases. The ratio of the responses to the first and fourth twitches is a sensitive indicator of nondepolarizing muscle paralysis. Because it is difficult to estimate the train-of-four ratio, it is more convenient to visually observe the sequential disappearance of the twitches, as this also correlates with the extent of blockade. Disappearance of the fourth twitch represents a 75% block, the third twitch an 80% block, and the second twitch a 90% block. Clinical relaxation usually requires 75% to 95% neuromuscular blockade.

Tetany at 50 or 100 Hz is a sensitive test of neuromuscular function. Sustained contraction for 5 s indicates adequate, but not necessarily complete, reversal from neuromuscular blockade. Double-burst stimulation (DBS) represents two variations of tetany that are less painful to the patient. The DBS₃,₃ pattern of nerve stimulation consists of three short (200-μs) high-frequency bursts separated by 20 ms intervals (50 Hz) followed 750 ms later by another three bursts. DBS₃,₂ consists of three 200-μs impulses at 50 Hz followed 750 ms later by two such impulses. DBS is more sensitive than train-of-four stimulation for the clinical (ie, visual) evaluation of fade.

Because muscle groups differ in their sensitivity to neuromuscular blocking agents, use of the peripheral nerve stimulator cannot replace direct observation of the muscles (eg, the diaphragm) that need to be relaxed for a specific surgical procedure. Furthermore, recovery of adductor pollicis function does not exactly parallel recovery of muscles required to maintain an airway. The diaphragm, rectus abdominis, laryngeal adductors, and orbicularis oculi muscles recover from neuromuscular blockade sooner than the adductor pollicis. Other indicators of adequate recovery include sustained (≥5 s) head lift, the ability to generate an inspiratory pressure of at least −25 cm H₂O, and a forceful hand grip. Twitch tension is reduced by hypothermia of the monitored muscle group (6%/°C). Decisions regarding adequacy of reversal of neuromuscular blockade, as well as timing of extubation, should be made only by considering both the patient’s clinical presentation and assessments determined by peripheral nerve stimulation 📈. Postoperative residual paralysis remains a problem in postanesthesia care, producing potentially injurious airway and respiratory function compromise and increasing length of stay and cost in the postanesthesia care unit (PACU). Reversal of neuromuscular blocking agents is warranted, as is the use of intermediate acting neuromuscular blocking agents instead of longer acting drugs. Quantitative monitors of neuromuscular blockade are recommended to reduce the incidence of patients admitted to the PACU with residual paralysis.
CASE DISCUSSION

Monitoring During Magnetic Resonance Imaging

A 50-year-old man with recent onset of seizures is scheduled for magnetic resonance (MR) imaging. A prior MR attempt was unsuccessful because of the patient’s severe claustrophobic reaction. The radiologist requests your help in providing either sedation or general anesthesia.

Why does the MR suite pose special problems for the patient and the anesthesiologist?

MR studies tend to be long (often more than 1 h), and many scanners totally surround the body, causing a high incidence of claustrophobia in patients already anxious about their health. Good imaging requires immobility, something that is difficult to achieve in many patients without sedation or general anesthesia.

Because the MR device uses a powerful magnet, no ferromagnetic objects can be placed near the scanner. This includes implanted prosthetic joints, artificial pacemakers, surgical clips, batteries, ordinary anesthesia machines, watches, pens, credit cards, intravenous poles, conventional oxygen cylinders, housekeeping buckets, and lead ankle weights, nearly all of which we have seen drawn in and “captured” by MR devices. Ordinary metal lead wires for pulse oximeters or electrocardiography act as antennas and may attract enough radiofrequency energy to distort the MR image or even cause patient burns. In addition, the scanner’s magnetic field causes severe monitor artifact. The more powerful the scanner’s magnet, as measured in Tesla units (1 T = 10,000 gauss), the greater is the potential problem. Other obstacles include poor access to the patient during the imaging (particularly the patient’s airway), hypothermia in pediatric patients, dim lighting within the patient tunnel, and very loud noise (up to 100 dB).

How have these monitoring and anesthesia machine problems been addressed?

Equipment manufacturers have modified monitors so that they are compatible with the MR environment. These modifications include
nonferromagnetic electrocardiographic electrodes, graphite and copper cables, extensive filtering and gating of signals, extra-long blood pressure cuff tubing, and use of fiberoptic technologies. Anesthesia machines with no ferromagnetic components (eg, aluminum gas cylinders) have been fitted with MR-compatible ventilators and long circle systems or Mapleson D breathing circuits.

**What factors influence the choice between general anesthesia and intravenous sedation?**

Although most patients will tolerate an MR study with sedation, head-injured and pediatric patients present special challenges and often require general anesthesia. Because of machine and monitoring limitations, an argument could be made that sedation, when possible, would be a safer choice. On the other hand, loss of airway control from deep sedation could prove catastrophic because of poor patient access and delayed detection. Other important considerations include the monitoring modalities available at a particular facility and the general medical condition of the patient.

**Which monitors should be considered mandatory in this case?**

The patient should receive at least the same level of monitoring and care in the MR suite as in the operating room for a similarly noninvasive procedure. Thus, the American Society of Anesthesiologists Standards for Basic Anesthetic Monitoring (see following Guidelines section) apply as they would to a patient undergoing general anesthesia.

Continuous auscultation of breath sounds with a plastic (not metal) precordial stethoscope can help to identify airway obstruction caused by excessive sedation. Palpation of a peripheral pulse or listening for Korotkoff sounds is impractical in this setting. Ensuring adequacy of circulation depends on electrocardiographic and oscillometric blood pressure monitoring. End-tidal CO\(_2\) analyzers can be adapted to sedation cases by connecting the sampling line to a site near the patient’s mouth or nose if nasal cannula with a CO\(_2\) sampling channel are not available. Because room air entrainment precludes exact measurements, this technique provides a qualitative indicator of ventilation. Whenever sedation is planned, equipment for emergency conversion to general anesthesia (eg, tracheal tubes, resuscitation bag) must be immediately available.

**Is the continuous presence of anesthesia personnel required**
Absolutely yes. Sedated patients must have continuous monitored anesthesia care to prevent a multitude of unforeseen complications, such as apnea or emesis.

GUIDELINES

SUGGESTED READINGS
Kertai M, White W, Gan T. Cumulative duration of “triple low” state of low blood pressure, low bispectral index, and low minimum alveolar concentration of volatile anesthesia is not associated with increased mortality. *Anesthesiology.* 2014;121:18.
Pharmacological Principles

KEY CONCEPTS

1. Drug molecules obey the law of mass action. When the plasma concentration exceeds the tissue concentration, the drug moves from the plasma into tissue. When the plasma concentration is less than the tissue concentration, the drug moves from the tissue back to plasma.

2. Most drugs that readily cross the blood–brain barrier (e.g., lipophilic drugs like hypnotics and opioids) are avidly taken up in body fat.

3. Biotransformation is the chemical process by which the drug molecule is altered in the body. The liver is the primary organ of metabolism for drugs.

4. Small unbound molecules freely pass from plasma into the glomerular filtrate. The nonionized (uncharged) fraction of drug is reabsorbed in the renal tubules, whereas the ionized (charged) portion is excreted in urine.

5. Elimination half-life is the time required for the drug concentration to fall by 50%. For drugs described by multicompartment pharmacokinetics (e.g., all drugs used in anesthesia), there are multiple elimination half-lives.

6. The offset of a drug’s effect cannot be predicted from half-lives. The context-sensitive half-time is a clinically useful concept to describe the rate of decrease in drug concentration and should be used instead of half-lives to compare the pharmacokinetic properties of intravenous drugs used in anesthesia.

The clinical practice of anesthesiology is directly connected to the science of clinical pharmacology. One would think, therefore, that the study of pharmacokinetics and pharmacodynamics would receive attention comparable to
that given to airway assessment, choice of inhalation anesthetic, neuromuscular blockade, or treatment of sepsis in anesthesiology curricula and examinations. Sadly, the frequent misidentification or misuse of pharmacokinetic principles and measurements suggests that this is not yet the case.

PHARMACOKINETICS
Pharmacokinetics defines the relationships among drug dosing, drug concentration in body fluids and tissues, and time. It consists of four linked processes: absorption, distribution, biotransformation, and excretion.

Absorption
Absorption defines the processes by which a drug moves from the site of administration to the bloodstream. There are many possible routes of drug administration: oral, sublingual, rectal, inhalational, transdermal, transmucosal, subcutaneous, intramuscular, perineural, peridural, intrathecal, and intravenous. Absorption is influenced by the physical characteristics of the drug (solubility, pKₐ, diluents, binders, and formulation), dose, the site of absorption (eg, gut, lung, skin, muscle), and in some cases (eg, perineural or subcutaneous administration of local anesthetics) by additives such as epinephrine. Bioavailability defines the fraction of the administered dose that reaches the systemic circulation. For example, nitroglycerin is well absorbed by the gastrointestinal tract but has low bioavailability when administered orally. The reason is that nitroglycerin undergoes extensive first-pass hepatic metabolism before reaching the systemic circulation.

Oral drug administration is convenient, inexpensive, and relatively tolerant of dosing errors. However, it requires cooperation of the patient, exposes the drug to first-pass hepatic metabolism, and permits gastric pH, digestive enzymes, motility, food, and other drugs to potentially reduce the predictability of systemic drug delivery.

Nonionized (uncharged) drugs are more readily absorbed than ionized (charged) forms. Therefore, an acidic environment (stomach) favors the absorption of acidic drugs (A⁻ + H⁺ → AH), whereas a more alkaline environment (intestine) favors basic drugs (BH⁺ → H⁺ + B). Nevertheless, in most cases, the greater aggregate amount of drugs is absorbed from the intestine rather than the stomach because of the greater surface area of the small intestine and longer transit duration.
All venous drainage from the stomach and small intestine flows to the liver. As a result, the bioavailability of highly metabolized drugs may be significantly reduced by first-pass hepatic metabolism. Because the venous drainage from the mouth and esophagus flows into the superior vena cava rather than into the portal system, sublingual or buccal drug absorption bypasses the liver and first-pass metabolism. Rectal administration partly bypasses the portal system, and represents an alternative route in small children or patients who are unable to tolerate oral ingestion. However, rectal absorption can be erratic, and many drugs irritate the rectal mucosa.

Transdermal drug administration can provide prolonged continuous administration for some drugs. However, the stratum corneum is an effective barrier to all but small, lipid-soluble drugs (eg, clonidine, nitroglycerin, scopolamine, fentanyl, and free-base local anesthetics [EMLA]).

Parenteral routes of drug administration include subcutaneous, intramuscular, and intravenous injection. Subcutaneous and intramuscular absorption depend on drug diffusion from the site of injection to the bloodstream. The rate at which a drug enters the bloodstream depends on both blood flow to the injected tissue and the injectate formulation. Drugs dissolved in solution are absorbed faster than those present in suspensions. Irritating preparations can cause pain and tissue necrosis (eg, intramuscular diazepam). Intravenous injections bypass the process of absorption.

**Distribution**

Once absorbed, a drug is distributed by the bloodstream throughout the body. Highly perfused organs (the so-called vessel-rich group) receive a disproportionate fraction of the cardiac output (Table 7–1). Therefore, these tissues receive a disproportionate amount of drug in the first minutes following drug administration. These tissues approach equilibration with the plasma concentration more rapidly than less well perfused tissues due to the differences in blood flow. However, less well perfused tissues such as fat and skin may have enormous capacity to absorb lipophilic drugs, resulting in a large reservoir of drug following long infusions.

**TABLE 7–1**  **Tissue group composition, relative body mass, and percentage of cardiac output.**
Drug molecules obey the law of mass action. When the plasma concentration exceeds the concentration in tissue, the drug moves from the plasma into tissue. When the plasma concentration is less than the tissue concentration, the drug moves from the tissue back to plasma.

The rate of rise in drug concentration in an organ is determined by that organ’s perfusion and the relative drug solubility in the organ compared with blood. The equilibrium concentration in an organ relative to blood depends only on the relative solubility of the drug in the organ relative to blood, unless the organ is capable of metabolizing the drug.

Molecules in blood are either free or bound to plasma proteins and lipids. The free concentration equilibrates between organs and tissues. However, the equilibration between bound and unbound molecules is instantaneous. As unbound molecules of drug diffuse into tissue, they are instantly replaced by previously bound molecules. Plasma protein binding does not affect the rate of transfer directly, but it does affect relative solubility of the drug in blood and tissue. When a drug is highly bound in blood a much larger dose will be required to achieve the same systemic effect. If the drug is highly bound in tissues, and unbound in plasma, then the relative solubility favors drug transfer into tissue. Put another way, a drug that is highly bound in tissue, but not in blood, will have a very large free drug concentration gradient driving drug into the tissue. Conversely, if the drug is highly protein bound in plasma and has few binding sites in the tissue, then transfer of a small amount of drug may be enough to bring the free drug concentration into equilibrium between blood and tissue.

Thus, high levels of binding in blood relative to tissues increase the rate of onset of drug effect, because fewer molecules need to transfer into the tissue to

produce an effective free drug concentration.

Albumin has two main binding sites with affinity for many acidic and neutral drugs (including diazepam and warfarin). Highly bound drugs (eg, warfarin) can be displaced by other drugs competing for the same binding site (eg, indocyanine green or ethacrynic acid) with dangerous consequences. α₁-Acid glycoprotein (AAG) binds basic drugs (local anesthetics, tricyclic antidepressants). If the concentrations of these proteins are diminished then the relative solubility of the drugs in blood is decreased, increasing tissue uptake. Kidney disease, liver disease, chronic congestive heart failure, and malignancies decrease albumin production. Major burns of more than 20% of body surface area lead to albumin loss. Trauma (including surgery), infection, myocardial infarction, and chronic pain increase AAG levels. Pregnancy is associated with reduced AAG concentrations. None of these factors have much relevance to propofol, which is administered with its own binding molecules (the lipid in the emulsion).

Lipophilic molecules can readily transfer between the blood and organs. Charged molecules are able to pass in small quantities into most organs. However, the blood–brain barrier is a special case. Permeation of the central nervous system by ionized drugs is limited by pericapillary glial cells and endothelial cell tight junctions. Most drugs that readily cross the blood–brain barrier (eg, lipophilic drugs like hypnotics and opioids) are avidly taken up in body fat.

The time course of distribution of drugs into peripheral tissues is complex and is best described using computer models and simulation. Following intravenous bolus administration, rapid distribution of drug from the plasma into tissues accounts for the profound decrease in plasma concentration observed in the first few minutes. For each tissue, there is a point in time at which the apparent concentration in the tissue is the same as the concentration in the plasma. The redistribution phase (from each tissue) follows this moment of equilibration. During redistribution, drug returns from tissues back into the plasma. This return of drug back to the plasma slows the rate of decline in plasma drug concentration.

Distribution generally contributes to rapid emergence by removing drug from the plasma for many minutes following administration of a bolus of an induction agent. Following prolonged infusions of lipophilic anesthetic drugs, redistribution generally delays emergence as drug returns from tissue reservoirs to the plasma for many hours.

The complex process of drug distribution into and out of tissues is one reason
that half-lives provide almost no guidance for predicting emergence times. The offset of a drug’s clinical actions is best predicted by computer models using the context sensitive half-time or decrement time. The context-sensitive half-time is the time required for a 50% decrease in plasma drug concentration to occur following a pseudo steady-state infusion (in other words, an infusion that has continued long enough to yield nearly steady-state concentrations). Here the “context” is the duration of the infusion. The context-sensitive decrement time is a more generalized concept referring to any clinically relevant decreased concentration in any tissue, particularly the brain or effect site.

The volume of distribution, \( V_d \), is the apparent volume into which a drug has “distributed” (ie, mixed). This volume is calculated by dividing a bolus dose of drug by the plasma concentration at time 0. In practice, the concentration used to define the \( V_d \) is often obtained by extrapolating subsequent concentrations back to “0 time” when the drug was injected (this assumes immediate and complete mixing), as follows:

\[
V_d = \frac{\text{Bolus dose}}{\text{Concentration}_{time0}}
\]

The concept of a single \( V_d \) does not apply to any intravenous drugs used in anesthesia. All intravenous anesthetic drugs are better modeled with at least two compartments: a central compartment and a peripheral compartment. The behavior of many of these drugs is more precisely described using three compartments: a central compartment, a rapidly equilibrating peripheral compartment, and a slowly equilibrating peripheral compartment. The central compartment may be thought of as including the blood and any ultra-rapidly equilibrating tissues such as the lungs. The peripheral compartment is composed of the other body tissues. For drugs with two peripheral compartments, the rapidly equilibrating compartment comprises the organs and muscles, while the slowly equilibrating compartment roughly represents distribution of the drug into fat and skin. These compartments are designated \( V_1 \) (central), \( V_2 \) (rapid distribution), and \( V_3 \) (slow distribution). The volume of distribution at steady state, \( V_{dss} \) is the algebraic sum of these compartment volumes. \( V_1 \) is calculated by the above equation showing the relationship between volume, dose, and concentration. The other volumes are calculated through pharmacokinetic modeling.

A small \( V_{dss} \) implies that the drug has high aqueous solubility and will remain
largely within the intravascular space. For example, the $V_{dss}$ of vecuronium is about 200 mL/kg in adult men and about 160 mL/kg in adult women, indicating that vecuronium is mostly present in body water, with little distribution into fat. However, the typical anesthetic drug is lipophilic, resulting in a $V_{dss}$ that exceeds total body water (approximately 600 mL/kg in adult males). For example, the $V_{dss}$ for fentanyl is about 350 L in adults, and the $V_{dss}$ for propofol may exceed 5000 L. $V_{dss}$ does not represent a real volume but rather reflects the volume into which the administered drug dose would need to distribute to account for the observed plasma concentration.

**Biotransformation**

Biotransformation is the chemical process by which the drug molecule is altered in the body. The liver is the primary organ of metabolism for most drugs. One exception is esters, which undergo hydrolysis in the plasma or tissues. The end products of biotransformation are often (but not necessarily) inactive and water soluble. Water solubility allows excretion by the kidneys.

Metabolic biotransformation is frequently divided into phase I and phase II reactions. Phase I reactions convert a parent compound into more polar metabolites through oxidation, reduction, or hydrolysis. Phase II reactions couple (conjugate) a parent drug or a phase I metabolite with an endogenous substrate (eg, glucuronic acid) to form water-soluble metabolites that can be eliminated in the urine or stool. Although this is usually a sequential process, phase I metabolites may be excreted without undergoing phase II biotransformation, and a phase II reaction can precede or occur without a phase I reaction.

Hepatic clearance is the volume of blood or plasma (whichever was measured in the assay) cleared of drug per unit of time. The units of clearance are units of flow: volume per unit time. Clearance may be expressed in milliliters per minute, liters per hour, or any other convenient unit of flow. If every molecule of drug that enters the liver is metabolized, then hepatic clearance will equal liver blood flow. This is true for very few drugs, although it is very nearly the case for propofol. For most drugs, only a fraction of the drug that enters the liver is removed. The fraction removed is called the extraction ratio. The hepatic clearance can therefore be expressed as the liver blood flow times the extraction ratio. If the extraction ratio is 50%, then hepatic clearance is 50% of liver blood flow. The clearance of drugs efficiently removed by the liver (ie, having a high hepatic extraction ratio) is proportional to hepatic blood flow. For example,
because the liver removes almost all of the propofol that goes through it, if the hepatic blood flow doubles, then the clearance of propofol doubles. Induction of liver enzymes has no effect on propofol clearance, because the liver so efficiently removes all of the propofol that goes through it. Even severe loss of liver tissue, as occurs in cirrhosis, has little effect on propofol clearance. Drugs such as propofol have flow-dependent clearance.

Many drugs have low hepatic extraction ratios and are slowly cleared by the liver. For these drugs, the rate-limiting step is not the flow of blood to the liver, but rather the metabolic capacity of the liver itself. Changes in liver blood flow have little effect on the clearance of such drugs. However, if liver enzymes are induced, then clearance will increase because the liver has more capacity to metabolize the drug. Conversely, if the liver is damaged, then less capacity is available for metabolism and clearance is reduced. Drugs with low hepatic extraction ratios thus have capacity-dependent clearance. The extraction ratios of methadone and alfentanil are 10% and 15% respectively, making these capacity-dependent drugs.

Excretion

Some drugs and many drug metabolites are excreted by the kidneys. Renal clearance is the rate of elimination of a drug from the body by kidney excretion. This concept is analogous to hepatic clearance, and similarly, renal clearance can be expressed as the renal blood flow times the renal extraction ratio. Small unbound drugs freely pass from plasma into the glomerular filtrate. The nonionized (uncharged) fraction of drug is reabsorbed in the renal tubules, whereas the ionized (charged) portion remains and is excreted in urine. The fraction of drug ionized depends on the pH; thus renal elimination of drugs that exist in ionized and nonionized forms depends in part on urinary pH. The kidney actively secretes some drugs into the renal tubules.

Many drugs and drug metabolites pass from the liver into the intestine via the biliary system. Some drugs excreted into the bile are then reabsorbed in the intestine, a process called enterohepatic recirculation. Occasionally metabolites excreted in bile are subsequently converted back to the parent drug. For example, lorazepam is converted by the liver to lorazepam glucuronide. In the intestine, β-glucuronidase breaks the ester linkage, converting lorazepam glucuronide back to lorazepam.

Compartment Models
Multicompartment models provide a mathematical framework that can be used to relate drug dose to changes in drug concentrations over time. Conceptually, the compartments in these models are tissues with a similar distributions time course. For example, the plasma and lungs are components of the central compartment. The organs and muscles, sometimes called the vessel-rich group, could be the second, or rapidly equilibrating, compartment. Fat and skin have the capacity to bind large quantities of lipophilic drug but are poorly perfused. These could represent the third, or slowly equilibrating, compartment. This is an intuitive definition of compartments, but it is important to recognize that the compartments of a pharmacokinetic model are mathematical abstractions that relate dose to observed concentration. A one-to-one relationship does not exist between any “mathematically identified” compartment and any organ or tissue in the body.

Many drugs used in anesthesia are well described by two-compartment models. This is generally the case if the studies used to characterize the pharmacokinetics do not include rapid arterial sampling over the first few minutes (Figure 7–1). Without rapid arterial sampling the ultrarapid initial drop in plasma concentration immediately after a bolus injection is missed, and the central compartment volume is blended into the rapidly equilibrating compartment. When rapid arterial sampling is used in pharmacokinetic experiments, the results generally support the use of a three-compartment model. Thus, the number of identifiable compartments reported in a pharmacokinetic study may be more a function of the experimental design than a characteristic of the drug.
FIGURE 7–1 Two-compartment model demonstrates the changes in drug concentrations in the distribution phase and the elimination phase. During the distribution phase, the drug moves from the central compartment to the peripheral compartment. In the elimination phase the drug returns from the peripheral compartment to the central compartment and is metabolized and excreted.

As previously noted, in compartmental models the instantaneous concentration at the time of a bolus injection is assumed to be the amount of the bolus divided by the central compartment volume. This is not correct. If the bolus is given over a few seconds, the instantaneous concentration is 0, because the drug is all in the vein, still flowing to the heart. It takes a minute or two for the drug to mix in the central compartment volume. This misspecification is common to conventional pharmacokinetic models. More physiologically based models, sometimes called front-end kinetic models, can characterize the initial delay in concentration. The additional complexity that these models introduce is useful only if the concentrations over the first few minutes are clinically important. After the first few minutes, front-end models resemble conventional compartmental models.

In the first few minutes following initial bolus administration of a drug the concentration drops very rapidly as the drug quickly diffuses into peripheral
compartments. Concentrations often decline by an order of magnitude over 10 minutes! For drugs with very rapid hepatic clearance (eg, propofol) or those that are metabolized in the blood (eg, remifentanil), metabolism contributes significantly to the rapid initial drop in concentration. Following this very rapid drop there is a period of slower decrease in plasma concentration. During this period, the rapidly equilibrating compartment is no longer removing drug from the plasma. Instead, drug returns to the plasma from the rapidly equilibrating compartment. The reversed role of the rapidly equilibrating tissues from extracting drug to returning drug accounts for the slower rate of decline in plasma concentration in this intermediate phase. Eventually there is an even slower rate of decrease in plasma concentration, which is log-linear until the drug is completely eliminated from the body. This terminal log-linear phase occurs after the slowly equilibrating compartment shifts from net removal of drug from the plasma to net return of drug to the plasma. During this terminal phase, the organ of elimination (typically the liver) is exposed to the body’s entire body drug load, which accounts for the very slow rate of decrease in plasma drug concentration during this final phase.

The mathematical models used to describe a drug with two or three compartments are, respectively:

\[ Cp(t) = Ae^{-\alpha t} + Be^{-\beta t} \]

and

\[ Cp(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t} \]

where \( Cp(t) \) equals plasma concentration at time \( t \), and \( \alpha \), \( \beta \), and \( \gamma \) are the exponents that characterize the very rapid (ie, very steep), intermediate, and slow (ie, log-linear) portions of the plasma concentration over time, respectively. Drugs described by two-compartment and three-compartment models will have two or three half-lives. Each half-life is calculated as the natural log of 2 (0.693), divided by the exponent. The coefficients \( A \), \( B \), and \( C \) represent the contribution of each of the exponents to the overall decrease in concentration over time.

The two-compartment model is described by a curve with two exponents and two coefficients, whereas the three-compartment model is described by a curve with three exponents and three coefficients. The mathematical relationships among compartments, clearances, coefficients, and exponents are complex. Every coefficient and every exponent is a function of every volume and every clearance.
Elimination half-time is the time required for the drug concentration to fall by 50%. For drugs described by multicompartment pharmacokinetics (e.g., fentanyl, sufentanil), there are multiple elimination half-times, in other words the elimination half-time is context dependent. The offset of a drug’s effect cannot be predicted from half-lives alone. Moreover, one cannot easily determine how rapidly a drug effect will disappear simply by looking at coefficients, exponents, and half-lives. For example, the terminal half-life of sufentanil is about 10 h, whereas that of alfentanil is 2 h. This does not mean that recovery from alfentanil will be faster, because clinical recovery from clinical dosing will be influenced by all half-lives, not just the terminal one. Computer models readily demonstrate that recovery from an infusion lasting several hours will be faster when the drug administered is sufentanil than it will be when the infused drug is alfentanil. The time required for a 50% decrease in concentration depends on the duration or “context” of the infusion. The context-sensitive half-time, mentioned earlier, captures this concept and should be used instead of half-lives to compare the pharmacokinetic properties of intravenous drugs used in anesthesia.

**PHARMACODYNAMICS**

Pharmacodynamics, the study of how drugs affect the body, involves the concepts of potency, efficacy, and therapeutic window. Pharmacokinetic models can range from entirely empirical dose versus response relationships to mechanistic models of ligand–receptor binding. The fundamental pharmacodynamic concepts are captured in the relationship between exposure to a drug and physiological response to the drug, often called the *dose–response* or *concentration–response relationship*.

**Exposure–Response Relationships**

As the body is exposed to an increasing amount of a drug, the response to the drug similarly increases, typically up to a maximal value. This fundamental concept in the exposure versus response relationship is captured graphically by plotting exposure (usually dose or concentration) on the *x* axis as the independent variable, and the body’s response on the *y* axis as the dependent variable. Depending on the circumstances, the dose or concentration may be plotted on a linear scale (*Figure 7–2A*) or a logarithmic scale (*Figure 7–2B*), while the response is typically plotted either as the actual measured response (*Figure 7–2A*) or as a fraction of the baseline or maximum physiological measurement (*Figure 7–2B*). For our purposes here, basic pharmacodynamic
properties are described in terms of concentration, but any metric of drug exposure (dose, area under the curve, etc) could be used.

FIGURE 7–2 The shape of the dose (or concentration)–response curve depends
on whether the dose or plasma concentration is plotted on a linear (A) or logarithmic (B) scale.

The shape of the relationship is typically sigmoidal, as shown in Figure 7–2. The sigmoidal shape reflects the observation that often a certain minimal amount of drug must be present before there is any measurable physiological response. Thus, the left side of the curve is flat until the drug concentration reaches a threshold. The right side is also flat, reflecting the maximum physiological response of the body, beyond which the body simply cannot respond to additional drug. Thus, the curve is flat on both the left and right sides. A sigmoidal curve is required to connect the baseline to the asymptote, which is why sigmoidal curves are ubiquitous when modeling pharmacodynamics.

The sigmoidal relationship between exposure and response is defined by one of two interchangeable relationships:

\[
\text{Effect} = E_0 = E_{\text{max}} \frac{C^\gamma}{C_{50}^\gamma + C^\gamma}
\]

or

\[
\text{Effect} = E_0 + (E_{\text{max}} - E_0) \frac{C^\gamma}{C_{50}^\gamma + C^\gamma}
\]

In both cases, \(E_0\) is the baseline effect in the absence of drug, \(C\) is drug concentration, \(C_{50}\) is the concentration associated with half-maximal effect, and \(\gamma\) describes the steepness of the concentration versus response relationship (and is also known as the Hill coefficient). For the first equation, \(E_{\text{max}}\) is the maximum change from baseline. In the second equation, \(E_{\text{max}}\) is the maximum physiological measurement, not the maximum change from baseline.

Once defined in this fashion, each parameter of the pharmacodynamic model speaks to the specific concepts mentioned earlier. \(E_{\text{max}}\) is related to the intrinsic efficacy of a drug. Highly efficacious drugs have a large maximum physiological effect, characterized by a large \(E_{\text{max}}\). For drugs that lack efficacy, \(E_{\text{max}}\) will equal \(E_0\). \(C_{50}\) is a measure of drug potency. Highly potent drugs have a low \(C_{50}\); thus small amounts produce the drug effect. Drugs lacking potency have a high \(C_{50}\), indicating that a large amount of drug is required to achieve the drug effect. The
parameter γ indicates steepness of the relationship between concentration and effect. A γ value less than 1 indicates a very gradual increase in drug effect with increasing concentration. A γ value greater than 4 suggests that once drug effect is observed, small increases in drug concentration produce large increases in drug effect until the maximum effect is reached.

The curve described above represents the relationship of drug concentration to a continuous physiological response. The same relationship can be used to characterize the probability of a binary (yes/no) response to a drug dose:

\[
\text{Probability} = P_0 + (P_{\max} - P_0) \frac{C^\gamma}{C_{50}^\gamma + C^\gamma}
\]

In this case, the probability \( P \) ranges from 0 (no chance) to 1 (certainty). \( P_0 \) is the probability of a “yes” response in the absence of drug. \( P_{\max} \) is the maximum probability, necessarily less than or equal to 1. As before, \( C \) is the concentration, \( C_{50} \) is the concentration associated with half-maximal effect, and \( \gamma \) describes the steepness of the concentration versus response relationship. Half-maximal effect is the same as 50% probability of a response when \( P_0 \) is 0 and \( P_{\max} \) is 1.

The therapeutic window for a drug is the range between the concentration associated with a desired therapeutic effect and the concentration associated with a toxic drug response. This range can be measured as either the difference between two points on the same concentration versus response curve (when the toxicity represents an exaggerated form of the desired drug response) or the distance between two distinct curves (when the toxicity represents a different response or process from the desired drug response). For a drug such as sodium nitroprusside, a single concentration versus response curve defines the relationship between concentration and decrease in blood pressure. The therapeutic window might be the difference in the concentration producing a desired 20% decrease in blood pressure and a toxic concentration that produces a 60% decrease in blood pressure. However, for a drug such as lidocaine, the therapeutic window might be the difference between the \( C_{50} \) for suppression of ventricular arrhythmias and the \( C_{50} \) for lidocaine-induced seizures, the two drug effects being described by separate concentration versus response relationships. The therapeutic index is the \( C_{50} \) for toxicity divided by the \( C_{50} \) for the desired therapeutic effect. Because of the risk of ventilatory and cardiovascular depression (even at concentrations only slightly greater than those producing
anesthesia), most inhaled and intravenous hypnotics are considered to have very low therapeutic indices relative to other drugs.

**Drug Receptors**

Drug receptors are macromolecules (typically proteins) that bind a drug (agonist) and mediate the drug response. Pharmacological antagonists reverse the effects of the agonist but do not otherwise exert an effect of their own. Competitive antagonism occurs when the antagonist competes with the agonist for the same binding site, each potentially displacing the other. Noncompetitive antagonism occurs when the antagonist, through covalent binding or another process, permanently impairs the drug’s access to the receptor.

The drug effect is governed by the fraction of receptors that are occupied by an agonist. That fraction is based on the concentration of the drug, the concentration of the receptor, and the strength of binding between the drug and the receptor. This binding is described by the law of mass action, which states that the reaction rate is proportional to the concentrations of the reactants:

$$ [D][RU] \overset{k_{on}}{\underset{k_{off}}{\rightleftharpoons}} [DR] $$

where $[D]$ is the concentration of the drug, $[RU]$ is the concentration of unbound receptor, and $[DR]$ is the concentration of bound receptor. The rate constant $k_{on}$ defines the rate of ligand binding to the receptor. The rate constant $k_{off}$ defines the rate of ligand unbinding from the receptor. According to the law of mass action, the rate of receptor binding, $d[DR]/dt$ is:

$$ \frac{d[DR]}{dt} = [D][RU]k_{on} - [DR]k_{off} $$

Steady state occurs almost instantly. Because the rate of formation at steady state is 0, it follows that:

$$ [D][RU]k_{on} = [DR]k_{off} $$

In this equation, $k_d$ is the dissociation rate constant, defined as $k_{on}/k_{off}$. If we define $f$, fractional receptor occupancy, as:
\[
\frac{[DR]}{[DR]+[RU]}
\]

then we can solve for receptor occupancy as:

\[
f = \frac{[D]}{k_d + [D]}
\]

The receptors are half occupied when \([D] = k_d\). Thus, \(k_d\) is the concentration of drug associated with 50% receptor occupancy.

Receptor occupancy is only the first step in mediating drug effect. Binding of the drug to the receptor can trigger myriad subsequent steps, including opening, closing, or inhibition of an ion channel; activation of a G protein; activation of an intracellular kinase; direct interaction with a cellular structure; or direct binding to DNA.

Like the concentration versus response curve, the shape of the curve relating fractional receptor occupancy to drug concentration is intrinsically sigmoidal. However, the concentration associated with 50% receptor occupancy and the concentration associated with 50% of maximal drug effect are not necessarily the same. Maximal drug effect could occur at very low receptor occupancy or (for partial agonists) at greater than 100% receptor occupancy.

Prolonged binding and activation of a receptor by an agonist may lead to hyporeactivity (“desensitization”) and tolerance. If the binding of an endogenous ligand is chronically blocked or chronically reduced, then receptors may proliferate resulting in hyperreactivity and increased sensitivity. For example, after spinal cord injury nicotinic acetylcholine receptors are not stimulated by impulses in motor nerves and proliferate in denervated muscle. This can lead to exaggerated responses (including hyperkalemia) to succinylcholine.

**SUGGESTED READINGS**

Inhalation Anesthetics

KEY CONCEPTS

1. The greater the uptake of anesthetic agent, the greater the difference between inspired and alveolar concentrations, and the slower the rate of induction.
2. Three factors affect anesthetic uptake: solubility in the blood, alveolar blood flow, and the difference in partial pressure between alveolar gas and venous blood.
3. Low-output states predispose patients to overdosage with soluble agents, as the rate of rise in alveolar concentrations will be markedly increased.
4. Many of the factors that speed induction also speed recovery: elimination of rebreathing, high fresh gas flows, low anesthetic-circuit volume, low absorption by the anesthetic circuit, decreased solubility, high cerebral blood flow, and increased ventilation.
5. The unitary hypothesis proposes that all inhalation agents share a common mechanism of action at the molecular level. This was previously supported by the observation that the anesthetic potency of inhalation agents correlates directly with their lipid solubility (Meyer–Overton rule). The implication is that anesthesia results from molecules dissolving at specific lipophilic sites; however, the correlation is only approximate.
6. The minimum alveolar concentration (MAC) of an inhaled anesthetic is the alveolar concentration that prevents movement in 50% of patients in response to a standardized stimulus (eg, surgical incision).
7. Prolonged exposure to anesthetic concentrations of nitrous oxide can result in bone marrow depression (megaloblastic anemia) and even neurological deficiencies (peripheral neuropathies).
8. “Halothane hepatitis” is extremely rare. Patients exposed to multiple
halothane anesthetics at short intervals, middle-aged obese women, and persons with a familial predisposition to halothane toxicity or a personal history of toxicity are considered to be at increased risk.

Isoflurane dilates coronary arteries, but not nearly as potently as nitroglycerin or adenosine. Dilation of normal coronary arteries could theoretically divert blood away from fixed stenotic lesions.

The low solubility of desflurane in blood and body tissues causes a very rapid induction of and emergence from anesthesia.

Rapid increases in desflurane concentration lead to transient but sometimes worrisome elevations in heart rate, blood pressure, and catecholamine levels that are more pronounced than occur with isoflurane, particularly in patients with cardiovascular disease.

Nonpungency and rapid increases in alveolar anesthetic concentration make sevoflurane an excellent choice for smooth and rapid inhalation inductions in pediatric and adult patients.

Nitrous oxide, chloroform, and ether were the first universally accepted general anesthetics. Inhalation agents currently in widespread use in clinical anesthesiology include nitrous oxide, halothane, isoflurane, desflurane, and sevoflurane.

The course of a general anesthetic can be divided into three phases: (1) induction, (2) maintenance, and (3) emergence. Inhalation anesthetics, notably halothane and sevoflurane, are particularly useful in the induction of pediatric patients in whom it may be difficult to start an intravenous line. Although adults are usually induced with intravenous agents, the nonpungency and rapid onset of sevoflurane make inhalation induction practical for them as well. Regardless of the patient’s age, anesthesia is often maintained with inhalation agents. Emergence depends primarily upon redistribution of the agent from the brain followed by pulmonary elimination. Because of their unique route of administration, inhalation anesthetics have useful pharmacological properties not shared by other anesthetic agents.

Pharmacokinetics of Inhalation Anesthetics

Although the mechanism of action of inhalation anesthetics is complex, likely involving multiple membrane proteins and ion channels, it is clear that producing their ultimate effect depends on attainment of a therapeutic tissue
concentration in the central nervous system (CNS). There are many steps in between the anesthetic vaporizer and the anesthetic’s deposition in the brain (Figure 8–1).

**FIGURE 8–1** Inhalation anesthetic agents must pass through many barriers between the anesthesia machine and the brain.

**FACTORS AFFECTING INSPIRATORY CONCENTRATION (FI)**

The fresh gas leaving the anesthesia machine mixes with gases in the breathing circuit before being inspired by the patient. Therefore, the patient is not necessarily receiving the concentration set on the vaporizer. The actual composition of the inspired gas mixture depends mainly on the fresh gas flow rate, the volume of the breathing system, and any absorption by the machine or breathing circuit. The greater the fresh gas flow rate, the smaller the breathing system volume, and the lower the circuit absorption, the closer the inspired gas concentration will be to the fresh gas concentration.

**FACTORS AFFECTING ALVEOLAR CONCENTRATION (FA)**
Uptake

If there were no uptake of anesthetic agent by the body, the alveolar gas concentration (FA) would rapidly approach the inspired gas concentration (FI). Because anesthetic agents are taken up by the pulmonary circulation during induction, alveolar concentrations lag behind inspired concentrations (FA/FI <1.0). The greater the uptake, the slower the rate of rise of the alveolar concentration and the lower the FA:FI ratio.

Because the concentration of a gas is directly proportional to its partial pressure, the alveolar partial pressure will also be slow to rise. The alveolar partial pressure is important because it determines the partial pressure of anesthetic in the blood and, ultimately, in the brain. Similarly, the partial pressure of the anesthetic in the brain is directly proportional to its brain tissue concentration, which determines clinical effect. Therefore, the greater the uptake of anesthetic agent, the greater the difference between inspired and alveolar concentrations, and the slower the rate of induction.

Three factors affect anesthetic uptake: solubility in the blood, alveolar blood flow, and the difference in partial pressure between alveolar gas and venous blood.

Relatively insoluble agents, such as nitrous oxide, are taken up by the blood less avidly than more soluble agents, such as halothane. As a consequence, the alveolar concentration of nitrous oxide rises and achieves a steady state faster than that of halothane. The relative solubilities of an anesthetic in air, blood, and tissues are expressed as partition coefficients (Table 8–1). Each coefficient is the ratio of the concentrations of the anesthetic gas in each of two phases at steady state. Steady state is defined as equal partial pressures in the two phases. For instance, the blood/gas partition coefficient (λb/g) of nitrous oxide at 37°C is 0.47. In other words, at steady state, 1 mL of blood contains 0.47 as much nitrous oxide as does 1 mL of alveolar gas, even though the partial pressures are the same. Stated another way, blood has 47% of the capacity for nitrous oxide as alveolar gas. Nitrous oxide is much less soluble in blood than is halothane, which has a blood/gas partition coefficient at 37°C of 2.4. Thus, almost five times more halothane than nitrous oxide must be dissolved to raise the partial pressure of blood by the same amount. The higher the blood/gas coefficient, the greater the anesthetic’s solubility and the greater its uptake by the pulmonary circulation. As a consequence of this increased solubility, alveolar partial pressure rises to a steady state more slowly. Because fat/blood partition coefficients are greater than 1, blood/gas solubility is increased by postprandial
lipidemia and is decreased by anemia.

¹These values are averages derived from multiple studies and should be used for comparison purposes, not as exact numbers.

The second factor that affects uptake is alveolar blood flow, which—in the absence of pulmonary shunting—is essentially equal to cardiac output. If the cardiac output drops to zero, so will anesthetic uptake. As cardiac output increases, anesthetic uptake increases, the rise in alveolar partial pressure slows, and induction is delayed. The effect of changing cardiac output is less pronounced for insoluble anesthetics, as so little is taken up regardless of alveolar blood flow. Low-output states predispose patients to overdosage with soluble agents, as the rate of rise in alveolar concentrations will be markedly increased.

The final factor affecting uptake of anesthetic by the pulmonary circulation is the partial pressure difference between alveolar gas and venous blood. This gradient depends on tissue uptake. If anesthetics did not pass into organs such as the brain, venous and alveolar partial pressures would become identical, and there would be no pulmonary uptake. The transfer of anesthetic from blood to tissues is determined by three factors analogous to systemic uptake: tissue solubility of the agent (tissue/blood partition coefficient), tissue blood flow, and the difference in partial pressure between arterial blood and the tissue.

To better understand inhaled anesthetic uptake and distribution, tissues have been classified into four groups based on their solubility and blood flow (**Table 8–2**). The highly perfused vessel-rich group (brain, heart, liver, kidney, and endocrine organs) is the first to encounter appreciable amounts of anesthetic. Moderate solubility and small volume limit the capacity of this group, so it is
also the first to reach steady state (ie, arterial and tissue partial pressures are equal). The muscle group (skin and muscle) is not as well perfused, so uptake is slower. In addition, it has a greater capacity due to a larger volume, and uptake will be sustained for hours. Perfusion of the fat group nearly equals that of the muscle group, but the tremendous solubility of anesthetic in fat leads to a total capacity (tissue/blood solubility × tissue volume) that would take days to approach steady state. The minimal perfusion of the vessel-poor group (bones, ligaments, teeth, hair, and cartilage) results in insignificant uptake.

Anesthetic uptake produces a characteristic curve that relates the rise in alveolar concentration to time (Figure 8–2). The shape of this graph is determined by the uptakes of individual tissue groups (Figure 8–3). The initial steep rise of $\text{FA/FI}$ is due to unopposed filling of the alveoli by ventilation. The rate of rise slows as the vessel-rich group—and eventually the muscle group—approach steady-state levels of saturation.
FIGURE 8–2 FA rises toward FI faster with nitrous oxide (an insoluble agent) than with halothane (a soluble agent). See Figure 8–1 for an explanation of FA and FI.

**Ventilation**

The lowering of alveolar partial pressure by uptake can be countered by increasing alveolar ventilation. In other words, constantly replacing anesthetic taken up by the pulmonary bloodstream results in better maintenance of alveolar concentration. The effect of increasing ventilation will be most obvious in raising the \( \text{F}_a/\text{F}_i \) for soluble anesthetics, as they are more subject to uptake. Because the \( \text{F}_a/\text{F}_i \) very rapidly approaches 1.0 for insoluble agents, increasing ventilation has minimal effect. In contrast to the effect of anesthetics on cardiac output, anesthetics and other drugs (eg, opioids) that depress spontaneous ventilation will decrease the rate of rise in alveolar concentration and create a negative feedback loop.

**Concentration**

The slowing of induction due to uptake from alveolar gas can be reduced by increasing the inspired concentration. Interestingly, increasing the inspired concentration not only increases the alveolar concentration, but also increases its rate of rise (ie, increases \( \text{F}_a/\text{F}_i \)), because of two phenomena (see Figure 8–1) that produce a so-called “concentrating effect.” First, if 50% of an anesthetic is taken up by the pulmonary circulation, an inspired concentration of 20% (20 parts of anesthetic per 100 parts of gas) will result in an alveolar concentration of 11% (10 parts of anesthetic remaining in a total volume of 90 parts of gas). On the other hand, if the inspired concentration is raised to 80% (80 parts of anesthetic per 100 parts of gas), the alveolar concentration will be 67% (40 parts of anesthetic remaining in a total volume of 60 parts of gas). Thus, even though 50% of the anesthetic is taken up in both examples, a higher inspired concentration results in a disproportionately higher alveolar concentration. In this example, increasing the inspired concentration four-fold results in a six-fold increase in alveolar concentration. The extreme case is an inspired concentration of 100% (100 parts of 100), which, despite a 50% uptake, will result in an alveolar concentration of 100% (50 parts of anesthetic remaining in a total volume of 50 parts of gas).

The second phenomenon responsible for the concentration effect is the augmented inflow effect. Using the example above, the 10 parts of absorbed gas must be replaced by an equal volume of the 20% mixture to prevent alveolar collapse. Thus, the alveolar concentration becomes 12% (10 plus 2 parts of anesthetic in a total of 100 parts of gas). In contrast, after absorption of 50% of the anesthetic in the 80% gas mixture, 40 parts of 80% gas must be inspired.
This further increases the alveolar concentration from 67% to 72% (40 plus 32 parts of anesthetic in a volume of 100 parts of gas).

The concentration effect is more significant with nitrous oxide than with the volatile anesthetics, as the former can be used in much higher concentrations. Nonetheless, a high concentration of nitrous oxide will augment (by the same mechanism) not only its own uptake, but theoretically that of a concurrently administered volatile anesthetic. The concentration effect of one gas upon another is called the second gas effect, which despite its presence in examination questions is probably insignificant in the clinical practice of anesthesiology.

**FACTORS AFFECTING ARTERIAL CONCENTRATION (Fa)**

**Ventilation/Perfusion Mismatch**

Normally, alveolar and arterial anesthetic partial pressures are assumed to be equal, but in fact, the arterial partial pressure is consistently less than end-expiratory gas would predict. Reasons for this may include venous admixture, alveolar dead space, and nonuniform alveolar gas distribution. Furthermore, the existence of ventilation/perfusion mismatching will increase the alveolar–arterial difference. Mismatch acts as a restriction to flow: It raises the pressure in front of the restriction, lowers the pressure beyond the restriction, and reduces the flow through the restriction. The overall effect is an increase in the alveolar partial pressure (particularly for highly soluble agents) and a decrease in the arterial partial pressure (particularly for poorly soluble agents). Thus, a bronchial intubation or a right-to-left intracardiac shunt will slow the rate of induction with nitrous oxide more than with sevoflurane.

**FACTORS AFFECTING ELIMINATION**

Recovery from anesthesia depends on lowering the concentration of anesthetic in brain tissue. Anesthetics can be eliminated by biotransformation, transcutaneous loss, or exhalation. Biotransformation usually accounts for a minimal increase in the rate of decline of alveolar partial pressure. Its greatest impact is on the elimination of soluble anesthetics that undergo extensive metabolism (eg, methoxyflurane). The greater biotransformation of halothane compared with isoflurane accounts for halothane’s faster elimination, even though it is more soluble. The CYP group of isozymes (specifically CYP 2E1) seems to be
important in the metabolism of some volatile anesthetics. Diffusion of anesthetic through the skin is insignificant.

The most important route for elimination of inhalation anesthetics is the alveolus. Many of the factors that speed induction also speed recovery: elimination of rebreathing, high fresh gas flows, low anesthetic-circuit volume, low absorption by the anesthetic circuit, decreased solubility, high cerebral blood flow (CBF), and increased ventilation. Elimination of nitrous oxide is so rapid that oxygen and CO₂ concentrations in alveolar gas are diluted. The resulting diffusion hypoxia is prevented by administering 100% oxygen for 5 to 10 min after discontinuing nitrous oxide. The rate of recovery is usually faster than induction because tissues that have not reached steady state will continue to take up anesthetic until the alveolar partial pressure falls below the tissue partial pressure. For instance, fat will continue to take up anesthetic and hasten recovery until the partial pressure exceeds the alveolar partial pressure. This redistribution is not as useful after prolonged anesthesia (fat partial pressures of anesthetic will have come “closer” to arterial partial pressures at the time the anesthetic was removed from fresh gas)—thus, the speed of recovery also depends on the length of time the anesthetic has been administered.

Pharmacodynamics of Inhalation Anesthetics

THEORIES OF ANESTHETIC ACTION

General anesthesia is an altered physiological state characterized by reversible loss of consciousness, analgesia, amnesia, and some degree of muscle relaxation. The multitude of substances capable of producing general anesthesia is remarkable: inert elements (xenon), simple inorganic compounds (nitrous oxide), halogenated hydrocarbons (halothane), ethers (isoflurane, sevoflurane, desflurane), and complex organic structures (propofol and ketamine). A unifying theory explaining anesthetic action would have to accommodate this diversity of structure. In fact, the various agents probably produce anesthesia by differing sets of molecular mechanisms. Inhalational agents interact with numerous ion channels present in the CNS and peripheral nervous system. Nitrous oxide and xenon are believed to inhibit N-methyl-D-aspartate (NMDA) receptors. NMDA receptors are excitatory receptors in the brain. Other inhalational agents may interact at other receptors (eg, γ-aminobutyric acid [GABA]-activated chloride channel conductance) leading to anesthetic effects. Additionally, some studies
suggest that inhalational agents continue to act in a nonspecific manner, thereby affecting the membrane bilayer. It is possible that inhalational anesthetics act on multiple protein receptors that block excitatory channels and promote the activity of inhibitory channels affecting neuronal activity, as well as by some nonspecific membrane effects.

There does not seem to be a single macroscopic site of action that is shared by all inhalation agents. Specific brain areas affected by various anesthetics include the reticular activating system, the cerebral cortex, the cuneate nucleus, the olfactory cortex, and the hippocampus; however, to be clear, general anesthetics bind throughout the CNS. Anesthetics have also been shown to depress excitatory transmission in the spinal cord, particularly at the level of the dorsal horn interneurons that are involved in pain transmission. Differing aspects of anesthesia may be related to different sites of anesthetic action. For example, unconsciousness and amnesia are probably mediated by cortical anesthetic action, whereas the suppression of purposeful withdrawal from pain likely relates to subcortical structures, such as the spinal cord or brainstem. One study in rats revealed that removal of the cerebral cortex did not alter the potency of the anesthetic! Indeed, measures of minimum alveolar concentration (MAC), the anesthetic concentration that prevents movement in 50% of subjects or animals, are dependent upon anesthetic effects at the spinal cord and not at the cortex.

Past understanding of anesthetic action attempted to identify a unitary hypothesis of anesthetic effects. This hypothesis proposes that all inhalation agents share a common mechanism of action at the molecular level. This was previously supported by the observation that the anesthetic potency of inhalation agents correlates directly with their lipid solubility (Meyer–Overton rule). The implication is that anesthesia results from molecules dissolving at specific lipophilic sites. Of course, not all lipid-soluble molecules are anesthetics (some are actually convulsants), and the correlation between anesthetic potency and lipid solubility is only approximate (Figure 8–4).
Neuronal membranes contain a multitude of hydrophobic sites in their phospholipid bilayer. Anesthetic binding to these sites could expand the bilayer beyond a critical amount, altering membrane function (critical volume hypothesis). Although this theory is almost certainly an oversimplification, it explains an interesting phenomenon: the reversal of anesthesia by increased pressure. Laboratory animals exposed to elevated hydrostatic pressure develop a resistance to anesthetic effects. Perhaps the pressure is displacing a number of molecules from the membrane or distorting the anesthetic binding sites in the membrane, increasing anesthetic requirements. Studies in the 1980s that demonstrated the ability of anesthetics to inhibit protein actions shifted scientific attention to the numerous ion channels that might affect neuronal transmission.
and away from theories based on critical volume or actions in lipids.

General anesthetic action could be due to alterations in any one (or a combination) of several cellular systems, including voltage-gated ion channels, ligand-gated ion channels, second messenger functions, or neurotransmitter receptors. For example, many anesthetics enhance GABA inhibition of the CNS. Furthermore, GABA receptor agonists seem to enhance anesthesia, whereas GABA antagonists reverse some anesthetic effects. There seems to be a strong correlation between anesthetic potency and potentiation of GABA receptor activity. Thus, anesthetic action may relate to binding in relatively hydrophobic domains in channel proteins (GABA receptors). Modulation of GABA function may prove to be a principal mechanism of action for many anesthetic drugs.

The glycine receptor $\alpha_1$-subunit, whose function is enhanced by inhalation anesthetics, is another potential anesthetic site of action.

The tertiary and quaternary structure of amino acids within an anesthetic-binding pocket could be modified by inhalation agents, perturbing the receptor itself, or indirectly producing an effect at a distant site.

Other ligand-gated ion channels whose modulation may play a role in anesthetic action include nicotinic acetylcholine receptors and NMDA receptors.

Investigations into mechanisms of anesthetic action are likely to remain ongoing for many years, as many protein channels may be affected by individual anesthetic agents, and no obligatory site has yet been identified. Selecting among so many molecular targets for the one(s) that provide optimum effects with minimal adverse actions will be the challenge in designing better inhalational agents.

**ANESTHETIC NEUROTOXICITY**

In recent years, there has been ongoing concern that general anesthetics damage the developing brain. It has been suggested that early exposure to anesthetics can promote cognitive impairment in later life. Concern has been raised that anesthetic exposure affects the development and the elimination of synapses in the infant brain. For example, animal studies have demonstrated that isoflurane exposure promotes neuronal apoptosis and subsequent learning disability. Volatile anesthetics have been shown to promote apoptosis by altering cellular calcium homeostatic mechanisms.

Human studies exploring whether anesthesia is harmful in children are difficult, as conducting a randomized controlled trial for that purpose only would be unethical. Studies that compare populations of children who have had
anesthetics with those who have not are also complicated by the reality that the former population is likewise having surgery and receiving the attention of the medical community. Consequently, children receiving anesthetics may be more likely to be diagnosed with learning difficulties in the first place. Data from one large study demonstrated that children who underwent surgery and anesthesia had a greater likelihood of carrying the diagnosis of a developmental disorder; however, the finding was not supported in twins (ie, the incidence of developmental disability was not greater in a twin who was exposed to anesthesia and surgery than in one who was not). Sun and colleagues reported that among healthy children with a single anesthesia exposure before 36 months of age, when compared with healthy siblings with no anesthesia exposure, there were no significant differences in IQ scores later in childhood. Additionally, preliminary reports comparing general versus spinal anesthesia in children younger than 6 months of age who underwent brief procedures did not demonstrate differences in cognitive development at 2 years of age. However, developmental changes may not yet be manifest at age 2 years. Further, cumulative exposure to volatile anesthetics has been shown to contribute to worse neurodevelopmental outcomes in children treated with hypoplastic left heart syndrome.

Human, animal, and laboratory trials demonstrating or refuting that anesthetic neurotoxicity leads to developmental disability in children are underway. SmartTots, a partnership between the International Anesthesia Research Society and the U.S. Food and Drug Administration (FDA), coordinates and funds research related to anesthesia in infants and young children. As their 2015 consensus statement notes: “It is not yet possible to know whether anesthetic drugs are safe for children in a single short-duration procedure. Similarly, it is not yet possible to know whether use of these drugs poses a risk, and if so, whether the risk is large enough to outweigh the benefit of needed surgery, tests, or other procedures…. Concerns regarding the unknown risk of anesthetic exposure to the child’s brain development must be weighed against potential harm associated with cancelling or delaying a needed procedure” (see www.smarttots.org). Of note, the FDA has issued a warning that repeated or prolonged use of general anesthetics or sedatives in children younger than 3 years of age may affect brain development.

Anesthetic agents have also been suggested to contribute to tau protein hyperphosphorylation. Tau hyperphosphorylation is associated with Alzheimer disease (AD), and it has been hypothesized that anesthetic exposures may contribute to AD progression. However, the proposed association between
anesthetic delivery, surgery, and AD development has not been sufficiently investigated to draw definitive conclusions.

**ANESTHETIC NEUROPROTECTION AND CARDIAC PRECONDITIONING**

Although inhalational agents have been suggested as contributing to neurotoxicity, they have also been shown to provide both neurological and cardiac protective effects against ischemia-reperfusion injury. Ischemic preconditioning implies that a brief ischemic episode protects a cell from future, more pronounced ischemic events. Various molecular mechanisms have been suggested to protect cells preconditioned either through ischemic events or secondary to pharmacological mechanisms, such as through the use of inhalational anesthetics. In the heart, preconditioning in part arises from actions at adenosine triphosphate (ATP)-sensitive potassium (K\text{ATP}) channels.

The exact mechanism of anesthetic preconditioning is likely to be multifocal and includes the opening of K\text{ATP} channels, resulting in less mitochondrial calcium ion concentration and reduction of reactive oxygen species (ROS) production. ROS contributes to cellular injury. Anesthetic preconditioning may be the result of increased production of antioxidants following initial anesthesia exposure. Additionally, excitatory NMDA receptors are linked to the development of neuronal injury. NMDA antagonists, such as the noble anesthetic gas xenon, have been shown to be neuroprotective. Xenon has an anti-apoptotic effect that may be secondary to its inhibition of calcium ion influx following cell injury. As with neurotoxicity, the role of inhalational anesthetics in tissue protection is the subject of ongoing investigation.

**MINIMUM ALVEOLAR CONCENTRATION**

The MAC of an inhaled anesthetic is the alveolar concentration that prevents movement in 50% of patients in response to a standardized stimulus (eg, surgical incision). MAC is a useful measure because it mirrors brain partial pressure, allows comparisons of potency between agents, and provides a standard for experimental evaluations (Table 8–3). Nonetheless, it should be remembered that this is a median value with limited usefulness in managing individual patients, particularly during times of rapidly changing alveolar concentrations (eg, induction and emergence).
The MAC values for different anesthetics are roughly additive. For example, a mixture of 0.5 MAC of nitrous oxide (53%) and 0.5 MAC of halothane (0.37%) produces the same likelihood that movement in response to surgical incision will be suppressed as 1.0 MAC of isoflurane (1.2%) or 1.0 MAC of any other single agent. In contrast to CNS depression, the degree of myocardial depression may not be equivalent at the same MAC: 0.5 MAC of halothane causes more myocardial depression than 0.5 MAC of nitrous oxide. MAC represents only one point on the concentration–response curve—it is the equivalent of a median effective concentration (EC$_{50}$). MAC multiples are clinically useful if the concentration–response curves of the anesthetics being compared are parallel, nearly linear, and continuous for the effect being predicted. Roughly 1.3 MAC of any of the volatile anesthetics (eg, for halothane: $1.3 \times 0.75\% = 0.97\%$) has been found to prevent movement in about 95% of patients (an approximation of the ED$_{95}$); 0.3 to 0.4 MAC is associated with awakening from anesthesia (MAC awake) when the inhaled drug is the only agent maintaining anesthetic (a rare circumstance).

MAC can be altered by several physiological and pharmacological variables.
One of the most striking is the 6% decrease in MAC per decade of age, regardless of volatile anesthetic. MAC is relatively unaffected by species, sex, or duration of anesthesia. Further, MAC is not altered after spinal cord transection in rats, leading to the hypothesis that the site of anesthetic inhibition of motor responses lies in the spinal cord.

**Clinical Pharmacology of Inhalation Anesthetics**

**NITROUS OXIDE**
Physical Properties

Nitrous oxide (N₂O; laughing gas) is colorless and essentially odorless. Although nonexplosive and nonflammable, nitrous oxide is as capable as oxygen of supporting combustion. Unlike the potent volatile agents, nitrous oxide is a gas at room temperature and ambient pressure. It can be kept as a liquid under pressure because its critical temperature lies above room temperature. Nitrous oxide is a relatively inexpensive anesthetic; however, concerns regarding its safety have led to continued interest in alternatives such as xenon (Table 8–5). As noted earlier, nitrous oxide, like xenon, is an NMDA receptor antagonist.

Effects on Organ Systems

A. Cardiovascular

Nitrous oxide has a tendency to stimulate the sympathetic nervous system. Thus, even though nitrous oxide directly depresses myocardial contractility in vitro, arterial blood pressure, cardiac output, and heart rate are essentially unchanged or slightly elevated in vivo because of its stimulation of catecholamines (Table 8–6). Myocardial depression may be unmasked in patients with coronary artery disease or severe hypovolemia. Constriction of pulmonary vascular smooth muscle increases pulmonary vascular resistance, which results in a generally
modest elevation of right ventricular end-diastolic pressure. Despite vasoconstriction of cutaneous vessels, peripheral vascular resistance is not significantly altered.

<sup>1</sup>N/C: no change.
<sup>2</sup>100% of the total cardiac output.
<sup>3</sup>Depolarizing blockade is probably also prolonged by these agents, but this is usually not clinically significant.
<sup>4</sup>Percentage of absorbed anesthetic undergoing metabolism.

**B. Respiratory**

Nitrous oxide increases respiratory rate (tachypnea) and decreases tidal volume as a result of CNS stimulation and, perhaps, activation of pulmonary stretch receptors. The net effect is a minimal change in minute ventilation and resting arterial CO<sub>2</sub> levels. Hypoxic drive, the ventilatory response to arterial hypoxia that is mediated by peripheral chemoreceptors in the carotid bodies, is markedly depressed by even small amounts of nitrous oxide.

**C. Cerebral**

By increasing CBF and cerebral blood volume, nitrous oxide produces a mild elevation of intracranial pressure. Nitrous oxide also increases cerebral oxygen consumption (CMRO<sub>2</sub>). Concentrations of nitrous oxide below MAC may provide analgesia in dental surgery, labor, traumatic injury, and minor surgical
procedures.

**D. Neuromuscular**
In contrast to other inhalation agents, nitrous oxide does not provide significant muscle relaxation. In fact, at high concentrations in hyperbaric chambers, nitrous oxide causes skeletal muscle rigidity. Nitrous oxide is not a triggering agent of malignant hyperthermia.

**E. Renal**
Nitrous oxide seems to decrease kidney blood flow by increasing renal vascular resistance. This leads to a drop in glomerular filtration rate and urinary output.

**F. Hepatic**
Hepatic blood flow probably falls during nitrous oxide anesthesia, but to a lesser extent than with the volatile agents.

**G. Gastrointestinal**
Use of nitrous oxide in adults increases the risk of postoperative nausea and vomiting, presumably as a result of activation of the chemoreceptor trigger zone and the vomiting center in the medulla.

**Biotransformation & Toxicity**
During emergence, almost all nitrous oxide is eliminated by exhalation. A small amount diffuses out through the skin. Biotransformation is limited to the less than 0.01% that undergoes reductive metabolism in the gastrointestinal tract by anaerobic bacteria.

By irreversibly oxidizing the cobalt atom in vitamin B\textsubscript{12}, nitrous oxide inhibits enzymes that are vitamin B\textsubscript{12} dependent. These enzymes include methionine synthetase, which is necessary for myelin formation, and thymidylate synthetase, which is necessary for DNA synthesis. Prolonged exposure to anesthetic concentrations of nitrous oxide can result in bone marrow depression (megaloblastic anemia) and even neurological deficiencies (peripheral neuropathies). However, administration of nitrous oxide for bone marrow harvest does not seem to affect the viability of bone marrow mononuclear cells. Because of possible teratogenic effects, nitrous oxide is often avoided in pregnant patients who are not yet in the third trimester. Nitrous oxide
may also alter the immunological response to infection by affecting chemotaxis
and motility of polymorphonuclear leukocytes.

**Contraindications**

Although nitrous oxide is insoluble in comparison with other inhalation agents, it
is 35 times more soluble than nitrogen in blood. Thus, it tends to diffuse into air-
containing cavities more rapidly than nitrogen is absorbed by the bloodstream.
For instance, if a patient with a 100-mL pneumothorax inhales 50% nitrous
oxide, the gas content of the pneumothorax will tend to approach that of the
bloodstream. Because nitrous oxide will diffuse into the cavity more rapidly than
the air (principally nitrogen) diffuses out, the pneumothorax expands until it
contains roughly 100 mL of air and 100 mL of nitrous oxide. If the walls
surrounding the cavity are rigid, pressure rises instead of volume. **Examples of
conditions in which nitrous oxide might be hazardous include venous or
arterial air embolism, pneumothorax, acute intestinal obstruction with
bowel distention, intracranial air (pneumocephalus following dural closure
or pneumoencephalography), pulmonary air cysts, intraocular air bubbles,
and tympanic membrane grafting.** Nitrous oxide will even diffuse into
tracheal tube cuffs, increasing the pressure against the tracheal mucosa.
Obviously, nitrous oxide is of limited value in patients requiring high inspired
oxygen concentrations.

**Drug Interactions**

Because the high MAC of nitrous oxide prevents its use as a complete general
anesthetic, it is frequently used in combination with the more potent volatile
agents. The addition of nitrous oxide decreases the requirements of these other
agents (65% nitrous oxide decreases the MAC of the volatile anesthetics by
approximately 50%). Although nitrous oxide should not be considered a benign
carrier gas, it does attenuate the circulatory and respiratory effects of volatile
anesthetics in adults. Nitrous oxide potentiates neuromuscular blockade, but less
so than the volatile agents. The concentration of nitrous oxide flowing through a
vaporizer can influence the concentration of volatile anesthetic delivered. For
example, decreasing nitrous oxide concentration (ie, increasing oxygen
concentration) increases the concentration of volatile agent despite a constant
vaporizer setting. This disparity is due to the relative solubilities of nitrous oxide
and oxygen in liquid volatile anesthetics. The second gas effect was discussed
earlier. Nitrous oxide is an ozone-depleting gas with greenhouse effects.
HALOTHANE

Physical Properties

Halothane is a halogenated alkane (see Table 8–3). The carbon–fluoride bonds are responsible for its nonflammable and nonexplosive nature. Thymol preservative and amber-colored bottles retard spontaneous oxidative decomposition. It is rarely used in the United States.

Effects on Organ Systems

A. Cardiovascular

A dose-dependent reduction of arterial blood pressure is due to direct myocardial depression; 2.0 MAC of halothane in patients not undergoing surgery results in a 50% decrease in blood pressure and cardiac output. Cardiac depression—from interference with sodium–calcium exchange and intracellular calcium utilization—causes an increase in right atrial pressure. Although halothane is a coronary artery vasodilator, coronary blood flow decreases, due to the drop in systemic arterial pressure. Adequate myocardial perfusion is usually maintained, as oxygen demand also drops. Normally, hypotension inhibits baroreceptors in the aortic arch and carotid bifurcation, causing a decrease in vagal stimulation and a compensatory rise in heart rate. Halothane blunts this reflex. Slowing of sinoatrial node conduction may result in a junctional rhythm or bradycardia. In infants, halothane decreases cardiac output by a combination of decreased heart rate and depressed myocardial contractility. Halothane sensitizes the heart to the arrhythmogenic effects of epinephrine, so that doses of epinephrine above 1.5 mcg/kg should be avoided. Although organ blood flow is redistributed, systemic vascular resistance is unchanged.

B. Respiratory

Halothane typically causes rapid, shallow breathing. The increased respiratory rate is not enough to counter the decreased tidal volume, so alveolar ventilation drops, and resting PaCO₂ is elevated. Apneic threshold, the highest PaCO₂ at which a patient remains apneic, also rises because the difference between it and resting PaCO₂ is not altered by general anesthesia. Similarly, halothane limits the increase in minute ventilation that normally accompanies a rise in PaCO₂. Halothane’s ventilatory effects are probably due to central (medullary
depression) and peripheral (intercostal muscle dysfunction) mechanisms. These changes are exaggerated by preexisting lung disease and attenuated by surgical stimulation. The increase in PaCO\textsubscript{2} and the decrease in intrathoracic pressure that accompany spontaneous ventilation with halothane partially reverse the depression in cardiac output, arterial blood pressure, and heart rate described above. Hypoxic drive is severely depressed by even low concentrations of halothane (0.1 MAC).

Halothane is considered a potent bronchodilator, as it often reverses asthma-induced bronchospasm. This action is not inhibited by β-adrenergic blocking agents. Halothane attenuates airway reflexes and relaxes bronchial smooth muscle by inhibiting intracellular calcium mobilization. Halothane also depresses clearance of mucus from the respiratory tract (mucociliary function), promoting postoperative hypoxia and atelectasis.

C. Cerebral
By dilating cerebral vessels, halothane lowers cerebral vascular resistance and increases cerebral blood volume and CBF. Autoregulation, the maintenance of constant CBF during changes in arterial blood pressure, is blunted. Concomitant rises in intracranial pressure can be prevented by establishing hyperventilation prior to administration of halothane. Cerebral activity is decreased, leading to electroencephalographic slowing and modest reductions in metabolic oxygen requirements.

D. Neuromuscular
Halothane relaxes skeletal muscle and potentiates nondepolarizing neuromuscular-blocking agents (NMBAs). Like the other potent volatile anesthetics, it is a trigger for malignant hyperthermia.

E. Renal
Halothane reduces renal blood flow, glomerular filtration rate, and urinary output. Part of this decrease can be explained by a fall in arterial blood pressure and cardiac output. Because the reduction in renal blood flow is greater than the reduction in glomerular filtration rate, the filtration fraction is increased. Preoperative hydration limits these changes.

F. Hepatic
Halothane causes hepatic blood flow to decrease in proportion to the depression
of cardiac output. Hepatic artery vasospasm has been reported during halothane anesthesia. The metabolism and clearance of some drugs (eg, fentanyl, phenytoin, verapamil) seem to be impaired by halothane. Other evidence of hepatic cellular dysfunction includes sulfobromophthalein (BSP) dye retention and minor liver transaminase elevations.

**Biotransformation & Toxicity**

Halothane is oxidized in the liver by a particular isozyme of CYP (2EI) to its principal metabolite, trifluoroacetic acid. In the absence of oxygen, reductive metabolism may result in a small amount of hepatotoxic end products that covalently bind to tissue macromolecules. This is more apt to occur following enzyme induction by phenobarbital. Elevated fluoride levels signal significant anaerobic metabolism.

Postoperative hepatic dysfunction has several causes: viral hepatitis, impaired hepatic perfusion, preexisting liver disease, hepatocyte hypoxia, sepsis, hemolysis, benign postoperative intrahepatic cholestasis, and drug-induced hepatitis. “**Halothane hepatitis**” is extremely rare. Patients exposed to multiple halothane anesthetics at short intervals, middle-aged obese women, and persons with a familial predisposition to halothane toxicity or a personal history of toxicity are considered to be at increased risk. Signs are mostly related to hepatic injury, such as increased serum alanine and aspartate transferase, elevated bilirubin (leading to jaundice), and encephalopathy.

The hepatic lesion seen in humans—centrilobular necrosis—also occurs in rats pretreated with an enzyme inducer (phenobarbital) and exposed to halothane under hypoxic conditions (FiO₂ <14%). This *halothane hypoxic model* implies hepatic damage from reductive metabolites or hypoxia.

Other evidence points to an immune mechanism. For instance, some signs of the disease indicate an allergic reaction (eg, eosinophilia, rash, fever) and do not appear until a few days after exposure. Furthermore, an antibody that binds to hepatocytes previously exposed to halothane has been isolated from patients with halothane-induced hepatic dysfunction. This antibody response may involve liver microsomal proteins that have been modified by trifluoroacetic acid as the triggering antigens (trifluoroacetylated liver proteins such as microsomal carboxylesterase). Other inhalational agents that undergo oxidative metabolism can likewise lead to hepatitis. However, newer agents undergo little to no metabolism, and therefore do not form trifluoroacetic acid protein adducts or produce the immune response leading to hepatitis.
Contraindications

It is prudent to withhold halothane from patients with unexplained liver dysfunction following previous anesthetic exposure.

Halothane, like all inhalational anesthetics, should be used with care (and only in combination with modest hyperventilation) in patients with intracranial mass lesions because of the possibility of intracranial hypertension secondary to increased cerebral blood volume and blood flow.

Hypovolemic patients and some patients with severe reductions in left ventricular function may not tolerate halothane’s negative inotropic effects. Sensitization of the heart to catecholamines limits the usefulness of halothane when exogenous epinephrine is administered (eg, in local anesthetic solutions) or in patients with pheochromocytoma.

Drug Interactions

The myocardial depression seen with halothane is exacerbated by β-adrenergic blocking agents and calcium channel blocking agents. Tricyclic antidepressants and monoamine oxidase inhibitors have been associated with fluctuations in blood pressure and arrhythmias, although neither represents an absolute contraindication. The combination of halothane and aminophylline has resulted in serious ventricular arrhythmias.

ISOFLURANE

Physical Properties

Isoflurane is a nonflammable volatile anesthetic with a pungent ethereal odor.

Effects on Organ Systems

A. Cardiovascular

Isoflurane causes minimal left ventricular depression in vivo. Cardiac output is maintained by a rise in heart rate due to partial preservation of carotid baroreflexes. Mild β-adrenergic stimulation increases skeletal muscle blood flow, decreases systemic vascular resistance, and lowers arterial blood pressure. Rapid increases in isoflurane concentration lead to transient increases in heart rate, arterial blood pressure, and plasma levels of norepinephrine. Isoflurane dilates coronary arteries, but not nearly as potently as nitroglycerin or adenosine.
Dilation of normal coronary arteries could theoretically divert blood away from fixed stenotic lesions, which was the basis for concern about coronary “steal” with this agent, a concern that has largely been forgotten.

**B. Respiratory**
Respiratory depression during isoflurane anesthesia resembles that of other volatile anesthetics, except that tachypnea is less pronounced. The net effect is a more pronounced fall in minute ventilation. Even low levels of isoflurane (0.1 MAC) blunt the normal ventilatory response to hypoxia and hypercapnia. Despite a tendency to irritate upper airway reflexes, isoflurane is considered a good bronchodilator, but may not be as potent a bronchodilator as halothane.

**C. Cerebral**
At concentrations greater than 1 MAC, isoflurane increases CBF and intracranial pressure. These effects are thought to be less pronounced than with halothane and are reversed by hyperventilation. In contrast to halothane, the hyperventilation does not have to be instituted prior to the use of isoflurane to prevent intracranial hypertension. Isoflurane reduces cerebral metabolic oxygen requirements, and at 2 MAC, it produces an electrically silent electroencephalogram (EEG).

**D. Neuromuscular**
Isoflurane relaxes skeletal muscle.

**E. Renal**
Isoflurane decreases renal blood flow, glomerular filtration rate, and urinary output.

**F. Hepatic**
Total hepatic blood flow (hepatic artery and portal vein flow) may be reduced during isoflurane anesthesia. Hepatic oxygen supply is better maintained with isoflurane than with halothane, however, because hepatic artery perfusion is preserved. Liver function tests are usually not affected.

**Biotransformation & Toxicity**
Isoflurane is metabolized to trifluoroacetic acid. Although serum fluoride fluid
levels may rise, nephrotoxicity is extremely unlikely, even in the presence of enzyme inducers. Prolonged sedation (>24 h at 0.1–0.6% isoflurane) of critically ill patients has resulted in elevated plasma fluoride levels (15–50 μmol/L) without evidence of kidney impairment. Similarly, up to 20 MAC-hours of isoflurane may lead to fluoride levels exceeding 50 μmol/L without detectable postoperative kidney dysfunction. Its limited oxidative metabolism also minimizes any possible risk of significant hepatic dysfunction.

**Contraindications**

Isoflurane presents no unique contraindications. Patients with severe hypovolemia may not tolerate its vasodilating effects. It can trigger malignant hyperthermia.

**Drug Interactions**

Epinephrine can be safely administered in doses up to 4.5 mcg/kg. Nondepolarizing NMBAs are potentiated by isoflurane.

**DESFLURANE**

**Physical Properties**

The structure of desflurane is very similar to that of isoflurane. In fact, the only difference is the substitution of a fluorine atom for isoflurane’s chlorine atom. That “minor” change has profound effects on the physical properties of the drug, however. For instance, because the vapor pressure of desflurane at 20°C is 681 mm Hg, at high altitudes (eg, Denver, Colorado) it boils at room temperature. This problem necessitated the development of a special desflurane vaporizer. Furthermore, the low solubility of desflurane in blood and body tissues causes a very rapid induction of and emergence from anesthesia. Therefore, the alveolar concentration of desflurane approaches the inspired concentration much more rapidly than with the other volatile agents, giving the anesthesiologist tighter control over anesthetic levels. **Wakeup times are approximately 50% less than those observed following isoflurane.** This is principally attributable to a blood/gas partition coefficient (0.42) that is even lower than that of nitrous oxide (0.47). Although desflurane is roughly one-fourth as potent as the other volatile agents, it is 17 times more potent than nitrous oxide. A high vapor pressure, an ultrashort duration of action, and moderate potency are the most characteristic
features of desflurane.

**Effects on Organ Systems**

**A. Cardiovascular**
The cardiovascular effects of desflurane seem to be similar to those of isoflurane. An increase in the concentration is associated with a decline in systemic vascular resistance that leads to a fall in arterial blood pressure. Cardiac output remains relatively unchanged or slightly depressed at 1 to 2 MAC. There is a moderate rise in heart rate, central venous pressure, and pulmonary artery pressure that often does not become apparent at low doses. Rapid increases in desflurane concentration lead to transient but sometimes worrisome elevations in heart rate, blood pressure, and catecholamine levels that are more pronounced than occur with isoflurane, particularly in patients with cardiovascular disease. These cardiovascular responses to rapidly increasing desflurane concentration can be attenuated by fentanyl, esmolol, or clonidine.

**B. Respiratory**
Desflurane causes a decrease in tidal volume and an increase in respiratory rate. There is an overall decrease in alveolar ventilation that causes a rise in resting PaCO\(_2\). Like other modern volatile anesthetic agents, desflurane depresses the ventilatory response to increasing PaCO\(_2\). Pungency and airway irritation during desflurane induction can be manifested by salivation, breath-holding, coughing, and laryngospasm. Airway resistance may increase in children with reactive airway susceptibility. These problems make desflurane a poor choice for inhalation induction.

**C. Cerebral**
Like the other volatile anesthetics, desflurane directly vasodilates the cerebral vasculature, increasing CBF, cerebral blood volume, and intracranial pressure at normotension and normocapnia. Countering the decrease in cerebral vascular resistance is a marked decline in the cerebral metabolic rate of oxygen (CMRO\(_2\)) that tends to cause cerebral vasoconstriction and moderate any increase in CBF. The cerebral vasculature remains responsive to changes in PaCO\(_2\), however, so that intracranial pressure can be lowered by hyperventilation. Cerebral oxygen consumption is decreased during desflurane anesthesia. Thus, during periods of desflurane-induced hypotension (mean arterial pressure = 60 mm Hg), CBF is
adequate to maintain aerobic metabolism despite a low cerebral perfusion pressure. The effect on the EEG is similar to that of isoflurane. Initially, EEG frequency is increased, but as anesthetic depth is increased, EEG slowing becomes manifest, leading to burst suppression at higher inhaled concentrations.

D. Neuromuscular
Desflurane is associated with a dose-dependent decrease in the response to train-of-four and tetanic peripheral nerve stimulation.

E. Renal
There is no evidence of any significant nephrotoxic effects caused by exposure to desflurane. However, as cardiac output declines, decreases in urine output and glomerular filtration should be expected with desflurane and all other anesthetics.

F. Hepatic
Hepatic function tests are generally unaffected by desflurane, assuming that organ perfusion is maintained perioperatively. Desflurane undergoes minimal metabolism; therefore, the risk of anesthetic-induced hepatitis is likewise minimal. As with isoflurane and sevoflurane, hepatic oxygen delivery is generally maintained.

Biotransformation & Toxicity
Desflurane undergoes minimal metabolism in humans. Serum and urine inorganic fluoride levels following desflurane anesthesia are essentially unchanged from preanesthetic levels. There is insignificant percutaneous loss. Desflurane, more than other volatile anesthetics, is degraded by desiccated CO₂ absorbent (particularly barium hydroxide lime, but also sodium and potassium hydroxide) into potentially clinically important levels of carbon monoxide. Carbon monoxide poisoning is difficult to diagnose under general anesthesia, but the presence of carboxyhemoglobin may be detectable by arterial blood gas analysis or lower than expected pulse oximetry readings (although still falsely high). Disposing of dried out absorbent or use of calcium hydroxide can minimize the risk of carbon monoxide poisoning.

Contraindications
Desflurane shares many of the contraindications of other modern volatile anesthetics: severe hypovolemia, malignant hyperthermia, and intracranial hypertension.

**Drug Interactions**

Desflurane potentiates nondepolarizing neuromuscular blocking agents to the same extent as isoflurane. Epinephrine can be safely administered in doses up to 4.5 mcg/kg as desflurane does not sensitize the myocardium to the arrhythmogenic effects of epinephrine. Although emergence is more rapid following desflurane anesthesia than after isoflurane anesthesia, switching from isoflurane to desflurane toward the end of anesthesia does not significantly accelerate recovery, nor does faster emergence translate into faster discharge times from the postanesthesia care unit. Desflurane emergence has been associated with delirium in some pediatric patients.

**SEVOFLURANE**

**Physical Properties**

Like desflurane, sevoflurane is halogenated with fluorine. Sevoflurane’s solubility in blood is slightly greater than desflurane ($\lambda_{b/g} 0.65$ versus $0.42$) (see Table 8–1). Nonpungency and rapid increases in alveolar anesthetic concentration make sevoflurane an excellent choice for smooth and rapid inhalation inductions in pediatric and adult patients. In fact, inhalation induction with 4% to 8% sevoflurane in a 50% mixture of nitrous oxide and oxygen can be achieved within 1 min. Likewise, its low blood solubility results in a rapid fall in alveolar anesthetic concentration upon discontinuation and a more rapid emergence compared with isoflurane (although not an earlier discharge from the postanesthesia care unit). Sevoflurane’s modest vapor pressure permits the use of a conventional variable bypass vaporizer.

**Effects on Organ Systems**

**A. Cardiovascular**

Sevoflurane mildly depresses myocardial contractility. Systemic vascular resistance and arterial blood pressure decline slightly less than with isoflurane or desflurane. Because sevoflurane causes little, if any, rise in heart rate, cardiac
output is not maintained as well as with isoflurane or desflurane. Sevoflurane may prolong the QT interval, the clinical significance of which is unknown. QT prolongation may be manifest 60 min following anesthetic emergence in infants.

**B. Respiratory**
Sevoflurane depresses respiration and reverses bronchospasm to an extent similar to that of isoflurane.

**C. Cerebral**
Similar to isoflurane and desflurane, sevoflurane causes slight increases in CBF and intracranial pressure at normocarbia, although some studies show a decrease in CBF. High concentrations of sevoflurane (>1.5 MAC) may impair autoregulation of CBF, thus allowing a drop in CBF during hemorrhagic hypotension. This effect on CBF autoregulation seems to be less pronounced than with isoflurane. Cerebral metabolic oxygen requirements decrease, and seizure activity has not been reported.

**D. Neuromuscular**
Sevoflurane produces adequate muscle relaxation for intubation following an inhalation induction, although most practitioners will deepen anesthesia with various combinations of propofol, lidocaine, or opioids; administer a neuromuscular blocker prior to intubation; or a combination of these two approaches.

**E. Renal**
Sevoflurane slightly decreases renal blood flow. Its metabolism to substances associated with impaired renal tubule function (eg, decreased concentrating ability) is discussed below.

**F. Hepatic**
Sevoflurane decreases portal vein blood flow, but increases hepatic artery blood flow, thereby maintaining total hepatic blood flow and oxygen delivery. It is generally not associated with immune-mediated anesthetic hepatotoxicity.

**Biotransformation & Toxicity**
The liver microsomal enzyme P-450 (specifically the 2E1 isoform) metabolizes
sevoflurane at a rate one-fourth that of halothane (5% versus 20%), but 10 to 25 times that of isoflurane or desflurane and may be induced with ethanol or phenobarbital pretreatment. The potential nephrotoxicity of the resulting rise in inorganic fluoride (F\(^-\)) was discussed earlier. Serum fluoride concentrations exceed 50 μmol/L in approximately 7% of patients who receive sevoflurane, yet clinically significant kidney dysfunction has not been associated with sevoflurane anesthesia. The overall rate of sevoflurane metabolism is 5%, or 10 times that of isoflurane. Nonetheless, there has been no association with peak fluoride levels following sevoflurane and any renal concentrating abnormality.

Alkali such as barium hydroxide lime or soda lime (but not calcium hydroxide) can degrade sevoflurane, producing another proven (at least in rats) nephrotoxic end product (compound A, fluoromethyl-2,2-difluoro-1-[trifluoromethyl]vinyl ether). Accumulation of compound A increases with increased respiratory gas temperature, low-flow anesthesia, dry barium hydroxide absorbent (Baralyme), high sevoflurane concentrations, and anesthetics of long duration.

We are not aware of a study that has associated sevoflurane with any detectable postoperative renal toxicity or injury. Nonetheless, some clinicians recommend that fresh gas flows be at least 2 L/min for anesthetics lasting more than a few hours. Sevoflurane can also be degraded into hydrogen fluoride by metal and environmental impurities present in manufacturing equipment, glass bottle packaging, and anesthesia equipment. Hydrogen fluoride can produce an acid burn on contact with respiratory mucosa. The risk of patient injury has been substantially reduced by inhibition of the degradation process by adding water to sevoflurane during the manufacturing process and packaging it in a special plastic container. Isolated incidents of fire in the respiratory circuits of anesthesia machines with desiccated CO\(_2\) absorbent have been reported when sevoflurane was used.

**Contraindications**

Contraindications include severe hypovolemia, susceptibility to malignant hyperthermia, and intracranial hypertension.

**Drug Interactions**

Like other volatile anesthetics, sevoflurane potentiates NMBAs. It does not sensitize the heart to catecholamine-induced arrhythmias.
XENON

Xenon is a noble gas that has long been known to have anesthetic properties. It is an inert element that does not form chemical bonds. Xenon is scavenged from the atmosphere through a costly distillation process. It is an odorless, nonexplosive, naturally occurring gas with a MAC of 71% and a blood/gas coefficient of 0.115, giving it very fast onset and emergence parameters. As previously mentioned, xenon’s anesthetic effects seem to be mediated by NMDA inhibition by competing with glycine at the glycine binding site. Xenon seems to have little effect on cardiovascular, hepatic, or renal systems and has been found to be protective against neuronal ischemia. Xenon inhalation combined with hypothermia has been suggested as a protective method to prevent cerebral damage following ischemic brain injury. Additionally, xenon anesthesia has been shown to produce less postoperative delirium compared with sevoflurane anesthesia in patients undergoing off-pump coronary artery bypass graft surgery. As a natural element, it has no effect upon the ozone layer compared with another NMDA antagonist, nitrous oxide. Cost and limited availability have prevented its widespread use.

Intravenous Anesthetics

KEY CONCEPTS

1. Repetitive administration of highly lipid-soluble barbiturates (eg, infusion of thiopental for “barbiturate coma” and brain protection) saturates the peripheral compartments, minimizing any effect of redistribution and rendering the duration of action more dependent on elimination. This is an example of context sensitivity.

2. Barbiturates constrict the cerebral vasculature, causing a decrease in cerebral blood flow, cerebral blood volume, and intracranial pressure.

3. Although apnea may be relatively uncommon after benzodiazepine induction, even small intravenous doses of these agents have resulted in respiratory arrest.

4. In contrast to other anesthetic agents, ketamine increases arterial blood pressure, heart rate, and cardiac output, particularly after rapid bolus injections.

5. Induction doses of etomidate transiently inhibit enzymes involved in cortisol and aldosterone synthesis. When used for sedation in the intensive care unit, etomidate was reported to produce consistent adrenocortical suppression.

6. Propofol formulations can support the growth of bacteria, so sterile technique must be observed in preparation and handling. Propofol should be administered within 6 h of opening the ampule.

General anesthesia began with the inhaled agents ether, nitrous oxide, and chloroform, but in current practice, anesthesia can be induced and maintained with drugs that enter the patient through a wide range of routes. Preoperative or procedural sedation is usually accomplished by way of oral or intravenous routes. Induction of general anesthesia is usually accomplished by inhalation or
intravenous drug administration. Alternatively, general anesthesia can be induced and maintained with intramuscular injection of ketamine. General anesthesia is maintained with a total intravenous anesthesia (TIVA) technique, an inhalation technique, or a combination of the two. This chapter focuses on the injectable agents used to produce narcosis (sleep), including barbiturates, benzodiazepines, ketamine, etomidate, propofol, and dexmedetomidine.

BARBITURATES

Mechanisms of Action

Barbiturates depress the reticular activating system in the brainstem, which controls consciousness. Their primary mechanism of action is believed to be through binding to the γ-aminobutyric acid type A (GABA_A) receptor. Barbiturates potentiate the action of GABA in increasing the duration of openings of a chloride-specific ion channel.

Structure–Activity Relationships

Barbiturates are derived from barbituric acid (Figure 9–1). Substitution at carbon C_5 determines hypnotic potency and anticonvulsant activity. The phenyl group in phenobarbital is anticonvulsive, whereas the methyl group in methohexital is not. Thus methohexital is useful for providing anesthesia for electroconvulsive therapy when a seizure is desired. Replacing the oxygen at C_2 (oxybarbiturates) with a sulfur atom (thiobarbiturates) increases lipid solubility. As a result, thiopental and thiamylal have a greater potency, more rapid onset of action, and shorter durations of action (after a single “sleep dose”) than pentobarbital. The sodium salts of the barbiturates are water soluble but markedly alkaline (pH of 2.5% thiopental ≥10) and relatively unstable (2-week shelf-life for 2.5% thiopental solution).
Pharmacokinetics

A. Absorption
Prior to the introduction of propofol, thiopental, thiamylal, and methohexital were frequently administered intravenously for induction of general anesthesia in adults and children. Rectal methohexital has been used for induction in children.

B. Distribution
The duration of induction doses of thiopental, thiamylal, and methohexital is determined by redistribution, not by metabolism or elimination. Thiopental’s great lipid solubility and high nonionized fraction (60%) account for rapid brain uptake (within 30 s). If the central compartment is contracted (eg, hypovolemic shock), if the serum albumin is low (eg, severe liver disease or malnutrition), or if the nonionized fraction is increased (eg, acidosis), larger brain and heart concentrations will be achieved for a given dose. Redistribution lowers plasma and brain concentration to 10% of peak levels within 20 to 30 min (Figure 9–2). This pharmacokinetic profile correlates with clinical experience—patients
typically lose consciousness within 30 s and awaken within 20 min.

**FIGURE 9–2** Distribution of thiopental from plasma to the vessel-rich group (VRG; brain, heart, liver, kidney, endocrine glands), to the muscle group (MG), and finally to the fat group (FG). Propofol follows the same pattern but on a different time scale. (Modified with permission from Price HL, Kovnat PJ, Safer JN, et al. The uptake of thiopental by body tissues and its relation to the duration of narcosis. *Clin Pharmacol Ther*. 1960 Jan;1(1):16–22.)

The minimal induction dose of thiopental will depend on body weight and age. Reduced induction doses are required for elderly patients. In contrast to the rapid initial distribution half-life of a few minutes, elimination of thiopental is prolonged (elimination half-life ranges of 10–12 h). Thiamylal and methohexital have similar distribution patterns, whereas less lipid-soluble barbiturates have much longer distribution half-lives and durations of action after a sleep dose. Repetitive administration of highly lipid-soluble barbiturates (eg, infusion of thiopental for “barbiturate coma” and brain protection) saturates the peripheral compartments, minimizing any effect of redistribution and rendering the duration of action more dependent on elimination. This is an example of context sensitivity as is also seen with other lipid-soluble agents (eg, potent inhaled anesthetics, fentanyl, and sufentanil; see Chapter 7).

**C. Biotransformation**
Barbiturates are principally biotransformed via hepatic oxidation to inactive, water-soluble metabolites. Because of greater hepatic extraction, methohexital is
cleared by the liver more rapidly than thiopental. Therefore, full recovery of psychomotor function is also more rapid following methohexital.

**D. Excretion**
Except for the less protein-bound and less lipid-soluble agents such as phenobarbital, renal excretion is limited to water-soluble end products of hepatic biotransformation. Methohexital is excreted in the feces.

**Effects on Organ Systems**

**A. Cardiovascular**
The cardiovascular effects of barbiturates vary markedly, depending on rate of administration, dose, volume status, baseline autonomic tone, and preexisting cardiovascular disease. A slow rate of injection with adequate preoperative hydration will attenuate or eliminate these changes in most patients. Intravenous bolus induction doses of barbiturates cause a decrease in blood pressure and an increase in heart rate. Depression of the medullary vasomotor center produces vasodilation of peripheral capacitance vessels, which increases peripheral pooling of blood, mimicking a reduced blood volume. Tachycardia following administration is probably due to a central vagolytic effect and reflex responses to decreases in blood pressure. Cardiac output is often maintained by an increased heart rate and increased myocardial contractility from compensatory baroreceptor reflexes. Sympathetically induced vasoconstriction of resistance vessels (particularly with intubation under light planes of general anesthesia) may actually increase peripheral vascular resistance. However, in situations where the baroreceptor response will be blunted or absent (eg, hypovolemia, congestive heart failure, β-adrenergic blockade), cardiac output and arterial blood pressure may fall dramatically due to uncompensated peripheral pooling of blood and direct myocardial depression. Patients with poorly controlled hypertension are particularly prone to wide swings in blood pressure during anesthesia induction.

**B. Respiratory**
Barbiturates depress the medullary ventilatory center, decreasing the ventilatory response to hypercapnia and hypoxia. Apnea often follows an induction dose. During awakening, tidal volume and respiratory rate are decreased. Barbiturates incompletely depress airway reflex responses to laryngoscopy and intubation, and airway instrumentation may lead to bronchospasm (in asthmatic patients) or
laryngospasm in lightly anesthetized patients.

C. Cerebral

Barbiturates constrict the cerebral vasculature, causing a decrease in cerebral blood flow, cerebral blood volume, and intracranial pressure. Intracranial pressure decreases to a greater extent than arterial blood pressure, so cerebral perfusion pressure (CPP) usually increases. (CPP equals cerebral artery pressure minus the greater of jugular venous pressure or intracranial pressure.) Barbiturates induce a greater decline in cerebral oxygen consumption (up to 50% of normal) than in cerebral blood flow; therefore, the decline in cerebral blood flow is not detrimental. Barbiturate-induced reductions in oxygen requirements and cerebral metabolic activity are mirrored by changes in the electroencephalogram (EEG), which progress from low-voltage fast activity with small doses to high-voltage slow activity, burst suppression, and electrical silence with larger doses. Barbiturates may protect the brain from transient episodes of focal ischemia (eg, cerebral embolism) but probably do not protect from global ischemia (eg, cardiac arrest). Abundant animal data document these effects, but the clinical data are sparse and inconsistent. Furthermore, thiopental doses required to maintain EEG burst suppression or flat line are associated with prolonged awakening, delayed extubation, and the need for inotropic support.

The degree of central nervous system depression induced by barbiturates ranges from mild sedation to unconsciousness, depending on the dose administered (Table 9–1). Some patients relate a taste sensation of garlic, onions, or pizza during induction with thiopental. Barbiturates do not impair the perception of pain. Small doses occasionally cause a state of excitement and disorientation. Barbiturates do not produce muscle relaxation, and some induce involuntary skeletal muscle contractions (eg, methohexital). Relatively small doses of thiopental (50–100 mg intravenously) rapidly (but briefly) control most grand mal seizures.

**D. Renal**
Barbiturates reduce renal blood flow and glomerular filtration rate in proportion to the fall in blood pressure.

**E. Hepatic**
Hepatic blood flow is decreased. Chronic exposure to barbiturates leads to induction of hepatic enzymes and an increased rate of metabolism. On the other hand, binding of barbiturates to the cytochrome P-450 enzyme system interferes with the biotransformation of other drugs (eg, tricyclic antidepressants). Barbiturates promote aminolevulinic acid synthetase, which stimulates the formation of porphyrin (an intermediary in heme synthesis). This may precipitate acute intermittent porphyria or variegate porphyria in susceptible individuals.

**F. Immunological**
Anaphylactic or anaphylactoid allergic reactions are rare. Sulfur-containing thiobarbiturates evoke mast cell histamine release in vitro, whereas oxybarbiturates do not.

**Drug Interactions**
Contrast media, sulfonamides, and other drugs that occupy the same protein-binding sites may displace thiopental, increasing the amount of free drug available and potentiating the effects of a given dose. Ethanol, opioids, antihistamines, and other central nervous system depressants potentiate the sedative effects of barbiturates.

**BENZODIAZEPINES**

**Mechanisms of Action**
Benzodiazepines bind the same set of receptors in the central nervous system as barbiturates but bind to a different site. Benzodiazepine binding to the GABA<sub>A</sub> receptor increases the frequency of openings of the associated chloride ion channel. Benzodiazepine-receptor binding by an agonist facilitates binding of GABA to its receptor. **Flumazenil** (an imidazobenzodiazepine) is a specific benzodiazepine–receptor antagonist that effectively reverses most of the central nervous system effects of benzodiazepines (see Chapter 17).
**Structure–Activity Relationships**

The chemical structure of benzodiazepines includes a benzene ring and a seven-member diazepine ring (Figure 9–3). Substitutions at various positions on these rings affect potency and biotransformation. The imidazole ring of midazolam contributes to its water solubility at low pH. Diazepam and lorazepam are insoluble in water so parenteral preparations contain propylene glycol, which can produce venous irritation.

**FIGURE 9–3** The structures of commonly used benzodiazepines and their antagonist, flumazenil, share a seven-member diazepine ring. (Modified with permission from White PF. Pharmacologic and clinical aspects of preoperative medication. Anesth Analg. 1986 Sep;65(9):963–974.)

**Pharmacokinetics**

**A. Absorption**

Benzodiazepines are commonly administered orally and intravenously (or, less commonly, intramuscularly) to provide sedation (or, less commonly, to induce general anesthesia) (Table 9–2). Diazepam and lorazepam are well absorbed from the gastrointestinal tract, with peak plasma levels usually achieved in 1 and 2 h, respectively. Intravenous midazolam (0.05–0.1 mg/kg) given for anxiolysis before general or regional anesthesia is nearly ubiquitous. Oral midazolam
(0.25–1 mg/kg), although not approved by the U.S. Food and Drug Administration, is popular for pediatric premedication. Likewise, intranasal (0.2–0.3 mg/kg), buccal (0.07 mg/kg), and sublingual (0.1 mg/kg) midazolam provide effective preoperative sedation.

¹IV, intravenous; IM, intramuscular.

Intramuscular injections of diazepam are painful and unreliably absorbed. In contrast, midazolam and lorazepam are well absorbed after intramuscular injection, with peak levels achieved in 30 and 90 min, respectively.

**B. Distribution**

Diazepam is relatively lipid soluble and readily penetrates the blood–brain barrier. Although midazolam is water soluble at reduced pH, its imidazole ring closes at physiological pH, increasing its lipid solubility (see Figure 9–3). The moderate lipid solubility of lorazepam accounts for its slower brain uptake and onset of action. Redistribution is fairly rapid for the benzodiazepines and, like the barbiturates, is responsible for awakening. Although we have used midazolam as an induction agent, none of the benzodiazepines can match the rapid onset and short duration of action of propofol or etomidate. All three benzodiazepines are highly protein bound (90–98%).

**C. Biotransformation**

The benzodiazepines rely on the liver for biotransformation into water-soluble glucuronidated end products. The phase I metabolites of diazepam are pharmacologically active.

Slow hepatic extraction and a large volume of distribution ($V_d$) result in a long elimination half-life for diazepam (30 h). Although lorazepam also has a
low hepatic extraction ratio, its lower lipid solubility limits its $V_{d}$, resulting in a shorter elimination half-life (15 h). Nonetheless, the clinical duration of lorazepam is often quite prolonged due to increased receptor affinity. These differences between lorazepam and diazepam underscore the low utility of individual pharmacokinetic half-lives in guiding clinical practice (see Chapter 7). Midazolam shares diazepam’s $V_{d}$, but its elimination half-life (2 h) is the shortest of the group because of its increased hepatic extraction ratio.

**D. Excretion**
The metabolites of benzodiazepines are excreted chiefly in the urine. Enterohepatic circulation produces a secondary peak in diazepam plasma concentration 6 to 12 h following administration.

**Effects on Organ Systems**

**A. Cardiovascular**
Benzodiazepines display minimal left-ventricular depressant effects, even at general anesthetic doses, except when they are coadministered with opioids (these agents interact to produce myocardial depression and arterial hypotension). Benzodiazepines given alone decrease arterial blood pressure, cardiac output, and peripheral vascular resistance slightly, and sometimes increase heart rate.

**B. Respiratory**
Benzodiazepines depress the ventilatory response to $CO_{2}$. This depression is usually insignificant unless the drugs are administered intravenously or given with other respiratory depressants. Although apnea may be relatively uncommon after benzodiazepine induction, even small intravenous doses of these agents have resulted in respiratory arrest. The steep dose–response curve and delayed onset (compared with propofol or etomidate) necessitate titration to avoid overdosage and apnea, particularly when these agents are used for conscious sedation. Ventilation must be monitored in all patients receiving intravenous benzodiazepines (we recommend end-tidal $CO_{2}$ monitoring), and resuscitation equipment and a practitioner with airway skills must be present.

**C. Cerebral**
Benzodiazepines reduce cerebral oxygen consumption, cerebral blood flow, and
intracranial pressure but not to the extent the barbiturates do. They are effective in controlling grand mal seizures. Sedative doses often produce anterograde amnesia. The mild muscle-relaxing property of these drugs is mediated at the spinal cord level. The antianxiety, amnestic, and sedative effects seen at lower doses progress to stupor and unconsciousness at anesthetic doses. Compared with propofol or etomidate, induction with benzodiazepines is associated with a slower rate of loss of consciousness and a longer recovery. Benzodiazepines have no direct analgesic properties.

**Drug Interactions**

Cimetidine binds to cytochrome P-450 and reduces the metabolism of diazepam. Erythromycin inhibits metabolism of midazolam and causes a two- to threefold prolongation and intensification of its effects.

As previously mentioned, the combination of opioids and benzodiazepines markedly reduces arterial blood pressure and peripheral vascular resistance. This synergistic interaction has often been observed in patients undergoing cardiac surgery who received benzodiazepines for premedication and who received larger doses of opioids during induction of anesthesia.

Benzodiazepines reduce the minimum alveolar concentration of volatile anesthetics as much as 30%. Ethanol, barbiturates, and other central nervous system depressants potentiate the sedative effects of the benzodiazepines.

**KETAMINE**

**Mechanisms of Action**

Ketamine has multiple effects throughout the central nervous system, and it is well recognized to inhibit N-methyl-D-aspartate (NMDA) channels and neuronal hyperpolarization-activated cationic ($\text{HCN}_1$) channels. Nevertheless, exactly how ketamine produces either anesthesia or analgesia remains controversial. Ketamine functionally “dissociates” sensory impulses from the limbic cortex (which is involved with the awareness of sensation). Clinically, this state of dissociative anesthesia may cause the patient to appear conscious (eg, eye opening, swallowing, muscle contracture) but unable to process or respond to sensory input. Ketamine may have additional actions on endogenous analgesic pathways.

Ketamine has effects on mood, and infusions of this agent are now being
widely used to treat severe, treatment-resistant depression, particularly when patients have suicidal ideation. Small infusion doses of ketamine are also being used to supplement general anesthesia and to reduce the need for opioids both during and after the surgical procedure. Low-dose infusions of ketamine have been used for analgesia in postoperative patients and others who are refractory to conventional analgesic approaches. Ketamine has been identified by the World Health Organization as a key necessary agent.

**Structure–Activity Relationships**

Ketamine (Figure 9–4) is a structural analogue of phencyclidine (a veterinary anesthetic and a drug of abuse). It is one-tenth as potent, yet retains many of phencyclidine’s psychotomimetic effects. Ketamine is used for intravenous induction of anesthesia, particularly in settings where its tendency to produce sympathetic stimulation are useful (hypovolemia, trauma). When intravenous access is lacking, ketamine is useful for intramuscular induction of general anesthesia in children and uncooperative adults. Ketamine can be combined with other agents (eg, propofol or midazolam) in small bolus doses or infusions for conscious sedation during procedures such as nerve blocks and endoscopy. Even subanesthetic doses of ketamine may cause hallucinations but usually do not do so in clinical practice, where many patients will have received at least a small dose of midazolam (or a related agent) for amnesia and sedation. The increased anesthetic potency and decreased psychotomimetic side effects of one isomer (S[+] versus R[−]) are the result of stereospecific receptors. The single S(+) stereoisomer preparation is not available in the United States (but widely available elsewhere throughout the world), and it has considerably greater affinity than the racemic mixture for the NMDA receptor as well as several-fold greater potency as a general anesthetic.
The structures of ketamine, etomidate, propofol, and dexmedetomidine.

**Pharmacokinetics**

**A. Absorption**
Ketamine has been administered orally, nasally, rectally, subcutaneously, and epidurally, but in usual clinical practice it is given intravenously or intramuscularly (Table 9–3). Peak plasma levels are usually achieved within 10 to 15 min after intramuscular injection.

**TABLE 9–3** Uses and doses of ketamine, etomidate, and propofol.
B. Distribution
Ketamine is highly lipid soluble and, along with ketamine-induced increase in cerebral blood flow and cardiac output, results in rapid brain uptake and subsequent redistribution (the distribution half-life is 10–15 min). Awakening is due to redistribution from brain to peripheral compartments.

C. Biotransformation
Ketamine is biotransformed in the liver to several metabolites, one of which (norketamine) retains anesthetic activity. Patients receiving repeated doses of ketamine (eg, for daily changing of dressings on burns) develop tolerance, and this can only be partially explained by induction of hepatic enzymes. Extensive hepatic uptake (hepatic extraction ratio of 0.9) explains ketamine’s relatively short elimination half-life (2 h).

D. Excretion
End products of ketamine biotransformation are excreted renally.

### Effects on Organ Systems

#### A. Cardiovascular
In contrast to other anesthetic agents, ketamine increases arterial blood pressure, heart rate, and cardiac output (Table 9–4), particularly after rapid bolus injections. These indirect cardiovascular effects are due to central stimulation of the sympathetic nervous system and inhibition of the reuptake of norepinephrine after release at nerve terminals. Accompanying these changes are increases in pulmonary artery pressure and myocardial work. For these reasons, ketamine should be administered carefully to patients with coronary artery disease,
uncontrolled hypertension, congestive heart failure, or arterial aneurysms. The **direct myocardial depressant** effects of large doses of ketamine, probably due to inhibition of calcium transients, are unmasked by sympathetic blockade (e.g., spinal cord transection) or exhaustion of catecholamine stores (e.g., severe end-stage shock).

1 HR, heart rate; MAP, mean arterial pressure; Vent, ventilatory drive; B’dil, bronchodilation; CBF, cerebral blood flow; CMRO2, cerebral oxygen consumption; ICP, intracranial pressure. ↓, no effect; 0, no change or mild increase; ↓, decrease (mild, moderate, marked); ↑, increase (mild, moderate, marked); T, unknown effect.

**B. Respiratory**

Ventilatory drive is minimally affected by induction doses of ketamine, although combinations of ketamine with opioids may produce apnea. Racemic ketamine is a potent bronchodilator, making it a good induction agent for asthmatic patients; however, S(+) ketamine produces minimal bronchodilation. Upper airway reflexes remain largely intact, but partial airway obstruction may occur, and patients at increased risk for aspiration pneumonia (“full stomachs”) should be intubated during ketamine general anesthesia (see Case Discussion, Chapter 17). The increased salivation associated with ketamine can be attenuated by premedication with an anticholinergic agent such as glycopyrrolate.

**C. Cerebral**

The received dogma about ketamine is that it increases cerebral oxygen consumption, cerebral blood flow, and intracranial pressure. These effects would seem to preclude its use in patients with space-occupying intracranial lesions such as occur with head trauma; however, recent publications offer convincing evidence that when combined with a benzodiazepine (or another agent acting on the same GABA receptor system) and controlled ventilation (in techniques that
exclude nitrous oxide), ketamine is not associated with increased intracranial pressure. Myoclonic activity is associated with increased subcortical electrical activity, which is not apparent on surface EEG. Undesirable psychotomimetic side effects (eg, disturbing dreams and delirium) during emergence and recovery are less common in children, in patients premedicated with benzodiazepines, or in those receiving ketamine combined with propofol in a total intravenous anesthesia (TIVA) technique. Of the nonvolatile agents, ketamine comes closest to being a “complete” anesthetic as it induces analgesia, amnesia, and unconsciousness.

**Drug Interactions**

Ketamine interacts synergistically (more than additive) with volatile anesthetics but in an additive way with propofol, benzodiazepines, and other GABA-receptor–mediated agents. In animal experiments nondepolarizing neuromuscular blocking agents are minimally potentiated by ketamine (see Chapter 11). Diazepam and midazolam attenuate ketamine’s cardiostimulatory effects and diazepam prolongs ketamine’s elimination half-life.

α-Adrenergic and β-adrenergic antagonists (and other agents and techniques that diminish sympathetic stimulation) unmask the direct myocardial depressant effects of ketamine, which are normally overwhelmed by sympathetic stimulation. Concurrent infusion of ketamine and propofol, often in a fixed infusion (mg:mg) ratio of 1:10, has achieved great popularity for sedation with local and regional anesthesia or intravenous general anesthesia in office-based settings.

**ETOMIDATE**

**Mechanisms of Action**

Etomidate depresses the reticular activating system and mimics the inhibitory effects of GABA. Specifically, etomidate—particularly the R(+) isomer—appears to bind to a subunit of the GABA  receptor, increasing the receptor’s affinity for GABA. Etomidate may have disinhibitory effects on the parts of the nervous system that control extrapyramidal motor activity. This disinhibition offers a potential explanation for the 30% to 60% incidence of myoclonus with induction of etomidate anesthesia.
**Structure–Activity Relationships**

Etomidate contains a carboxylated imidazole and is structurally unrelated to other anesthetic agents (see Figure 9–4). The imidazole ring provides water solubility in acidic solutions and lipid solubility at physiological pH. Therefore, etomidate is dissolved in propylene glycol for injection. This solution often causes pain on injection that can be lessened by a prior intravenous injection of lidocaine.

**Pharmacokinetics**

**A. Absorption**

Etomidate is available only for intravenous administration and is used primarily for induction of general anesthesia (see Table 9–3). It is sometimes used for brief production of deep (unconscious) sedation such as prior to placement of retrobulbar blocks.

**B. Distribution**

Although it is highly protein bound, etomidate is characterized by a very rapid onset of action due to its great lipid solubility and large nonionized fraction at physiological pH. Redistribution is responsible for decreasing the plasma concentration to awakening levels. Etomidate plasma kinetics are well explained by a two-compartment model.

**C. Biotransformation**

Hepatic microsomal enzymes and plasma esterases rapidly hydrolyze etomidate to an inactive metabolite.

**D. Excretion**

The end products of etomidate hydrolysis are primarily excreted in the urine.

**Effects on Organ Systems**

**A. Cardiovascular**

Etomidate has minimal effects on the cardiovascular system when given by itself. A mild reduction in peripheral vascular resistance is responsible for a decline in arterial blood pressure. Myocardial contractility and cardiac output are usually unchanged. Etomidate does not release histamine. However, etomidate
by itself, even in large doses, produces relatively light anesthesia for laryngoscopy, and marked increases in heart rate and blood pressure may be recorded when etomidate provides the only anesthetic depth for intubation.

**B. Respiratory**

Ventilation is affected less with etomidate than with barbiturates or benzodiazepines. Even induction doses usually do not result in apnea unless opioids have also been administered.

**C. Cerebral**

Etomidate decreases cerebral metabolic rate, cerebral blood flow, and intracranial pressure. Because of minimal cardiovascular effects, cerebral perfusion pressure is well maintained. Although changes on EEG resemble those associated with barbiturates, etomidate (like ketamine) increases the amplitude of somatosensory evoked potentials. Postoperative nausea and vomiting are more common following etomidate than following propofol or barbiturate induction. Etomidate lacks analgesic properties.

**D. Endocrine**

Induction doses of etomidate transiently inhibit enzymes involved in cortisol and aldosterone synthesis. When infused for sedation in the intensive care unit (ICU), etomidate was reported to produce consistent adrenocortical suppression with an increased mortality rate in critically ill (particularly septic) patients.

**Drug Interactions**

Fentanyl increases the plasma level and prolongs the elimination half-life of etomidate. Opioids decrease the myoclonus characteristic of an etomidate induction.

**PROPOFOL**

**Mechanisms of Action**

Propofol induction of general anesthesia may involve facilitation of inhibitory neurotransmission mediated by GABA<sub>A</sub> receptor binding. Propofol allosterically increases binding affinity of GABA for the GABA<sub>A</sub> receptor. This receptor, as previously noted, is coupled to a chloride channel, and activation of the receptor
leads to hyperpolarization of the nerve membrane. Propofol (like most general anesthetics) binds multiple ion channels and receptors. Propofol actions are not reversed by the specific benzodiazepine antagonist flumazenil.

**Structure–Activity Relationships**

Propofol consists of a phenol ring substituted with two isopropyl groups (see Figure 9–4). Propofol is not water soluble, but a 1% aqueous solution (10 mg/mL) is available for intravenous administration as an oil-in-water emulsion containing soybean oil, glycerol, and egg lecithin. A history of egg allergy does not necessarily contraindicate the use of propofol because most egg allergies involve a reaction to egg white (egg albumin), whereas egg lecithin is extracted from egg yolk. This formulation will often cause pain during injection that can be decreased by prior injection of lidocaine or less effectively by mixing lidocaine with propofol prior to injection (2 mL of 1% lidocaine in 18 mL propofol). Propofol formulations can support the growth of bacteria, so sterile technique must be observed in preparation and handling. Propofol should be administered within 6 h of opening the ampule. Sepsis and death have been linked to contaminated propofol preparations. Current formulations of propofol contain 0.005% disodium edetate or 0.025% sodium metabisulfite to help retard the rate of growth of microorganisms; however, these additives do not render the product “antimicrobially preserved” under United States Pharmacopeia standards.

**Pharmacokinetics**

**A. Absorption**

Propofol is available only for intravenous administration for the induction of general anesthesia and for moderate to deep sedation (see Table 9–3).

**B. Distribution**

Propofol has a rapid onset of action. Awakening from a single bolus dose is also rapid due to a very short initial distribution half-life (2–8 min). Recovery from propofol is more rapid and is accompanied by less “hangover” than recovery from methohexital, thiopental, ketamine, or etomidate. This makes it a good anesthetic for ambulatory surgery. A smaller induction dose is recommended in elderly patients because of their smaller $V_d$. Age is also a key factor determining required propofol infusion rates for TIVA. In countries other than the United
States, a device called the Diprifusor™ is used to provide target (concentration) controlled infusion of propofol. The user must enter the patient’s age and weight and the desired target concentration. The device uses these data, a microcomputer, and standard pharmacokinetic parameters to continuously adjust the infusion rate. Unfortunately, this device is not available in the United States.

C. Biotransformation
The clearance of propofol exceeds hepatic blood flow, implying the existence of extrahepatic metabolism. This exceptionally high clearance rate probably contributes to rapid recovery after continuous infusions. Conjugation in the liver results in inactive metabolites that are eliminated by renal clearance. The pharmacokinetics of propofol do not appear to be affected by obesity, cirrhosis, or kidney failure. Use of propofol infusion for long-term sedation of children who are critically ill or young adult neurosurgical patients has been associated with sporadic cases of lipemia, metabolic acidosis, and death, the so-termed propofol infusion syndrome.

D. Excretion
Although metabolites of propofol are primarily excreted in the urine, end-stage kidney disease does not affect clearance of the parent drug.

Effects on Organ Systems

A. Cardiovascular
The major cardiovascular effect of propofol is a decrease in arterial blood pressure due to a drop in systemic vascular resistance (inhibition of sympathetic vasoconstrictor activity), preload, and cardiac contractility. Hypotension following induction is usually reversed by the stimulation accompanying laryngoscopy and intubation. Factors associated with propofol-induced hypotension include large doses, rapid injection, and old age. Propofol markedly impairs the normal arterial baroreflex response to hypotension. Rarely, a marked drop in cardiac filling may lead to a vagally mediated reflex bradycardia. Changes in heart rate and cardiac output are usually transient and insignificant in healthy patients, but may be severe in patients at the extremes of age, those receiving β-adrenergic blockers, or those with impaired ventricular function. Although myocardial oxygen consumption and coronary blood flow usually decrease comparably, coronary sinus lactate production increases in some patients, indicating some mismatch between myocardial oxygen supply and
demand.

**B. Respiratory**

Propofol is a profound respiratory depressant that usually causes apnea following an induction dose. Even when used for conscious sedation in subanesthetic doses, propofol inhibits hypoxic ventilatory drive and depresses the normal response to hypercarbia. As a result, only properly educated and qualified personnel should administer propofol for sedation. Propofol-induced depression of upper airway reflexes exceeds that of thiopental, allowing intubation, endoscopy, or laryngeal mask placement in the absence of neuromuscular blockade. Although propofol can cause histamine release, induction with propofol is accompanied by a lower incidence of wheezing in both asthmatic and nonasthmatic patients compared with barbiturates or etomidate.

**C. Cerebral**

Propofol decreases cerebral blood flow, cerebral blood volume, and intracranial pressure. In patients with elevated intracranial pressure, propofol can cause a critical reduction in CPP (<50 mm Hg) unless steps are taken to support mean arterial blood pressure. Propofol and thiopental provide a comparable degree of cerebral protection during experimental focal ischemia. Unique to propofol are its antipruritic properties. Its antiemetic effects provide yet another reason for it to be a preferred drug for outpatient anesthesia. Induction is occasionally accompanied by excitatory phenomena such as muscle twitching, spontaneous movement, opisthotonus, or hiccups. Propofol has anticonvulsant properties, has been used successfully to terminate status epilepticus, and may safely be administered to epileptic patients. Propofol decreases intraocular pressure. Tolerance does not develop after long-term propofol infusions. Propofol is an uncommon agent of physical dependence or addiction; however, anesthesia personnel, celebrities, and other medically untrained individuals have died while using propofol inappropriately to induce sleep in nonsurgical settings.

**Drug Interactions**

Many clinicians administer a small amount of midazolam (eg, 30 mcg/kg) prior to induction with propofol; midazolam can reduce the required propofol dose by more than 10%. Propofol is often combined with either remifentanil or ketamine for TIVA.
FOSPROPOFOL
Fospropofol is a water-soluble prodrug that is metabolized in vivo to propofol, phosphate, and formaldehyde. It was released in the United States (2008) and other countries based on studies showing that it produces more complete amnesia and better conscious sedation for endoscopy than midazolam plus fentanyl. It has a slower onset and slower recovery than propofol, offering little reason for anesthesiologists to favor it over propofol. The place (if any) of fospropofol relative to other competing agents has not yet been established in clinical practice.

DEXMEDEXTOMIDINE
Dexmedetomidine is an $\alpha_2$-adrenergic agonist that can be used for anxiolysis, sedation, and analgesia. Strictly speaking, it is not an anesthetic in humans; however, anesthesiologists have used it in combination with other agents to produce anesthesia. It has also been used in combination with local anesthetics to prolong regional blocks. This agent can be used for premedication by nasal (1–2 mcg/kg) or oral (2.5–4 mcg/kg) administration in children where it compares very favorably with oral midazolam.

Most commonly, dexmedetomidine is used for procedural sedation (eg, during awake craniotomy procedures or fiberoptic intubation), ICU sedation (eg, ventilated patients recovering from cardiac surgery), or as a supplement to general anesthesia to reduce the need for intraoperative opioids or to reduce the likelihood of emergence delirium (most often in children) after an inhalation anesthetic. It has also been used to treat alcohol withdrawal and side effects of cocaine intoxication. Typically, intravenous dexmedetomidine sedation in awake adults is initiated with a 1 mcg/kg loading dose given over 5 to 10 min followed by a maintenance infusion of 0.2 to 1.4 mcg/kg/h.

Dexmedetomidine has very rapid redistribution and a relatively short elimination half-life. It is metabolized in the liver by the CYP450 system and through glucuronidation. Nearly all metabolites are excreted in the urine.

CASE DISCUSSION
Premedication of the Surgical Patient
An extremely anxious patient presents for outpatient surgery. The patient demands to be asleep before going to the operating room and does not want to remember anything.

**What are the goals of administering preoperative medication?**

Anxiety is a normal response to impending surgery. Diminishing anxiety is usually the main purpose for administering premedication. For many patients, the preoperative interview with the anesthesiologist allays fears more effectively than sedative drugs. Preoperative medication may also provide relief of preoperative pain or perioperative amnesia.

There may also be specific medical indications for certain preoperative medications: prophylaxis against postoperative nausea and vomiting (5-HT$_3$s) and against aspiration pneumonia (eg, antacids), or decreasing upper airway secretions (eg, anticholinergics). The goals of preoperative medication depend on many factors, including the health and emotional status of the patient, the proposed surgical procedure, and the anesthetic plan. For this reason, the choice of anesthetic premedication must be individualized and must follow a thorough preoperative evaluation.

**Do all patients require preoperative medication?**

Customary levels of preoperative anxiety do not harm most patients; therefore, preoperative sedation is not a requirement for all patients. Some patients dread intramuscular injections, and others find altered states of consciousness more unpleasant than anxiety. If the surgical procedure is brief, the effects of some sedatives may extend into the postoperative period and prolong recovery time. This is particularly troublesome for patients undergoing ambulatory surgery. Specific contraindications for sedative premedication include severe lung disease, hypovolemia, impending airway obstruction, increased intracranial pressure, and depressed baseline mental status. Premedication with sedative drugs should never be given before informed consent has been obtained.

**Which patients are most likely to benefit from preoperative medication?**

Some patients are quite anxious despite the preoperative interview. Separation of young children from their parents is often a traumatic ordeal for all concerned, particularly if children have undergone multiple prior surgeries. Medical conditions such as coronary artery disease or
hypertension may be aggravated by psychological stress.

**How does preoperative medication influence the induction of general anesthesia?**

Some medications often given preoperatively (eg, opioids) decrease anesthetic requirements and can contribute to a smooth induction. However, intravenous administration of these medications just prior to induction is a more reliable method of achieving the same benefits.

**What governs the choice among the preoperative medications commonly administered?**

After the goals of premedication have been determined, the clinical effects of the agents dictate choice. For instance, in a patient experiencing preoperative pain from a femoral fracture, the analgesic effects of an opioid (eg, fentanyl, morphine, hydromorphone) will decrease the discomfort associated with transportation to the operating room and positioning on the operating room table. On the other hand, respiratory depression, orthostatic hypotension, and nausea and vomiting may result from opioid premedication.

Benzodiazepines relieve anxiety, often provide amnesia, and are relatively free of side effects; however, they are not analgesics. Diazepam and lorazepam are often administered orally. Intramuscular midazolam has a rapid onset and short duration but intravenous midazolam has an even better pharmacokinetic profile.

**Which factors must be considered in selecting the anesthetic premedication for this patient?**

First, it must be made clear to the patient that in most centers, lack of necessary equipment and concern for patient safety preclude anesthesia being induced in the preoperative holding room. Long-acting agents such as morphine or lorazepam are poor choices for an outpatient procedure. Diazepam can also affect mental function for several hours. One common approach is to establish an intravenous line in the preoperative holding area and titrate small doses of midazolam using slurred speech as an end point. At that time, the patient can be taken to the operating room. Vital signs—particularly respiratory rate—must be monitored.
SUGGESTED READINGS

The accumulation of morphine metabolites (morphine 3-glucuronide and morphine 6-glucuronide) in patients with kidney failure has been associated with narcosis and ventilatory depression.

Rapid administration of larger doses of opioids (particularly fentanyl, sufentanil, remifentanil, and alfentanil) can induce chest wall rigidity severe enough to make ventilation with bag and mask nearly impossible.

Prolonged dosing of opioids can produce “opioid-induced hyperalgesia,” in which patients become more sensitive to painful stimuli. Infusion of large doses of (in particular) remifentanil during general anesthesia can produce acute tolerance, in which much larger than usual doses of opioids are required for postoperative analgesia.

The neuroendocrine stress response to surgery is measured in terms of the secretion of specific hormones, including catecholamines, antidiuretic hormone, and cortisol. Large doses of opioids inhibit the release of these hormones in response to surgery more completely than volatile anesthetics.

Aspirin is unique in that it irreversibly inhibits COX-1 by acetylating a serine residue in the enzyme. The irreversible nature of its inhibition underlies the nearly 1-week persistence of its clinical effects (eg, inhibition of platelet aggregation to normal) after drug discontinuation.

Regardless of how expertly surgical and anesthetic procedures are performed, appropriate use of analgesic drugs such as local anesthetics, opioids, ketamine, gabapentinoids, acetaminophen, and cyclooxygenase (COX) inhibitors can make the difference between a satisfied and an unsatisfied postoperative patient.
Moreover, studies have shown that outcomes can be improved when analgesia is provided in a “multimodal” format (typically minimizing opioid use) as one part of a well-organized plan for enhanced recovery after surgery (ERAS; see Chapter 48).

**OPIOIDS**

**Mechanisms of Action**

Opioids bind to specific receptors located throughout the central nervous system and other tissues. Four major opioid receptor types have been identified (Table 10–1): mu (µ, with subtypes µ₁ and µ₂), kappa (κ), delta (δ), and sigma (σ). All opioid receptors couple to G proteins; binding of an agonist to an opioid receptor causes membrane hyperpolarization. Acute opioid effects are mediated by inhibition of adenylyl cyclase (reductions in intracellular cyclic adenosine monophosphate concentrations) and activation of phospholipase C. Opioids inhibit voltage-gated calcium channels and activate inwardly rectifying potassium channels. Opioid effects vary based on the duration of exposure, and opioid tolerance leads to changes in opioid responses.

**TABLE 10–1 Classification of opioid receptors.**

---

1
Although opioids provide some degree of sedation and in some species can produce general anesthesia when given in large doses, they are principally used to provide analgesia. The clinical actions of opioids depend on which receptor is bound (and in the case of spinal and epidural administration of opioids, the location in the neuraxis where the receptor is located) and the binding affinity of the drug. Agonist–antagonists (eg, nalbuphine, nalorphine, butorphanol, and buprenorphine) have less efficacy than full agonists (eg, fentanyl or morphine), and under some circumstances agonist–antagonists will antagonize the actions of full agonists. Pure opioid antagonists (eg, naloxone or naltrexone) are discussed in Chapter 17. Opioid compounds mimic endorphins, enkephalins, and dynorphins, endogenous peptides that bind to opioid receptors.

Opioid receptor activation inhibits the presynaptic release and postsynaptic response to excitatory neurotransmitters (eg, acetylcholine, substance P) released by nociceptive neurons. Transmission of pain impulses can be selectively modified at the level of the dorsal horn of the spinal cord with

²Endogenous opioid.
intrathecal or epidural administration of opioids. Opioid receptors also respond to systemically administered opioids. Modulation through a descending inhibitory pathway from the periaqueductal gray matter to the dorsal horn of the spinal cord may also play a role in opioid analgesia. Although opioids exert their greatest effect within the central nervous system, opioid receptors have also been identified on somatic and sympathetic peripheral nerves. Certain opioid side effects (eg, constipation) are the result of opioid binding to receptors in peripheral tissues (eg, the gastrointestinal tract), and there are now selective antagonists for opioid actions outside the central nervous system (alvimopan and methylnaltrexone). The clinical importance of opioid receptors on primary sensory nerves (if present) remains speculative, despite the persisting practice of compounding of opioids in local anesthetic solutions applied to peripheral nerves.

**Structure–Activity Relationships**

A chemically diverse group of compounds bind opioid receptors. These agents have common structural characteristics, which are shown in Figure 10–1. Small molecular changes convert an agonist into an antagonist. The levorotatory opioid isomers are generally more potent than the dextrorotatory isomers.
FIGURE 10–1 Opioid agonists and antagonists share part of their chemical structure, which is outlined in cyan.

**Pharmacokinetics**

**A. Absorption**

Rapid and complete absorption follows intramuscular or subcutaneous injection
of hydromorphone, morphine, or meperidine, with peak plasma levels usually reached after 20–60 min. A wide variety of opioids are effective by oral administration, including oxycodone, hydrocodone, codeine, tramadol, morphine, hydromorphone, and methadone. Oral transmucosal fentanyl citrate absorption (fentanyl “lollipop”) provides rapid onset of analgesia and sedation in patients who are not good candidates for oral, intravenous, or intramuscular dosing of opioids.

The low molecular weight and high lipid solubility of fentanyl also favor transdermal absorption (the transdermal fentanyl “patch”). The amount of fentanyl absorbed per unit of time depends on the surface area of skin covered by the patch and also on local skin conditions (eg, blood flow). The time required to establish a reservoir of drug in the upper dermis delays by several hours the achievement of effective blood concentrations. Serum concentrations of fentanyl reach a plateau by 14 to 24 h of application (with greater delays in elderly than in younger patients) and remain constant for up to 72 h. Continued absorption from the dermal reservoir accounts for persisting fentanyl serum levels many hours after patch removal. Fentanyl patches are most often used for outpatient management of chronic pain and should be reserved for patients who require continuous opioid dosing but cannot use the much less expensive, but equally efficacious and long-acting oral agents.

Fentanyl is often administered in small doses (10–25 mcg) intrathecally with local anesthetics for spinal anesthesia, and adds to the analgesia when included with local anesthetics in epidural infusions. Morphine in doses between 0.1 and 0.5 mg and hydromorphone in doses between 0.05 and 0.2 mg provide 12 to 18 h of analgesia after intrathecal administration. Morphine and hydromorphone are commonly included in local anesthetic solutions infused for postoperative epidural analgesia.

B. Distribution

Table 10–2 summarizes the physical characteristics that determine distribution and tissue binding of opioid analgesics. After intravenous administration, the distribution half-lives of the opioids are short (5–20 min). The low lipid solubility of morphine delays its passage across the blood–brain barrier, however, so that its onset of action is slow and its duration of action is prolonged. This contrasts with the increased lipid solubility of fentanyl and sufentanil, which are associated with a faster onset and shorter duration of action when administered in small doses. Interestingly, alfentanil has a more rapid onset of action and shorter duration of action than fentanyl following a bolus
injection, even though it is less lipid soluble than fentanyl. The high nonionized fraction of alfentanil at physiological pH and its small volume of distribution ($V_d$) increase the amount of drug (as a percentage of the administered dose) available for binding in the brain.

Significant amounts of lipid-soluble opioids can be retained by the lungs (first-pass uptake); as systemic concentrations fall they will return to the bloodstream. The amount of pulmonary uptake is reduced by prior accumulation of other drugs, increased by a history of tobacco use, and decreased by concurrent inhalation anesthetic administration. Unbinding of opioid receptors and redistribution (of drug from effect sites) terminate the clinical effects of all opioids. After smaller doses of the lipid-soluble drugs (eg, fentanyl or sufentanil), redistribution alone is paramount for reducing blood concentrations, whereas after larger doses biotransformation becomes an important driver in reducing plasma levels below those that have clinical effects. Thus, the time required for fentanyl or sufentanil concentrations to decrease by half (the “half-time”) is context sensitive; in other words, the context-sensitive half-time increases as the total dose of drug or duration of exposure, or both, increase (see Chapter 7).

**C. Biotransformation**

With the exception of remifentanil, all opioids depend primarily on the liver for
biotransformation and are metabolized by the cytochrome P (CYP) system, are conjugated in the liver, or both. Because of the high hepatic extraction ratio of opioids, their clearance depends on liver blood flow. Morphine and hydromorphone undergo conjugation with glucuronic acid to form, in the former case, morphine 3-glucuronide and morphine 6-glucuronide, and in the latter case, hydromorphone 3-glucuronide. Meperidine is N-demethylated to normeperidine, an active metabolite associated with seizure activity, particularly with very large meperidine doses. The end products of fentanyl, sufentanil, and alfentanil are inactive. Norfentanyl, the metabolite of fentanyl, can be measured in urine long after the native compound is no longer detectable in blood to determine chronic fentanyl ingestion. This has its greatest importance in diagnosing fentanyl abuse.

Codeine is a prodrug that becomes active after it is metabolized by CYP2D6 to morphine. Ultrarapid metabolizers of this drug (with genetic variants of CYP2D6) are subject to greater drug effects and side effects; slow metabolizers (including genetic variants and those exposed to inhibitors of CYP2D6 such as fluoxetine and bupropion) experience reduced efficacy of codeine. Tramadol similarly must be metabolized by CYP to O-desmethyltramadol to be active. Hydrocodone is metabolized by CYP2D6 to hydromorphone (a more potent compound) and by CYP3A4 to norhydrocodone (a less potent compound). Oxycodone is metabolized by CYP2D6 and other enzymes to series of active compounds that are less potent than the parent one.

The ester structure of remifentanil makes it susceptible to hydrolysis (in a manner similar to esmolol) by nonspecific esterases in red blood cells and tissue (see Figure 10–1), yielding a terminal elimination half-life of less than 10 min. Remifentanil biotransformation is rapid and the duration of a remifentanil infusion has little effect on wake-up time (Figure 10–2). The half-time of remifentanil remains approximately 3 min regardless of the dose or duration of infusion. In its lack of accumulation (and lack of context sensitivity) remifentanil differs from other currently available opioids. Hepatic dysfunction requires no adjustment in remifentanil dosing. Finally, patients with pseudocholinesterase deficiency have a normal response to remifentanil (as also appears true for esmolol).
In contrast to other opioids, the time necessary to achieve a 50% decrease in the plasma concentration of remifentanil (its **half-time**) is very short and is not influenced by the duration of the infusion (it is not **context sensitive**). (Reproduced with permission from Egan TD. The pharmacokinetics of the new short-acting opioid remifentanil [GI87084B] in healthy adult male volunteers. *Anesthesiology*. 1993 Nov;79(5):881–892.)

**D. Excretion**

The end products of morphine and meperidine biotransformation are eliminated by the kidneys, with less than 10% undergoing biliary excretion. Because 5% to 10% of morphine is excreted unchanged in the urine, kidney failure prolongs morphine duration of action. The accumulation of morphine metabolites (morphine 3-glucuronide and morphine 6-glucuronide) in patients with kidney failure has been associated with prolonged narcosis and ventilatory depression. In fact, morphine 6-glucuronide is a more potent and longer-lasting opioid agonist than morphine. As previously noted, normeperidine at increased concentrations may produce seizures; these are not reversed by naloxone. Renal dysfunction increases the likelihood of toxic effects from normeperidine accumulation. However, both morphine and meperidine have been used safely in patients with kidney failure. Metabolites of sufentanil are excreted in urine and bile. The main metabolite of remifentanil is several thousand times less potent than its parent compound and is unlikely to produce any clinical opioid effects. It is renally excreted.

**Effects on Organ Systems**
A. Cardiovascular

In general, opioids have minimal direct effects on the heart. Meperidine tends to increase heart rate (it is structurally similar to atropine and was originally synthesized as an atropine replacement), whereas larger doses of morphine, fentanyl, sufentanil, remifentanil, and alfentanil are associated with a vagus nerve–mediated bradycardia. With the exception of meperidine (and only then at very large doses), the opioids do not depress cardiac contractility provided they are administered alone (which is almost never the case in surgical anesthetic settings). Nonetheless, arterial blood pressure often falls as a result of opioid-induced bradycardia, venodilation, and decreased sympathetic reflexes. The inherent cardiac stability provided by opioids is greatly diminished in practice when other anesthetic drugs, including benzodiazepines, propofol, or volatile agents are added. For example, sufentanil and fentanyl can be associated with reduced cardiac output when administered in combination with benzodiazepines. Bolus doses of meperidine, hydromorphone, and morphine evoke varying amounts of histamine release that can lead to profound drops in systemic vascular resistance and arterial blood pressure. The potential hazards of histamine release can be minimized by infusing opioids slowly or by pretreatment with H_1 and H_2 antagonists. Histamine side effects can be treated by infusion of intravenous fluid and vasopressors.

Intraoperative hypertension during opioid-based intravenous or nitrous oxide–opioid anesthesia is common. Such hypertension is often attributed to inadequate anesthetic depth; thus it is conventionally treated by the addition of other anesthetic agents (benzodiazepines, propofol, or potent inhaled agents). When depth of anesthesia is adequate we recommend treating hypertension with antihypertensives rather than with additional anesthetics.

B. Respiratory

Opioids depress ventilation, particularly respiratory rate. Thus, respiratory rate and end-tidal CO_2 tension (in contrast to arterial oxygen saturation) provide simple metrics for the early detection of respiratory depression in patients receiving opioid analgesia. Opioids increase the partial pressure of carbon dioxide (Paco_2) and blunt the response to a CO_2 challenge, resulting in a shift of the CO_2 response curve downward and to the right (Figure 10–3). These effects result from opioid binding to neurons in the respiratory centers of the brainstem. The apneic threshold—the greatest Paco_2 at which a patient remains apneic—rises, and hypoxic drive is decreased. Morphine and meperidine can cause
histamine-induced bronchospasm in susceptible patients. **Rapid administration of larger doses of opioids (particularly fentanyl, sufentanil, remifentanil, and alfentanil) can induce chest wall rigidity severe enough to make ventilation with bag and mask nearly impossible.** This centrally mediated muscle contraction is effectively treated with neuromuscular blocking agents. This problem is rarely seen now that large-dose opioid anesthesia is no longer a mainstay of cardiovascular anesthesia practice. Opioids can blunt the bronchoconstrictive response to airway stimulation such as occurs during tracheal intubation.

**FIGURE 10–3** Opioids depress ventilation. This is graphically displayed by a shift of the CO$_2$ curve downward and to the right.

**C. Cerebral**
The effects of opioids on cerebral perfusion and intracranial pressure must be separated from any effects of opioids on Paco$_2$. In general, opioids reduce cerebral oxygen consumption, cerebral blood flow, cerebral blood volume, and intracranial pressure, but to a much lesser extent than propofol, benzodiazepines, or barbiturates, provided normocarbia is maintained by artificial ventilation. There are some reports of mild—but transient and almost certainly unimportant
increases in cerebral artery blood flow velocity and intracranial pressure following opioid boluses in patients with brain tumors or head trauma. If combined with hypotension, the resulting fall in cerebral perfusion pressure could be deleterious to patients with abnormal intracranial pressure–volume relationships. Nevertheless, the important clinical message is that any trivial opioid-induced increase in intracranial pressure would be much less important than the predictably large increases in intracranial pressure associated with intubation of an inadequately anesthetized patient (from whom opioids were withheld). Opioids usually have almost no effects on the electroencephalogram (EEG), although large doses are associated with slow δ-wave activity. There are case reports that large doses of fentanyl may rarely cause seizure-like activity; however, some of these apparent seizures have been retrospectively diagnosed as severe opioid-induced muscle rigidity. EEG activation and seizures have been associated with the meperidine metabolite normeperidine, as previously noted.

Stimulation of the medullary chemoreceptor trigger zone is responsible for opioid-induced nausea and vomiting. Curiously, nausea and vomiting are more common following smaller (analgesic) than very large (anesthetic) doses of opioids. Repeated dosing of opioids (eg, prolonged oral dosing) will reliably produce tolerance, a phenomenon in which progressively larger doses are required to produce the same response. This is not the same as physical dependence or addiction, which may also be associated with repeated opioid administration. Prolonged dosing of opioids can also produce “opioid-induced hyperalgesia,” in which patients become more sensitive to painful stimuli. Infusion of large doses of (in particular) remifentanil during general anesthesia can produce acute tolerance, in which much larger than usual doses of opioids will be required for immediate, postoperative analgesia. Relatively large doses of opioids are required to render patients unconscious (Table 10–3). However, even at very large doses opioids will not reliably produce amnesia. The use of opioids in epidural and intrathecal spaces has revolutionized acute and chronic pain management (see Chapters 47 and 48).

**TABLE 10–3** Uses and doses of common opioids.
Unique among the commonly used opioids, meperidine has minor local anesthetic qualities, particularly when administered into the subarachnoid space. Meperidine’s clinical use as a local anesthetic has been limited by its relatively low potency and propensity to cause typical opioid side effects (nausea, sedation, and pruritus) at the doses required to induce local anesthesia. **Intravenous meperidine (10–25 mg)** is more effective than morphine or fentanyl for decreasing shivering in the postanesthetic care unit and meperidine appears to be the best agent for this indication.

### D. Gastrointestinal

Opioids slow gastrointestinal motility by binding to opioid receptors in the gut and reducing peristalsis. Biliary colic may result from opioid-induced contraction of the sphincter of Oddi. Biliary spasm, which can mimic a common bile duct stone on cholangiography, is reversed with the opioid antagonist naloxone or glucagon. Patients receiving long-term opioid therapy (eg, for cancer pain) usually become tolerant to many of the side effects but rarely to constipation. This is the basis for the development of the peripheral opioid antagonists methylnaltrexone, alvimopan, naloxegol, and naldeedine, which promote gastrointestinal motility in patients with varying indications, such as treatment of opioid bowel syndrome, side effects from opioid treatment of noncancer pain, or reduction of ileus in those receiving intravenous opioids after abdominal surgery.

### E. Endocrine

The neuroendocrine stress response to surgery is measured in terms of the
secretion of specific hormones, including catecholamines, antidiuretic hormone, and cortisol. Large doses of fentanyl or sufentanil inhibit the release of these hormones in response to surgery more completely than volatile anesthetics. The actual clinical outcome benefit produced by attenuating the stress response with opioids, even in high-risk cardiac patients, remains speculative (and we suspect nonexistent), whereas the many drawbacks of excessive doses of opioids are readily apparent.

**Other Effects**

A. **Cancer Reoccurrence**

Retrospective studies have associated general anesthesia (including opioids) with an increased risk of cancer reoccurrence after surgery as compared to techniques that emphasize opioid-sparing regional anesthetic techniques for analgesia. Ongoing clinical trials will likely clarify whether general anesthesia, opioids, both, or neither influence outcomes after cancer surgery.

B. **Substance Abuse**

There is a well-publicized epidemic of opioid abuse in western democracies, particularly in the United States. Although it comprises less than 5% of the world’s population, the United States consumes 80% of the world’s prescription opioids (and nearly all of the world’s supply of hydrocodone)! Large numbers of patients admit to using prescribed opioids in a recreational fashion, and drug overdosage (most often from prescribed drugs) is the leading cause of accidental death in the United States. Many opioid addicts can trace their addiction to opioids prescribed by a physician for acute or chronic pain. There are many causes of this terrible problem, including excessive and misleading marketing of opioids to physicians, unwise prescribing practices by physicians, inappropriate and misleading assertions by “thought leaders” (many with ties to the pharmaceutical industry) regarding opioids, and well-intended but poorly thought out recommendations for assessment and treatment of pain by certifying agencies. In response the U.S. Centers for Disease Control and Prevention and many other agencies have released guidelines for responsible prescribing of opioids.

**Drug Interactions**

The combination of meperidine and monoamine oxidase inhibitors may result in
hemodynamic instability, hyperpyrexia, coma, respiratory arrest, or death. The cause of this catastrophic interaction is incompletely understood. (The failure to appreciate this drug interaction in the controversial Libby Zion case led to changes in work hour rules for house officers in the United States.)

Propofol, barbiturates, benzodiazepines, inhaled anesthetics, and other central nervous system depressants can have synergistic cardiovascular, respiratory, and sedative effects with opioids.

The clearance of alfentanil may be impaired and the elimination half-life prolonged following treatment with erythromycin.

**CYCLOOXYGENASE INHIBITORS**

**Mechanisms of Action**

Many over-the-counter nonsteroidal antiinflammatory agents (NSAIDs) work through inhibition of cyclooxygenase (COX), the key step in prostaglandin synthesis. COX catalyzes the production of prostaglandin H₁ from arachidonic acid. The two forms of the enzyme, COX-1 and COX-2, have differing distribution in tissue. COX-1 receptors are widely distributed throughout the body, including the gut and platelets. COX-2 is produced in response to inflammation.

COX-1 and COX-2 enzymes differ further in the size of their binding sites: the COX-2 site can accommodate larger molecules that are restricted from binding at the COX-1 site. This distinction is in part responsible for selective COX-2 inhibition. Agents that inhibit COX nonselectively (eg, aspirin) will control fever, inflammation, pain, and thrombosis. COX-2 selective agents (eg, celecoxib, etoricoxib) can be used perioperatively without concerns about platelet inhibition or gastrointestinal upset. Curiously, while COX-1 inhibition decreases thrombosis, selective COX-2 inhibition increases the risk of heart attack, thrombosis, and stroke. Acetaminophen inhibits COX in the brain without binding to the active site of the enzyme (as is true for NSAIDs) to produce its antipyretic activities. Acetaminophen analgesia may result from modulation of the endogenous cannabinoid vanilloid receptor systems in the brain, but the actual mechanism of action remains speculative. Acetaminophen has no major effects on COX outside the brain.

Aspirin, the first of the NSAIDs, formerly was used as an antipyretic and analgesic. Now it is used almost exclusively for prevention of thrombosis in susceptible individuals or for acute myocardial infarction. Aspirin is unique in
that it irreversibly inhibits COX-1 by acetylating a serine residue in the enzyme, resulting in a nearly 1-week persistence of its clinical effects (eg, inhibition of platelet aggregation) after drug discontinuation.

COX inhibitors are most often administered orally. Acetaminophen, ibuprofen, diclofenac, and ketorolac are available for intravenous administration. Unfortunately, intravenous acetaminophen has an acquisition cost several orders of magnitude greater than oral acetaminophen; therefore its use is tightly restricted in many medical centers.

“Multimodal” analgesia typically includes the use of acetaminophen, COX inhibitors, possibly a gabapentinoid, regional or local anesthesia techniques, and other approaches aimed at improving the analgesia while reducing the requirement for opioids in postoperative patients. Multimodal analgesia protocols are best used as part of an enhanced recovery after surgery (ERAS) protocol, a topic that is extensively considered in Chapter 48.

Structure–Activity Relationships

The COX enzyme is inhibited by an unusually diverse group of compounds that can be grouped into salicylic acids (eg, aspirin), acetic acid derivatives (eg, ketorolac), propionic acid derivatives (eg, ibuprofen), heterocyclics (eg, celecoxib), and others. Thus, a conventional discussion of structure to potency (and other factors) is not useful for these chemicals, other than to note that the heterocyclics tend to be the compounds with the greatest selectivity for the COX-2 rather than COX-1 form of the enzyme.

Pharmacokinetics

A. Absorption

COX inhibitors when taken orally will typically achieve their peak blood concentrations in less than 3 h. Some COX inhibitors are formulated for topical application (eg, as a gel to be applied over joints or as liquid drops to be instilled on the eye). Ketorolac has been widely used as part of a local anesthetic “cocktail” to be injected around the surgical site and joint after arthroplasty.

B. Distribution

In blood, COX inhibitors are highly bound by plasma proteins, chiefly albumin. Their lipid solubility allows them to readily permeate the blood–brain barrier to produce a central analgesia and antipyresis, and to penetrate joint spaces to
produce (with the exception of acetaminophen) an antiinflammatory effect.

C. Biotransformation
Most COX inhibitors undergo hepatic biotransformation. Acetaminophen at increased doses yields sufficiently large concentrations of N-acetyl-p-benzoquinone imine to produce hepatic failure.

D. Excretion
Nearly all COX inhibitors are excreted in urine after biotransformation.

Effects on Organ Systems

A. Cardiovascular
COX inhibitors do not act directly on the cardiovascular system. Any cardiovascular effects result from the actions of these agents on coagulation. Prostaglandins maintain the patency of the ductus arteriosus; thus COX inhibitors have been administered to neonates to promote closure of a persistently patent ductus arteriosus and prostaglandins have been infused to maintain patency of the ductus in neonates awaiting surgery for ductal-dependent congenital cardiac lesions.

B. Respiratory
At appropriate clinical doses, none of the COX inhibitors have effects on respiration or lung function. Aspirin overdosage has very complex effects on acid–base balance and respiration.

C. Gastrointestinal
The classic complication of COX-1 inhibition is gastrointestinal upset. In its most extreme form this can cause upper gastrointestinal bleeding. Both complications result from direct actions of the drug, in the former case, on protective effects of prostaglandins in the mucosa, and in the latter case, on the combination of mucosal effects and inhibition of platelet aggregation.

Acetaminophen toxicity is a common cause of fulminant hepatic failure and need for hepatic transplantation in western societies; it has replaced viral hepatitis as the most common cause of acute hepatic failure.

D. Renal
There is good evidence that NSAIDs, especially selective COX-2 inhibitors, adversely affect renal function in certain patients. Therefore, NSAIDs are generally avoided in patients with reduced creatinine clearance and in others who are dependent upon renal prostaglandin release for vasodilation to avoid hemodynamically mediated acute kidney injury (eg, patients with hypovolemia, heart failure, cirrhosis, diabetic nephropathy, or hypercalcemia).

**GABAPENTIN & PREGABALIN**

Gabapentin was introduced as an antiepileptic agent but was serendipitously discovered to have analgesic properties. It found its earliest applications in the treatment of chronic neuropathic pain and is now licensed for postherpetic neuralgia. It and the closely related compound pregabalin are also widely prescribed for diabetic neuropathy. These agents form part of many multimodal postoperative pain protocols, particularly after total joint arthroplasty. There is no evidence that one agent is predictably more efficacious than the other. Although these agents have been shown to bind to voltage-gated calcium channels and N-methyl-d-aspartate (NMDA) receptors, their exact mechanism of action remains speculative. Despite the structural similarities these agents have to γ-aminobutyric acid (GABA) their clinical effects do not appear to arise from binding to GABA receptors.

When used for treatment of chronic pain these agents are generally started at relatively small doses and increased incrementally until side effects of dizziness or sedation appear. An adequate trial of gabapentin can require as much a month to achieve the optimal dosage. Determining the optimal dosage of the more potent pregabalin generally requires less time. When used as part of a multimodal postoperative pain protocol these agents are generally prescribed in a standard dose that is maintained for the several days during which the protocol runs its course.

# Neuromuscular Blocking Agents

## KEY CONCEPTS

1. It is important to realize that muscle relaxation does not ensure unconsciousness, amnesia, or analgesia.
2. Depolarizing muscle relaxants act as acetylcholine (ACh) receptor agonists, whereas nondepolarizing muscle relaxants function as competitive antagonists.
3. Because depolarizing muscle relaxants are not metabolized by acetylcholinesterase, they diffuse away from the neuromuscular junction and are hydrolyzed in the plasma and liver by another enzyme, pseudocholinesterase (nonspecific cholinesterase, plasma cholinesterase, or butyrylcholinesterase).
4. Muscle relaxants owe their paralytic properties to mimicry of ACh. For example, succinylcholine consists of two joined ACh molecules.
5. In contrast to patients with low enzyme levels or heterozygous atypical enzyme in whom blockade duration is doubled or tripled, patients with homozygous atypical enzyme will have a very long blockade (eg, 4–8 h) following succinylcholine administration.
6. Succinylcholine is considered relatively contraindicated in the routine management of children and adolescents because of the risk of hyperkalemia, rhabdomyolysis, and cardiac arrest in children with undiagnosed myopathies.
7. Normal muscle releases enough potassium during succinylcholine-induced depolarization to raise serum potassium by 0.5 mEq/L. Although this is usually insignificant in patients with normal baseline potassium levels, a life-threatening potassium elevation is possible in patients with burn injury, massive trauma, neurological disorders, and several other conditions.
8. Pancuronium and vecuronium are partially excreted by the kidneys, and
their action is prolonged in patients with kidney failure.

Cirrhotic liver disease and chronic kidney failure often result in an increased volume of distribution and a lower plasma concentration for a given dose of water-soluble drugs, such as muscle relaxants. On the other hand, drugs dependent on hepatic or renal excretion may demonstrate prolonged clearance. Thus, depending on the drug, a greater initial dose—but smaller maintenance doses—might be required in these diseases.

Atracurium and cisatracurium undergo degradation in plasma at physiological pH and temperature by organ-independent Hofmann elimination. The resulting metabolites (a monoquaternary acrylate and laudanosine) have no intrinsic neuromuscular blocking effects.

Hypertension and tachycardia may occur in patients given pancuronium. These cardiovascular effects are caused by the combination of vagal blockade and catecholamine release from adrenergic nerve endings.

After long-term administration of vecuronium to patients in intensive care units, prolonged neuromuscular blockade (up to several days), may be present after drug discontinuation, possibly from accumulation of its active 3-hydroxy metabolite, changing drug clearance, or the development of a polyneuropathy.

Rocuronium (0.9–1.2 mg/kg) has an onset of action that approaches succinylcholine (60–90 s), making it a suitable alternative for rapid-sequence inductions, but at the cost of a much longer duration of action. The new reversal agent, sugammadex, permits rapid reversal of rocuronium-induced neuromuscular blockade.

Skeletal muscle relaxation can be produced by deep inhalational anesthesia, regional nerve block, or neuromuscular blocking agents (commonly called muscle relaxants). In 1942, Harold Griffith published the results of a study using an extract of curare (a South American arrow poison) during anesthesia. Following the introduction of succinylcholine as a “new approach to muscular relaxation,” these agents rapidly became a routine part of the anesthesiologist’s drug arsenal. However, as noted by Beecher and Todd in 1954: “[m]uscle relaxants given inappropriately may provide the surgeon with optimal [operating] conditions in … a patient [who] is paralyzed but not anesthetized—a state [that] is wholly unacceptable for the patient.” In other words, muscle
Neuromuscular Transmission

Association between a motor neuron and a muscle cell occurs at the neuromuscular junction (Figure 11–1). The cell membranes of the neuron and muscle fiber are separated by a narrow (20-nm) gap, the synaptic cleft. As a nerve’s action potential depolarizes its terminal, an influx of calcium ions through voltage-gated calcium channels into the nerve cytoplasm allows storage vesicles to fuse with the terminal plasma membrane and release their contents (acetylcholine [ACh]). The ACh molecules diffuse across the synaptic cleft to bind with nicotinic cholinergic receptors on a specialized portion of the muscle membrane, the motor end-plate. Each neuromuscular junction contains approximately 5 million of these receptors, but activation of only about 500,000 receptors is required for normal muscle contraction.

**FIGURE 11–1** The neuromuscular junction. V, transmitter vesicle; M, mitochondrion; ACh, acetylcholine; AChE, acetylcholinesterase; JF, junctional folds. (Reproduced with permission from Drachman DB. Myasthenia gravis (1st of 2 parts). *N Engl J Med*. 1975;293:400–404.)
The structure of ACh receptors varies in different tissues and at different times in development. Each ACh receptor in the neuromuscular junction normally consists of five protein subunits: two α subunits, and single β, δ, and ε subunits. Only the two identical α subunits are capable of binding ACh molecules. If both binding sites are occupied by ACh, a conformational change in the subunits briefly (1 ms) opens an ion channel in the core of the receptor (Figure 11–2). The channel will not open if ACh binds to only one site. In contrast to the normal (or mature) junctional ACh receptor, another isoform contains a γ subunit instead of the ε subunit. This isoform is referred to as the fetal or immature receptor because it is in the form initially expressed in fetal muscle. It is also often referred to as extrajunctional because, unlike the mature isoform, it may be located anywhere in the muscle membrane, inside or outside the neuromuscular junction when expressed in adults.
FIGURE 11–2  A: Structure of the ACh receptor. Note the two α subunits that actually bind ACh and the center channel. B: Binding of ACh to receptors on muscle end-plate causes channel opening and ion flux.

Cations flow through the open ACh receptor channel (sodium and calcium in; potassium out), generating an **end-plate potential**. The contents of a single vesicle, a quantum of ACh ($10^4$ molecules per quantum), produce a miniature end-plate potential. The number of quanta released by each depolarized nerve fiber, normally at least 200, is very sensitive to extracellular ionized calcium concentration; increasing calcium concentration increases the number of quanta
released. When sufficient receptors are occupied by ACh, the end-plate potential will be strong enough to depolarize the perijunctional membrane. Voltage-gated sodium channels within this portion of the muscle membrane open when a threshold voltage is developed across them, as is true for voltage-gated sodium channels in nerve or heart (Figure 11–3). Perijunctional areas of muscle membrane have a higher density of these sodium channels than other parts of the membrane. The resulting action potential propagates along the muscle membrane and T-tubule system, opening sodium channels and releasing calcium from the sarcoplasmic reticulum. This intracellular calcium allows the contractile proteins actin and myosin to interact, bringing about muscle contraction. The amount of ACh released and the number of receptors subsequently activated with efferent nerve depolarization will normally far exceed the minimum required for the initiation of an action potential in the muscle. The nearly tenfold margin of safety is reduced in Eaton–Lambert myasthenic syndrome (decreased release of ACh) and myasthenia gravis (decreased number of receptors).

**FIGURE 11–3** Schematic of the sodium channel. The sodium channel is a
transmembrane protein that can be conceptualized as having two gates. Sodium ions pass only when both gates are open. Opening of the gates is time dependent and voltage dependent. The channel therefore possesses three functional states. At rest, the lower gate is open but the upper gate is closed (A). When the muscle membrane reaches threshold voltage depolarization, the upper gate opens and sodium can pass (B). Shortly after the upper gate opens the time-dependent lower gate closes (C). When the membrane repolarizes to its resting voltage, the upper gate closes and the lower gate opens (A).

ACh is rapidly hydrolyzed into acetate and choline by the substrate-specific enzyme acetylcholinesterase. This enzyme is embedded into the motor end-plate membrane immediately adjacent to the ACh receptors. After unbinding ACh, the receptors’ ion channels close, permitting the end-plate to repolarize. Calcium is resequestered in the sarcoplasmic reticulum, and the muscle cell relaxes.

---

**Distinctions Between Depolarizing & Nondepolarizing Blockade**

Neuromuscular blocking agents are divided into two classes: depolarizing and nondepolarizing (Table 11–1). This division reflects distinct differences in the mechanism of action, response to peripheral nerve stimulation, and reversal of block.

**TABLE 11–1 Depolarizing and nondepolarizing muscle relaxants.**

¹Not yet commercially available in the United States.
MECHANISM OF ACTION

Similar to ACh, all neuromuscular blocking agents are quaternary ammonium compounds whose positively charged nitrogen imparts an affinity for nicotinic ACh receptors. Whereas most agents have two quaternary ammonium atoms, a few have one quaternary ammonium cation and one tertiary amine that is protonated at physiological pH.

Depolarizing muscle relaxants very closely resemble ACh and readily bind to ACh receptors, generating a muscle action potential. Unlike ACh, however, these drugs are not metabolized by acetylcholinesterase, and their concentration in the synaptic cleft does not fall as rapidly, resulting in a prolonged depolarization of the muscle end-plate.

Continuous end-plate depolarization causes muscle relaxation because opening of perijunctional sodium channels is time limited (sodium channels rapidly “inactivate” with continuing depolarization; Figure 11–3). After the initial excitation and opening (Figure 11–3B), these sodium channels inactivate (Figure 11–3C) and cannot reopen until the end-plate repolarizes. The end-plate cannot repolarize as long as the depolarizing muscle relaxant continues to bind to ACh receptors; this is called a phase I block. More prolonged end-plate depolarization can cause poorly understood changes in the ACh receptor that result in a phase II block, which clinically resembles that of nondepolarizing muscle relaxants.

Nondepolarizing muscle relaxants bind ACh receptors but are incapable of inducing the conformational change necessary for ion channel opening. Because ACh is prevented from binding to its receptors, no end-plate potential develops. Neuromuscular blockade occurs even if only one α subunit is blocked. Thus, depolarizing muscle relaxants act as ACh receptor agonists, whereas nondepolarizing muscle relaxants function as competitive antagonists. This basic difference in mechanism of action explains their varying effects in certain disease states. For example, conditions associated with a chronic decrease in ACh release (eg, muscle denervation injuries) stimulate a compensatory increase in the number of ACh receptors within muscle membranes. These states also promote the expression of the immature (extrajunctional) isoform of the ACh receptor, which displays low channel conductance properties and prolonged open-channel time. This upregulation causes an exaggerated response to depolarizing muscle relaxants (with more receptors being depolarized), but a resistance to nondepolarizing relaxants (more receptors that must be blocked). In contrast, conditions associated with fewer ACh receptors (eg, downregulation in myasthenia gravis) demonstrate a resistance to depolarizing relaxants and an
increased sensitivity to nondepolarizing relaxants.

OTHER MECHANISMS OF NEUROMUSCULAR BLOCKADE

Some drugs may interfere with the function of the ACh receptor without acting as an agonist or antagonist. They interfere with normal functioning of the ACh receptor binding site or with the opening and closing of the receptor channel. These may include inhaled anesthetic agents, local anesthetics, and ketamine. The ACh receptor–lipid membrane interface may be an important site of action.

Drugs may also cause either closed or open channel blockade. During closed channel blockade, the drug physically plugs up the channel, preventing passage of cations whether or not ACh has activated the receptor. Open channel blockade is “use dependent,” because the drug enters and obstructs the ACh receptor channel only after it is opened by ACh binding. The clinical relevance of open channel blockade is unknown. Based on laboratory experiments, one would expect that increasing the concentration of ACh with a cholinesterase inhibitor would not overcome this form of neuromuscular blockade. Drugs that may cause channel block under laboratory conditions include neostigmine, some antibiotics, cocaine and other local anesthetics, and quinidine. Other drugs may impair the presynaptic release of ACh. Prejunctional receptors play a role in mobilizing ACh to maintain muscle contraction. Blocking these receptors can lead to a fading of the train-of-four response.

REVERSAL OF NEUROMUSCULAR BLOCKADE

Because succinylcholine is not metabolized by acetylcholinesterase, it unbinds the receptor and diffuses away from the neuromuscular junction to be hydrolyzed in the plasma and liver by another enzyme, pseudocholinesterase (nonspecific cholinesterase, plasma cholinesterase, or butyrylcholinesterase). Fortunately, this normally is a fairly rapid process, because no specific agent to reverse a depolarizing blockade is available.

With the exception of mivacurium, nondepolarizing agents are not metabolized by either acetylcholinesterase or pseudocholinesterase. Reversal of their blockade depends on unbinding the receptor, redistribution, metabolism, and excretion of the relaxant by the body, or administration of specific reversal agents (eg, cholinesterase inhibitors) that inhibit acetylcholinesterase enzyme activity. Because this inhibition increases the amount of ACh that is available at
the neuromuscular junction and can compete with the nondepolarizing agent, the reversal agents clearly are of no benefit in reversing a phase I depolarizing block. In fact, by increasing neuromuscular junction ACh concentration and inhibiting pseudocholinesterase-induced metabolism of succinylcholine, *cholinesterase inhibitors can prolong neuromuscular blockade produced by succinylcholine*. The only time neostigmine reverses neuromuscular block after succinylcholine is when there is a phase II block (fade of the train-of-four) and sufficient time has passed for the circulating concentration of succinylcholine to be negligible.

Sugammadex, a cyclodextrin, is the first selective relaxant-binding agent; it exerts its reversal effect by forming tight complexes in a 1:1 ratio with steroidal nondepolarizing agents (vecuronium, rocuronium). Investigational neuromuscular blocking agents, such as gantacurium, show promise as ultrashort-acting nondepolarizing agents.

**RESPONSE TO PERIPHERAL NERVE STIMULATION**

The use of peripheral nerve stimulators to monitor neuromuscular function is discussed in Chapter 6. Four patterns of electrical stimulation with supramaximal square-wave pulses are considered:

- **Tetany**—a sustained stimulus of 50 to 100 Hz, usually lasting 5 s
- **Single twitch**—a single pulse 0.2 ms in duration
- **Train-of-four**—a series of four twitches in 2 s (2-Hz frequency), each 0.2 ms long
- **Double-burst stimulation (DBS)**—three short (0.2 ms) high-frequency stimulations separated by a 20-ms interval (50 Hz) and followed 750 ms later by two (DBS_{3,2}) or three (DBS_{3,3}) additional impulses

The occurrence of fade, a gradual diminution of evoked response during prolonged or repeated nerve stimulation, is indicative of a nondepolarizing block (*Figure 11–4*), or of a phase II block if only succinylcholine has been administered. Fade may be due to a prejunctional effect of nondepolarizing relaxants that reduces the amount of ACh in the nerve terminal available for release during stimulation (blockade of ACh mobilization). Adequate clinical recovery correlates well with the absence of fade. Because fade is more obvious during sustained tetanic stimulation or double-burst stimulation than following a
train-of-four pattern or repeated twitches, the first two patterns are the preferred methods for determining adequacy of recovery from a nondepolarizing block.

**FIGURE 11–4** Evoked responses during depolarizing (phase I and phase II) and nondepolarizing block.

The ability of tetanic stimulation during a partial nondepolarizing block to increase the evoked response to a subsequent twitch is termed *posttetanic potentiation*. This phenomenon may relate to a transient increase in ACh mobilization following tetanic stimulation.

In contrast, a phase I depolarization block from succinylcholine does not exhibit fade during tetanus or train-of-four; neither does it demonstrate posttetanic potentiation. With prolonged exposure to succinylcholine, however, the quality of the block will sometimes change to resemble a nondepolarizing block (phase II block).

Newer quantitative methods of assessment of neuromuscular blockade, such as acceleromyography, permit determination of exact train-of-four ratios, as
opposed to subjective interpretations. Acceleromyography may reduce the incidence of unexpected postoperative residual neuromuscular blockade.

Depolarizing Muscle Relaxants

SUCCINYLCHOLINE

The only depolarizing muscle relaxant in clinical use today is succinylcholine.

Physical Structure

Succinylcholine—also called suxamethonium—consists of two joined ACh molecules (Figure 11–5). This structure underlies succinylcholine’s mechanism of action, side effects, and metabolism.

FIGURE 11–5 Chemical structures of neuromuscular blocking agents.
Metabolism & Excretion

Succinylcholine remains popular due to its rapid onset of action (30–60 s) and short duration of action (typically less than 10 min). Its rapid onset of action relative to other neuromuscular blockers is largely due to the relative overdose that is usually administered. Succinylcholine, like all neuromuscular blockers, has a small volume of distribution due to its very low lipid solubility, and this also underlies a rapid onset of action. As succinylcholine enters the circulation, most of it is rapidly metabolized by pseudocholinesterase into succinylmonocholine. This process is so efficient that only a small fraction of the injected dose ever reaches the neuromuscular junction. As drug levels fall in blood, succinylcholine molecules diffuse away from the neuromuscular junction, limiting the duration of action. However, this duration of action can be prolonged by high doses, infusion of succinylcholine, or abnormal metabolism. The latter may result from hypothermia, reduced pseudocholinesterase levels, or a genetically aberrant enzyme. Hypothermia decreases the rate of hydrolysis. Reduced levels of pseudocholinesterase accompany pregnancy, liver disease, kidney failure, and certain drug therapies (Table 11–2). Reduced pseudocholinesterase levels generally produce only modest prolongation of succinylcholine’s actions (2–20 min).

TABLE 11–2 Drugs known to decrease pseudocholinesterase activity.
Heterozygote patients with one normal and one abnormal (atypical) pseudocholinesterase gene may have slightly prolonged block (20–30 min) following succinylcholine administration. Far fewer (1 in 3000) patients have two copies of the most prevalent abnormal gene (homozygous atypical) that produce an enzyme with little or no affinity for succinylcholine. In contrast to the doubling or tripling of blockade duration seen in patients with low enzyme levels or heterozygous atypical enzyme, patients with homozygous atypical enzyme will have a very long blockade (eg, 4–8 h) following administration of succinylcholine. Of the recognized abnormal pseudocholinesterase genes, the dibucaine-resistant (variant) allele, which produces an enzyme with 1/100 of normal affinity for succinylcholine, is the most common. Other variants include fluoride-resistant and silent (no activity) alleles.

Dibucaine, a local anesthetic, inhibits normal pseudocholinesterase activity by 80% but inhibits atypical enzyme activity by only 20%. Serum from an individual who is heterozygous for the atypical enzyme is characterized by an intermediate 40% to 60% inhibition. The percentage of inhibition of pseudocholinesterase activity is termed the dibucaine number. A patient with normal pseudocholinesterase has a dibucaine number of 80; a homozygote for the most common abnormal allele will have a dibucaine number of 20. The dibucaine number measures pseudocholinesterase function, not the amount of

enzyme. Therefore, adequacy of pseudocholinesterase can be determined in the laboratory quantitatively in units per liter (a minor factor) and qualitatively by dibucaine number (the major factor). **Prolonged paralysis from succinylcholine caused by abnormal pseudocholinesterase (atypical cholinesterase) should be treated with continued mechanical ventilation and sedation until muscle function returns to normal by clinical signs.**

**Drug Interactions**

The effects of muscle relaxants can be modified by concurrent drug therapy (Table 11–3). Succinylcholine is involved in two interactions deserving special comment.

**A. Cholinesterase Inhibitors**

Although cholinesterase inhibitors reverse nondepolarizing paralysis, they markedly prolong a depolarizing phase I block by two mechanisms. By inhibiting acetylcholinesterase, they lead to a higher ACh concentration at the nerve terminal, which intensifies depolarization. They also reduce the hydrolysis of succinylcholine by inhibiting pseudocholinesterase. Organophosphate pesticides, for example, cause an irreversible inhibition of acetylcholinesterase and can prolong the action of succinylcholine by 20 to 30 min. Echotothiophate eye drops, used in the past for glaucoma, can markedly prolong succinylcholine
by this mechanism.

B. Nondepolarizing Relaxants
In general, small doses of nondepolarizing relaxants antagonize a depolarizing phase I block. Because the drugs occupy some ACh receptors, depolarization by succinylcholine is partially prevented. In the presence of a phase II block, a nondepolarizer will potentiate succinylcholine paralysis.

Dosage
Because of the rapid onset, short duration, and low cost of succinylcholine, some clinicians believe that it remains a good choice for routine intubation in adults. The usual adult dose of succinylcholine for intubation is 1 to 1.5 mg/kg intravenously. Doses as small as 0.5 mg/kg usually provide acceptable intubating conditions if a defasciculating dose of a nondepolarizing agent is not used. Repeated small boluses (5–10 mg) or a succinylcholine drip (1 g in 500 or 1000 mL, titrated to effect) can be used during surgical procedures that require brief but intense paralysis (eg, otolaryngological endoscopies). Neuromuscular function should be frequently monitored with a nerve stimulator to prevent overdosing and to watch for phase II block. The availability of intermediate-acting nondepolarizing muscle relaxants has reduced the popularity of succinylcholine infusions. In the past, succinylcholine infusions were a mainstay of ambulatory practice in the United States.

Because succinylcholine is not lipid soluble, it has a small volume of distribution. Per kilogram, infants and neonates have a larger extracellular space than adults. Therefore, on a per-kilogram basis, dosage requirements for pediatric patients are often greater than for adults. If succinylcholine is administered intramuscularly to children, a dose as high as 4 to 5 mg/kg does not always produce complete paralysis.

Succinylcholine should be stored under refrigeration (2–8°C), and should generally be used within 14 days after removal from refrigeration and exposure to room temperature.

Side Effects & Clinical Considerations
Succinylcholine is a relatively safe drug—assuming that its many potential complications are understood and avoided. Because of the risk of hyperkalemia, rhabdomyolysis, and cardiac arrest in children with undiagnosed
myopathies, succinylcholine is considered relatively contraindicated in the routine management of children. Some clinicians have also abandoned the routine use of succinylcholine for adults. Succinylcholine is still useful for rapid sequence induction and for short periods of intense paralysis because none of the presently available nondepolarizing muscle relaxants can match its very rapid onset and short duration.

A. Cardiovascular
Because of the resemblance of muscle relaxants to ACh, it is not surprising that they affect cholinergic receptors in addition to those at the neuromuscular junction. The entire parasympathetic nervous system and parts of the sympathetic nervous system (sympathetic ganglia, adrenal medulla, and sweat glands) depend on ACh as a neurotransmitter.

Succinylcholine not only stimulates nicotinic cholinergic receptors at the neuromuscular junction, it stimulates all ACh receptors. The cardiovascular actions of succinylcholine are therefore very complex. Stimulation of nicotinic receptors in parasympathetic and sympathetic ganglia, and muscarinic receptors in the sinoatrial node of the heart, can increase or decrease blood pressure and heart rate. Low doses of succinylcholine can produce negative chronotropic and inotropic effects, but higher doses usually increase heart rate and contractility and elevate circulating catecholamine levels. In most patients, the hemodynamic consequences are inconsequential in comparison to the effects of the induction agent and laryngoscopy.

Children are particularly susceptible to profound bradycardia following administration of succinylcholine. Bradycardia will sometimes occur in adults when a second bolus of succinylcholine is administered approximately 3 to 8 min after the first dose. The dogma (based on no real evidence) is that the succinylcholine metabolite, succinylmonocholine, sensitizes muscarinic cholinergic receptors in the sinoatrial node to the second dose of succinylcholine, resulting in bradycardia. Intravenous atropine (0.02 mg/kg in children, 0.4 mg in adults) is normally given prophylactically to children prior to the first and subsequent doses, and usually before a second dose of succinylcholine is given to adults. Other arrhythmias, such as nodal bradycardia and ventricular ectopy, have been reported.

B. Fasciculations
The onset of paralysis by succinylcholine is usually signaled by visible motor unit contractions called fasciculations. These can be prevented by pretreatment
with a small dose of nondepolarizing relaxant. Because this pretreatment usually antagonizes a depolarizing block, a larger dose of succinylcholine is required (1.5 mg/kg). Fasciculations are typically not observed in young children and elderly patients.

C. Hyperkalemia

Normal muscle releases enough potassium during succinylcholine-induced depolarization to increase serum potassium by 0.5 mEq/L. Although this is usually insignificant in patients with normal baseline potassium levels, it can be life-threatening in patients with preexisting hyperkalemia. The increase in potassium in patients with burn injury, massive trauma, neurological disorders, and several other conditions (Table 11–4) can be large and catastrophic. Hyperkalemic cardiac arrest can prove to be quite refractory to routine cardiopulmonary resuscitation, requiring calcium, insulin, glucose, bicarbonate, and even cardiopulmonary bypass to support the circulation while reducing serum potassium levels.

</table>
Following denervation injuries (spinal cord injuries, larger burns), the immature isoform of the ACh receptor may be expressed inside and outside the neuromuscular junction (upregulation). These extrajunctional receptors allow succinylcholine to effect widespread depolarization and extensive potassium release. Life-threatening potassium release is not reliably prevented by pretreatment with a nondepolarizer. The risk of hyperkalemia usually seems to peak in 7 to 10 days following the injury, but the exact time of onset and the duration of the risk period vary. The risk of hyperkalemia from succinylcholine is minimal in the first 2 days after spinal cord or burn injury.

D. Muscle Pains
Patients who have received succinylcholine have an increased incidence of postoperative myalgia. The efficacy of nondepolarizing pretreatment is controversial. Administration of rocuronium (0.06–0.1 mg/kg) prior to succinylcholine has been reported to be effective in preventing fasciculations and reducing postoperative myalgias. The relationship between fasciculations and postoperative myalgias is also inconsistent. The myalgias are theorized to be due to the initial unsynchronized contraction of muscle groups; myoglobinemia and increases in serum creatine kinase can be detected following administration of succinylcholine. Perioperative use of nonsteroidal antiinflammatory drugs and benzodiazepines may reduce the incidence and severity of myalgias.

E. Intragastric Pressure Elevation
Abdominal wall muscle fasciculations increase intragastric pressure, which is offset by an increase in lower esophageal sphincter tone. Therefore, despite being much discussed, there is no evidence that the risk of gastric reflux or pulmonary aspiration is increased by succinylcholine.

F. Intraocular Pressure Elevation
Extraocular muscle differs from other striated muscle in that it has multiple motor end-plates on each cell. Prolonged membrane depolarization and contraction of extraocular muscles following administration of succinylcholine transiently raise intraocular pressure and theoretically could compromise an injured eye. However, there is no evidence that succinylcholine leads to worsened outcome in patients with “open” eye injuries. The elevation in intraocular pressure is not always prevented by pretreatment with a nondepolarizing agent.
G. Masseter Muscle Rigidity
Succinylcholine transiently increases muscle tone in the masseter muscles. Some difficulty may initially be encountered in opening the mouth because of incomplete relaxation of the jaw. A marked increase in tone preventing laryngoscopy is abnormal and can be a premonitory sign of malignant hyperthermia.

H. Malignant Hyperthermia
Succinylcholine is a potent triggering agent in patients susceptible to malignant hyperthermia, a hypermetabolic disorder of skeletal muscle (see Chapter 52). Although some of the signs and symptoms of neuroleptic malignant syndrome (NMS) resemble those of malignant hyperthermia, the pathogenesis is completely different and there is no need to avoid use of succinylcholine in patients with NMS.

I. Generalized Contractions
Patients afflicted with myotonia may develop myoclonus after administration of succinylcholine.

J. Prolonged Paralysis
As previously discussed, patients with reduced levels of normal pseudocholinesterase may have a longer than normal duration of action, whereas patients with atypical pseudocholinesterase will experience markedly prolonged paralysis.

K. Intracranial Pressure
Succinylcholine may lead to an activation of the electroencephalogram and slight increases in cerebral blood flow and intracranial pressure in some patients. Muscle fasciculations stimulate muscle stretch receptors, which subsequently increase cerebral activity. The increase in intracranial pressure can be attenuated by maintaining good airway control and instituting hyperventilation. It can also be prevented by pretreating with a nondepolarizing muscle relaxant and administering intravenous lidocaine (1.5–2.0 mg/kg) 2 to 3 min prior to intubation. The effects of intubation on intracranial pressure far outweigh any increase caused by succinylcholine, and succinylcholine is not contraindicated for rapid sequence induction of patients with intracranial mass lesions or other causes of increased intracranial pressure.
L. Histamine Release
Slight histamine release may be observed following succinylcholine in some patients.

Nondepolarizing Muscle Relaxants

Unique Pharmacological Characteristics
In contrast to there being only a single depolarizing muscle relaxant, there is a wide selection of nondepolarizing muscle relaxants (Tables 11–5 and 11–6). Based on their chemical structure, they can be classified as benzylisoquinolinium, steroidal, or other compounds. It is often said that choice of a particular drug depends on its unique characteristics, which are often related to its structure; however, for most patients, the differences among the intermediate-acting neuromuscular blockers are inconsequential. Steroidal compounds can be vagolytic, most notably with pancuronium but inconsequentially with vecuronium or rocuronium. Benzylisoquinolines tend to release histamine. Because of structural similarities, an allergic history to one muscle relaxant strongly suggests the possibility of allergic reactions to other muscle relaxants, particularly those in the same chemical class.

A. Suitability for Intubation
None of the currently available nondepolarizing muscle relaxants equals succinylcholine’s rapid onset of action or short duration. However, the onset of nondepolarizing relaxants can be quickened by using either a larger dose or a
priming dose. The ED₉₅ of any drug is the effective dose of a drug in 95% of individuals. For neuromuscular blockers, one often specifies the dose that produces 95% twitch depression in 50% of individuals. One to two times the ED₉₅ or twice the dose that produces 95% twitch depression is usually used for intubation. Although a larger intubating dose speeds onset, it prolongs the duration of blockade. The availability of sugammadex has largely eliminated this concern in regard to the steroidal nondepolarizing muscle relaxant, rocuronium (see Chapter 12).

Muscle groups vary in their sensitivity to muscle relaxants. For example, the laryngeal muscles—whose relaxation is important during intubation—recover from blockade more quickly than the adductor pollicis, which is commonly monitored by the peripheral nerve stimulator.

B. Suitability for Preventing Fasciculations

To prevent fasciculations and myalgias, 10% to 15% of a nondepolarizer intubating dose can be administered 5 min before succinylcholine. Similarly, priming with a small dose of a nondepolarizing relaxant (10% of the total dose) a few minutes before intubation can speed the onset of acceptable intubating conditions when followed by the remaining 90% of the drug to be administered. Dysphagia, diplopia, and patient distress will occasionally develop following administration of a priming or defasciculating dose of nondepolarizing muscle relaxants.

C. Maintenance Relaxation

Following intubation, muscle paralysis may need to be maintained to facilitate surgery, (eg, abdominal operations), to permit a reduced depth of anesthesia, or to control ventilation. There is great variability among patients in response to muscle relaxants. Monitoring neuromuscular function with a nerve stimulator helps to prevent over- and underdosing and to reduce the likelihood of serious residual muscle paralysis in the recovery room. Maintenance doses, whether by intermittent boluses or continuous infusion (Table 11–6), should be guided by the nerve stimulator and clinical signs (eg, spontaneous respiratory efforts or movement). In some instances, clinical signs may precede twitch recovery because of differing sensitivities to muscle relaxants between muscle groups or technical problems with the nerve stimulator. Some return of neuromuscular transmission should be evident prior to administering each maintenance dose, if the patient needs to resume spontaneous ventilation at the end of the anesthetic. When an infusion is used for maintenance, the rate should be adjusted at or just
above the rate that allows some return of neuromuscular transmission so that drug effects can be monitored.

### D. Potentiation by Inhalational Anesthetics

Volatile agents decrease nondepolarizer dosage requirements by at least 15%. The actual degree of this postsynaptic augmentation depends on the inhalational anesthetic (desflurane > sevoflurane > isoflurane > halothane > N$_2$O/O$_2$/narcotic > total intravenous anesthesia).

### E. Potentiation by Other Nondepolarizers

Some combinations of different classes of nondepolarizers (eg, steroidal and benzylisoquinolinium) produce a greater than additive (synergistic) neuromuscular blockade.

### F. Autonomic Side Effects

In clinical doses, the nondepolarizers differ in their relative effects on nicotinic and muscarinic cholinergic receptors. Previously used agents (eg, tubocurarine) blocked autonomic ganglia, reducing the ability of the sympathetic nervous system to increase heart contractility and rate in response to hypotension and other intraoperative stresses. In contrast, pancuronium blocks vagal muscarinic receptors in the sinoatrial node, resulting in tachycardia. All newer nondepolarizing relaxants, including atracurium, cisatracurium, mivacurium, vecuronium, and rocuronium, are devoid of significant autonomic effects in their recommended dosage ranges.
G. Histamine Release
Histamine release from mast cells can result in bronchospasm, skin flushing, and hypotension from peripheral vasodilation. Atracurium and mivacurium are capable of triggering histamine release, particularly at higher doses. Slow injection rates and H₁ and H₂ antihistamine pretreatment ameliorate these side effects.

H. Hepatic Clearance
Only pancuronium, vecuronium, and rocuronium are metabolized to varying degrees by the liver. Active metabolites likely contribute to their clinical effect. Vecuronium and rocuronium depend heavily on biliary excretion. Clinically, liver failure prolongs blockade. Atracurium, cisatracurium, and mivacurium, although extensively metabolized, depend on extrahepatic mechanisms. Severe liver disease does not significantly affect clearance of atracurium or cisatracurium, but the associated decrease in pseudocholinesterase levels may slow the metabolism of mivacurium.

I. Renal Excretion
Pancuronium, vecuronium, and rocuronium are partially excreted by the kidneys. The duration of action or pancuronium and vecuronium is prolonged in patients with kidney failure. The elimination of atracurium and cisatracurium is independent of kidney function. The duration of action of rocuronium and mivacurium is not significantly affected by renal dysfunction.

General Pharmacological Characteristics
Some variables affect all nondepolarizing muscle relaxants.

A. Temperature
Hypothermia prolongs blockade by decreasing metabolism (eg, mivacurium, atracurium, and cisatracurium) and delaying excretion (eg, pancuronium and vecuronium).

B. Acid–Base Balance
Respiratory acidosis potentiates the blockade of most nondepolarizing relaxants and antagonizes its reversal. This could prevent complete neuromuscular recovery in a hypoventilating postoperative patient. Conflicting findings
regarding the neuromuscular effects of other acid–base changes may be due to coexisting alterations in extracellular pH, intracellular pH, electrolyte concentrations, or structural differences between drugs (eg, monoquaternary versus bisquaternary; steroidal versus isoquinolinium).

C. Electrolyte Abnormalities
Hypokalemia and hypocalcemia augment a nondepolarizing block. The responses of patients with hypercalcemia are unpredictable. Hypermagnesemia, as may be seen in preeclamptic patients being managed with magnesium sulfate (or after intravenous magnesium administered in the operating room), potentiates a nondepolarizing blockade by competing with calcium at the motor end-plate.

D. Age
Neonates have an increased sensitivity to nondepolarizing relaxants because of their immature neuromuscular junctions (Table 11-7). This sensitivity does not necessarily decrease dosage requirements, as the neonate’s greater extracellular space provides a larger volume of distribution.

TABLE 11–7 Additional considerations of muscle relaxants in special populations.
**E. Drug Interactions**

As noted earlier, many drugs augment nondepolarizing blockade (see Table 11–3). They have multiple sites of interaction: prejunctional structures, postjunctional cholinergic receptors, and muscle membranes.

**F. Concurrent Disease**

The presence of neurological or muscular disease can have profound effects on an individual’s response to muscle relaxants (Table 11–8). Cirrhotic liver disease and chronic kidney failure often result in an increased volume of distribution and a lower plasma concentration for a given dose of water-soluble drugs, such as muscle relaxants. On the other hand, drugs dependent on hepatic
or renal excretion may demonstrate prolonged clearance (Table 11–7). Thus, depending on the drug chosen, a greater initial (loading) dose—but smaller maintenance doses—might be required in these diseases.

**G. Muscle Groups**

The onset and intensity of blockade vary among muscle groups. This may be due to differences in blood flow, distance from the central circulation, or different fiber types. Furthermore, the relative sensitivity of a muscle group may depend on the choice of muscle relaxant. In general, the diaphragm, jaw, larynx, and facial muscles (orbicularis oculi) respond to and recover from muscle relaxation sooner than the thumb. Although they are a fortuitous safety feature, persistent diaphragmatic contractions can be disconcerting in the face of complete adductor pollicis paralysis. Glottic musculature is also quite resistant to blockade, as is often confirmed during laryngoscopy. The dose that produces 95% twitch depression in laryngeal muscles is nearly two times that for the adductor pollicis muscle. Good intubating conditions are usually associated with visual loss of the orbicularis oculi twitch response.

Considering the multitude of factors influencing the duration and magnitude of muscle relaxation, it becomes clear that an individual’s response to neuromuscular blocking agents should be monitored. Dosage recommendations, including those in this chapter, should be considered guidelines that require
modification for individual patients. Wide variability in sensitivity to nondepolarizing muscle relaxants is often encountered in clinical practice.

**ATRACURIUM**

**Physical Structure**

Like all muscle relaxants, atracurium has a quaternary group; however, a benzylisoquinoline structure is responsible for its unique method of degradation. The drug is a mixture of ten stereoisomers.

**Metabolism & Excretion**

Atracurium is so extensively metabolized that its pharmacokinetics are independent of renal and hepatic function, and less than 10% is excreted unchanged by renal and biliary routes. Two separate processes are responsible for metabolism.

**A. Ester Hydrolysis**

This action is catalyzed by nonspecific esterases, not by acetylcholinesterase or pseudocholinesterase.

**B. Hofmann Elimination**

A spontaneous nonenzymatic chemical breakdown occurs at physiological pH and temperature.

**Dosage**

A dose of 0.5 mg/kg is administered intravenously for intubation. After succinylcholine, intraoperative relaxation is achieved with 0.25 mg/kg initially, then in incremental doses of 0.1 mg/kg every 10 to 20 min. An infusion of 5 to 10 mcg/kg/min can effectively replace intermittent boluses.

Although dosage requirements do not significantly vary with age, atracurium may be shorter acting in children and infants than in adults.

Atracurium is available as a solution of 10 mg/mL. It must be stored at 2°C to 8°C, as it loses 5% to 10% of its potency for each month it is exposed to room temperature. At room temperature, it should be used within 14 days to preserve potency.
Side Effects & Clinical Considerations
Atracurium triggers dose-dependent histamine release that becomes significant at doses above 0.5 mg/kg.

A. Hypotension and Tachycardia
Cardiovascular side effects are unusual unless doses in excess of 0.5 mg/kg are administered. Atracurium may also cause a transient drop in systemic vascular resistance and an increase in cardiac index independent of any histamine release. A slow rate of injection minimizes these effects.

B. Bronchospasm
Atracurium should be avoided in asthmatic patients. Severe bronchospasm is occasionally seen in patients without a history of asthma.

C. Laudanosine Toxicity
Laudanosine, a tertiary amine, is a breakdown product of atracurium’s Hofmann elimination and has been associated with central nervous system excitation, resulting in elevation of the minimum alveolar concentration and even precipitation of seizures. Concerns about laudanosine are probably irrelevant unless a patient has received an extremely large total dose or has hepatic failure. Laudanosine is metabolized by the liver and excreted in urine and bile.

D. Temperature and pH Sensitivity
Because of its unique metabolism, atracurium’s duration of action can be markedly prolonged by hypothermia and to a lesser extent by acidosis.

E. Chemical Incompatibility
Atracurium will precipitate as a free acid if it is introduced into an intravenous line containing an alkaline solution such as thiopental.

F. Allergic Reactions
Rare anaphylactoid reactions to atracurium have been described. Proposed mechanisms include direct immunogenicity and acrylate-mediated immune activation. Immunoglobulin E-mediated antibody reactions directed against substituted ammonium compounds, including muscle relaxants, have been described. Reactions to acrylate, a metabolite of atracurium and a structural
component of some dialysis membranes, have also been reported in patients undergoing hemodialysis.

**CISATRACURIUM**

**Physical Structure**

Cisatracurium is a stereoisomer of atracurium that is four times more potent. Atracurium contains approximately 15% cisatracurium.

**Metabolism & Excretion**

Like atracurium, cisatracurium undergoes degradation in plasma at physiological pH and temperature by organ-independent Hofmann elimination. The resulting metabolites (a monoquaternary acrylate and laudanosine) have no neuromuscular blocking effects. Because of cisatracurium’s greater potency, the amount of laudanosine produced for the same extent and duration of neuromuscular blockade is much less than with atracurium. Metabolism and elimination are independent of kidney or liver failure. Minor variations in pharmacokinetic patterns due to age result in no clinically important changes in duration of action.

**Dosage**

Cisatracurium produces good intubating conditions following a dose of 0.1 to 0.15 mg/kg within 2 min and results in muscle blockade of intermediate duration. The typical maintenance infusion rate ranges from 1.0 to 2.0 mcg/kg/min. Thus, it is more potent than atracurium.

Cisatracurium should be stored under refrigeration (2–8°C) and should be used within 21 days after removal from refrigeration and exposure to room temperature.

**Side Effects & Clinical Considerations**

Unlike atracurium, cisatracurium does not produce a consistent, dose-dependent increase in plasma histamine levels following administration. Cisatracurium does not alter heart rate or blood pressure, nor does it produce autonomic effects, even at doses as high as eight times ED$_{95}$.

Cisatracurium shares with atracurium the production of laudanosine, pH and
temperature sensitivity, and chemical incompatibility.

**MIVACURIUM**

Mivacurium is a short-acting, benzylisoquinoline, nondepolarizing neuromuscular blocker. It has recently returned to the North American anesthesia market after having been unavailable for a number of years.

**Metabolism & Excretion**

Mivacurium, like succinylcholine, is metabolized by pseudocholinesterase. Consequently, patients with low pseudocholinesterase concentration or activity may experience prolonged neuromuscular blockade following mivacurium administration. However, like other nondepolarizing agents, cholinesterase inhibitors will antagonize mivacurium-induced neuromuscular blockade. Edrophonium more effectively reverses mivacurium blockade than neostigmine because neostigmine inhibits plasma cholinesterase activity.

**Dosage**

The usual intubating dose of mivacurium is 0.15 to 0.2 mg/kg.

**Side Effects & Clinical Considerations**

Mivacurium releases histamine to about the same degree as atracurium. The onset time of mivacurium is approximately 2 to 3 min. The main advantage of mivacurium compared with atracurium is its relatively brief duration of action (20–30 min).

**PANCURONIUM**

**Physical Structure**

Pancuronium consists of a steroid structure on which two modified ACh molecules are positioned (a bisquaternary relaxant). In all of the steroid-based relaxants the steroid “backbone” serves as a “spacer” between the two quaternary amines. Pancuronium resembles ACh enough to bind (but not activate) the nicotinic ACh receptor.
Metabolism & Excretion

Pancuronium is metabolized (deacetylated) by the liver to a limited degree. Its metabolic products have some neuromuscular blocking activity. Excretion is primarily renal (40%), although some of the drug is cleared by the bile (10%). Not surprisingly, elimination of pancuronium is slowed and neuromuscular blockade is prolonged by kidney failure. Patients with cirrhosis may require a larger initial dose due to an increased volume of distribution but have reduced maintenance requirements because of a decreased rate of plasma clearance.

Dosage

A dose of 0.08 to 0.12 mg/kg of pancuronium provides adequate relaxation for intubation in 2 to 3 min. Intraoperative relaxation is achieved by administering 0.04 mg/kg initially followed every 20 to 40 min by 0.01 mg/kg.

Children may require moderately larger doses of pancuronium. Pancuronium is available as a solution of 1 or 2 mg/mL and is stored at 2°C to 8°C but may be stable for up to 6 months at normal room temperature.

Side Effects & Clinical Considerations

A. Hypertension and Tachycardia

These cardiovascular effects are caused by the combination of vagal blockade and sympathetic stimulation. The latter is due to a combination of ganglionic stimulation, catecholamine release from adrenergic nerve endings, and decreased catecholamine reuptake. Large bolus doses of pancuronium should be given with caution to patients in whom an increased heart rate would be particularly detrimental (eg, coronary artery disease, hypertrophic cardiomyopathy, aortic stenosis).

B. Arrhythmias

Increased atrioventricular conduction and catecholamine release increase the likelihood of ventricular arrhythmias in predisposed individuals. The combination of pancuronium, tricyclic antidepressants, and halothane has been reported to be particularly arrhythmogenic.

C. Allergic Reactions

Patients who are hypersensitive to bromides may exhibit allergic reactions to
pancuronium (pancuronium bromide).

**VECURONIUM**

**Physical Structure**
Vecuronium is pancuronium minus a quaternary methyl group (a monoquaternary relaxant). This minor structural change beneficially alters side effects without affecting potency.

**Metabolism & Excretion**
Vecuronium is metabolized to a small extent by the liver. It depends primarily on biliary excretion and secondarily (25%) on renal excretion. Although it is a satisfactory drug for patients with kidney failure, its duration of action will be moderately prolonged. Vecuronium’s brief duration of action is explained by its shorter elimination half-life and more rapid clearance compared with pancuronium. After long-term administration of vecuronium to patients in intensive care units prolonged neuromuscular blockade (up to several days) may be present after drug discontinuation, possibly from accumulation of its active 3-hydroxy metabolite, changing drug clearance, and in some patients, leading to the development of a polyneuropathy. Risk factors seem to include female gender, kidney failure, long-term or high-dose corticosteroid therapy, and sepsis. Thus, these patients must be closely monitored, and the dose of vecuronium carefully titrated. Long-term relaxant administration and the subsequent prolonged lack of ACh binding at the postsynaptic nicotinic ACh receptors may mimic a chronic denervation state and cause lasting receptor dysfunction and paralysis. Tolerance to nondepolarizing muscle relaxants can also develop after long-term use. The best approach is to avoid unnecessary paralysis of patients in critical care units.

**Dosage**
Vecuronium is equipotent with pancuronium, and the intubating dose is 0.08 to 0.12 mg/kg. A dose of 0.04 mg/kg initially followed by increments of 0.01 mg/kg every 15 to 20 min provides intraoperative relaxation. Alternatively, an infusion of 1 to 2 mcg/kg/min produces good maintenance of relaxation. Age does not affect initial dose requirements, although subsequent doses are required less frequently in neonates and infants. Women seem to be
approximately 30% more sensitive than men to vecuronium, as evidenced by a greater degree of blockade and longer duration of action (this has also been seen with pancuronium and rocuronium). The cause for this sensitivity is likely related to gender-related differences in fat and muscle mass and volume of distribution. The duration of action of vecuronium may be further prolonged in postpartum patients due to alterations in hepatic blood flow or liver uptake.

**Side Effects & Clinical Considerations**

**A. Cardiovascular**
Even at doses of 0.28 mg/kg, vecuronium is devoid of significant cardiovascular effects. Potentiation of opioid-induced bradycardia may be observed in some patients.

**B. Liver Failure**
Although it is dependent on biliary excretion, the duration of action of vecuronium is usually not significantly prolonged in patients with cirrhosis unless doses greater than 0.15 mg/kg are given. Vecuronium requirements are reduced during the anhepatic phase of liver transplantation.

**ROCURONIUM**

**Physical Structure**
This monoquaternary steroid analogue of vecuronium was designed to provide a rapid onset of action.

**Metabolism & Excretion**
Rocuronium undergoes no metabolism and is eliminated primarily by the liver and slightly by the kidneys. Its duration of action is not significantly affected by renal disease, but it is modestly prolonged by severe liver failure and pregnancy. Because rocuronium does not have active metabolites, it may be a better choice than vecuronium in the rare patient requiring prolonged infusions in the intensive care unit setting. Elderly patients may experience a prolonged duration of action due to decreased liver mass.

**Dosage**
Rocuronium is less potent than most other steroidal muscle relaxants (potency seems to be inversely related to speed of onset). It requires 0.45 to 0.9 mg/kg intravenously for intubation and 0.15 mg/kg boluses for maintenance. Intramuscular rocuronium (1 mg/kg for infants; 2 mg/kg for children) provides adequate vocal cord and diaphragmatic paralysis for intubation, but not until after 3 to 6 min (deltoid injection has a faster onset than quadriceps). The infusion requirements for rocuronium range from 5 to 12 mcg/kg/min. Rocuronium can produce an unexpectedly prolonged duration of action in elderly patients. Initial dosage requirements are modestly increased in patients with advanced liver disease, presumably due to a larger volume of distribution.

**Side Effects & Clinical Considerations**

Rocuronium (at a dose of 0.9–1.2 mg/kg) has an onset of action that approaches succinylcholine (60–90 s), making it a suitable alternative for rapid-sequence inductions, but at the cost of a much longer duration of action. This intermediate duration of action is comparable to vecuronium or atracurium. Sugammadex permits rapid reversal of dense rocuronium-induced neuromuscular blockade.

Rocuronium (0.1 mg/kg) has been shown to be a rapid (90 s) and effective agent (decreased fasciculations and postoperative myalgias) for precurarization prior to administration of succinylcholine. It has slight vagolytic tendencies.

**NEWER MUSCLE RELAXANTS**

Gantacurium belongs to a new class of nondepolarizing neuromuscular blockers called chlorofumarates. In preclinical trials, gantacurium demonstrated an ultrashort duration of action, similar to that of succinylcholine. Its pharmacokinetic profile is explained by the fact that it undergoes nonenzymatic degradation by two chemical mechanisms: rapid formation of inactive cysteine adduction product and ester hydrolysis. At a dose of 0.2 mg/kg (ED$_{95}$), the onset of action has been estimated to be 1 to 2 min, with a duration of blockade similar to that of succinylcholine. Its clinical duration of action ranged from 5 to 10 min. Recovery can be accelerated by edrophonium, as well as by the administration of exogenous cysteine. Cardiovascular effects suggestive of histamine release were observed following the use of three times the ED$_{95}$ dosage.

CW002 is another investigational nondepolarizing agent. It is a benzyliisoquinolinium fumarate ester-based compound with an intermediate
duration of action that undergoes metabolism and elimination similar to that of gantacurium.

CASE DISCUSSION

Delayed Recovery from General Anesthesia
A 72-year-old man has undergone general anesthesia for robot-assisted laparoscopic prostatectomy. Twenty minutes after conclusion of the procedure, he is still intubated and shows no evidence of spontaneous respiration or consciousness.

What is your general approach to this diagnostic dilemma?

Clues to the solution of complex clinical problems are usually found in a pertinent review of the medical and surgical history, the history of drug ingestions, the physical examination, and laboratory results. In this case, the perioperative anesthetic management should also be considered.

What medical illnesses predispose a patient to delayed awakening or prolonged paralysis?

Chronic hypertension alters cerebral blood flow autoregulation and decreases the brain’s tolerance to episodes of hypotension. Liver disease reduces hepatic drug metabolism and biliary excretion, resulting in prolonged drug action. Reduced serum albumin concentrations increase free drug (active drug) availability. Hepatic encephalopathy can alter consciousness. Kidney disease decreases the renal excretion of many drugs. Uremia can also affect consciousness. Diabetic patients are prone to hypoglycemia and hyperosmotic, hyperglycemic, and nonketotic coma. A prior stroke or symptomatic carotid bruit increases the risk of intraoperative cerebral vascular accident. Right-to-left heart shunts, particularly in children with congenital heart disease, allow air emboli to pass directly from the venous circulation to the systemic (possibly cerebral) arterial circulation. A paradoxic air embolism can result in permanent brain damage. Severe hypothyroidism is associated with impaired drug metabolism and, rarely, myxedema coma.

Does an uneventful history of general anesthesia narrow the
**differential?**

Hereditary atypical pseudocholinesterase is ruled out by uneventful prior general anesthesia, assuming succinylcholine was administered. Decreased levels of normal enzyme would not result in postoperative apnea unless the surgery was of very short duration. Malignant hyperthermia does not typically present as delayed awakening, although prolonged somnolence is not unusual. Uneventful prior anesthetics do not, however, rule out malignant hyperthermia. Persons unusually sensitive to anesthetic agents (eg, geriatric patients) may have a history of delayed emergence.

**How do drugs that a patient takes at home affect awakening from general anesthesia?**

Drugs that decrease minimum alveolar concentration, such as methyldopa, predispose patients to anesthetic overdose. Acute ethanol intoxication decreases barbiturate metabolism and acts independently as a sedative. Drugs that decrease liver blood flow, such as cimetidine, will limit hepatic drug metabolism. Antiparkinsonian drugs and tricyclic antidepressants have anticholinergic side effects that augment the sedation produced by scopolamine. Long-acting sedatives, such as the benzodiazepines, can delay awakening.

**Does anesthetic technique alter awakening?**

Preoperative medications can affect awakening. In particular, opioids and benzodiazepines can interfere with postoperative recovery.

Intraoperative hyperventilation is a common cause of postoperative apnea. Because volatile agents and opioids raise the apneic threshold, the Pa\textsubscript{CO\textsubscript{2}} level at which spontaneous ventilation ceases, moderate postoperative hypoventilation may be required to stimulate the respiratory centers. Severe intraoperative hypotension or hypertension may lead to cerebral hypoxia and edema.

Hypothermia decreases minimum alveolar concentration, antagonizes muscle relaxation reversal, and limits drug metabolism. Arterial hypoxia or severe hypercapnia (Pa\textsubscript{CO\textsubscript{2}} > 70 mm Hg) can alter consciousness.

Certain surgical procedures, such as carotid endarterectomy, cardiopulmonary bypass, and intracranial procedures, are associated with an increased incidence of postoperative neurological deficits. Subdural hematomas can occur in severely coagulopathic patients. Transurethral
Resection of the prostate can be associated with hyponatremia from the dilutional effects of absorbed irrigating solution.

**What clues does a physical examination provide?**

Pupil size is not always a reliable indicator of central nervous system integrity. Fixed and dilated pupils in the absence of anticholinergic medication or ganglionic blockade, however, may be an ominous sign. Response to physical stimulation, such as a forceful jaw thrust, may differentiate somnolence from paralysis. Peripheral nerve stimulation also differentiates paralysis from coma.

**What specific laboratory findings would you order?**

Arterial blood gases, plasma glucose, and serum electrolytes may be helpful. Computed tomographic scanning may be necessary if unresponsiveness is prolonged. Increased concentrations of inhalational agent provided by respiratory gas analysis, as well as processed electroencephalogram (EEG) measurements, may assist in determining if the patient is still under the effects of anesthesia. Slow EEG signals can be indicative of both anesthesia and cerebral pathology. Processed EEG awareness monitors can also be employed with the realization that low numbers on the bispectral index can be caused both by anesthetic suppression of the EEG and ischemic brain injury.

**What therapeutic interventions should be considered?**

Supportive mechanical ventilation should be continued in the unresponsive patient. Naloxone, flumazenil, and physostigmine may be indicated, depending on the probable cause of the delayed emergence, if drug effects are suspected and reversal is considered both safe and desirable.

**SUGGESTED READINGS**

Heerdt PM, Sunaga H, Savarese JJ. Novel neuromuscular blocking drugs and

The primary clinical use of cholinesterase inhibitors is to reverse nondepolarizing neuromuscular blockers.

Acetylcholine is the neurotransmitter for the entire parasympathetic nervous system (parasympathetic ganglia and effector cells), parts of the sympathetic nervous system (sympathetic ganglia, adrenal medulla, and sweat glands), some neurons in the central nervous system, and somatic nerves innervating skeletal muscle.

Neuromuscular transmission is blocked when nondepolarizing muscle relaxants compete with acetylcholine to bind to nicotinic cholinergic receptors. The cholinesterase inhibitors indirectly increase the amount of acetylcholine available to compete with the nondepolarizing agent, thereby reestablishing neuromuscular transmission.

Acetylcholinesterase inhibitors prolong the depolarization blockade of succinylcholine.

Any prolongation of action of a nondepolarizing muscle relaxant from renal or hepatic insufficiency will probably be accompanied by a corresponding increase in the duration of action of a cholinesterase inhibitor.

The time required to fully reverse a nondepolarizing block depends on several factors, including the choice and dose of cholinesterase inhibitor administered, the muscle relaxant being antagonized, and the extent of the blockade before reversal.
A reversal agent should be routinely given to patients who have received nondepolarizing muscle relaxants unless full reversal can be demonstrated or the postoperative plan includes continued intubation and ventilation.

Newer quantitative methods for assessing recovery from neuromuscular blockade, such as acceleromyography, may further reduce the incidence of undetected residual postoperative neuromuscular paralysis.

Sugammadex exerts its effects by forming tight complexes in a 1:1 ratio with steroidal neuromuscular blocking agents.

Cysteine causes inactivation of gantacurium via metabolic degradation and adduct formation.

Incomplete reversal of neuromuscular blocking agents and residual postprocedure paralysis are associated with morbidity; therefore, careful evaluation of neuromuscular blockade and appropriate pharmacological antagonism are strongly recommended whenever muscle relaxants are administered. The primary clinical use of cholinesterase inhibitors is to reverse nondepolarizing neuromuscular blockers. Some of these agents are also used to diagnose and treat myasthenia gravis. More recently, newer agents, such as cyclodextrins and cysteine, with superior ability to reverse neuromuscular blockade from specific agents, are being employed or investigated. This chapter reviews cholinergic pharmacology and mechanisms of acetylcholinesterase inhibition and presents the clinical pharmacology of commonly used cholinesterase inhibitors (neostigmine, edrophonium, pyridostigmine, and physostigmine). It concludes with a brief description and mechanisms of action of new reversal agents.

### Cholinergic Pharmacology

The term *cholinergic* refers to the effects of the neurotransmitter *acetylcholine*. Acetylcholine is synthesized in the nerve terminal by the enzyme cholineacetyltransferase, which catalyzes the reaction between acetylcoenzyme A and choline (*Figure 12–1*). After its release, acetylcholine is rapidly hydrolyzed by acetylcholinesterase (true cholinesterase) into acetate and choline.
Acetylcholine is the neurotransmitter for the entire parasympathetic nervous system (parasympathetic ganglions and effector cells), parts of the sympathetic nervous system (sympathetic ganglions, adrenal medulla, and sweat glands), some neurons in the central nervous system, and somatic nerves innervating skeletal muscle (Figure 12–2).
FIGURE 12–2 The parasympathetic nervous system uses acetylcholine as a preganglionic and postganglionic neurotransmitter.

Cholinergic receptors have been subdivided into two major groups based on their reaction to the alkaloids muscarine and nicotine (Figure 12–3). Nicotine stimulates the autonomic ganglia and skeletal muscle receptors (nicotinic receptors), whereas muscarine activates end-organ effector cells in bronchial smooth muscle, salivary glands, and the sinoatrial node (muscarinic receptors). The central nervous system has both nicotinic and muscarinic receptors. Nicotinic receptors are blocked by muscle relaxants (also called neuromuscular blockers), and muscarinic receptors are blocked by anticholinergic drugs, such as atropine. Although nicotinic and muscarinic receptors differ in their response to some agonists (eg, nicotine, muscarine) and some antagonists (eg, vecuronium versus atropine), they both respond to acetylcholine (Table 12–1). Clinically available cholinergic agonists resist hydrolysis by cholinesterase. Methacholine
and bethanechol are primarily muscarinic agonists, whereas carbachol has both muscarinic and nicotinic agonist activities. Methacholine by inhalation has been used as a provocative test in asthma, bethanechol is used for bladder atony, and carbachol may be used topically for wide-angle glaucoma.

When reversing neuromuscular blockade, the goal is to maximize nicotinic transmission with a minimum of muscarinic side effects.

**MECHANISM OF ACTION**

Normal neuromuscular transmission depends on acetylcholine binding to nicotinic cholinergic receptors on the motor end-plate. Nondepolarizing muscle relaxants act by competing with acetylcholine for these binding sites, thereby blocking neuromuscular transmission. Reversal of blockade depends on diffusion, redistribution, metabolism, and excretion from the body of the nondepolarizing relaxant (spontaneous reversal), often assisted by the administration of specific reversal agents (pharmacological reversal). Cholinesterase inhibitors indirectly increase the amount of acetylcholine available to compete with the nondepolarizing agent, thereby reestablishing normal neuromuscular transmission.

Cholinesterase inhibitors inactivate acetylcholinesterase by reversibly binding to the enzyme. The stability of the bond influences the duration of action. The electrostatic attraction and hydrogen bonding of edrophonium are short-lived; the covalent bonds of neostigmine and pyridostigmine are longer lasting.

**Organophosphates**, a special class of cholinesterase inhibitors that have
been used in ophthalmology and as pesticides, form stable, irreversible bonds to the enzyme for a long-lasting effect that persists beyond the persistence of the drug in the circulation. Chemical warfare nerve agents (eg, VX, sarin) are also organophosphates that produce cholinesterase inhibition. Death occurs secondary to overstimulation of both nicotinic and muscarinic receptors.

The clinical duration of the cholinesterase inhibitors used in anesthesia, however, is probably most influenced by the rate of drug disappearance from the plasma. Differences in duration of action can be overcome by dosage adjustments. Thus, the normally short duration of action of edrophonium can be partially overcome by increasing the dosage. Cholinesterase inhibitors are also used in the diagnosis and treatment of myasthenia gravis.

Acetylcholinesterase inhibitors prolong the depolarization blockade of succinylcholine. Two mechanisms may explain this latter effect: an increase in acetylcholine (which increases motor end-plate depolarization and receptor desensitization) and inhibition of pseudocholinesterase activity. Neostigmine and to some extent pyridostigmine display some limited pseudocholinesterase-inhibiting activity, but their effect on acetylcholinesterase is much greater. Edrophonium has little or no effect on pseudocholinesterase. In astronomical doses, neostigmine can cause a weak depolarizing neuromuscular blockade.

**CLINICAL PHARMACOLOGY**

**General Pharmacological Characteristics**

The increase in acetylcholine caused by cholinesterase inhibitors affects more than the nicotinic receptors of skeletal muscle (Table 12–2). Cholinesterase inhibitors can act at cholinergic receptors of several other organ systems, including the cardiovascular and gastrointestinal systems.

**TABLE 12–2  Muscarinic side effects of cholinesterase inhibitors.**
Cardiovascular receptors—The predominant muscarinic effect on the heart is bradycardia that can progress to sinus arrest.

Pulmonary receptors—Muscarinic stimulation can result in bronchospasm (smooth muscle contraction) and increased respiratory tract secretions.

Cerebral receptors—Physostigmine is a cholinesterase inhibitor that crosses the blood–brain barrier and stimulates muscarinic and nicotinic receptors within the central nervous system, reversing the effects of scopolamine or high-dose atropine on the brain. Unlike physostigmine, cholinesterase inhibitors used to reverse neuromuscular blockers do not cross the blood–brain barrier.

Gastrointestinal receptors—Muscarinic stimulation increases peristaltic activity (esophageal, gastric, and intestinal) and glandular secretions (eg, salivary). Postoperative nausea, vomiting, and fecal incontinence have been attributed to the use of cholinesterase inhibitors.

Unwanted muscarinic side effects are minimized by prior or concomitant administration of anticholinergic medications, such as atropine or glycopyrrolate. The duration of action is similar among the cholinesterase inhibitors. Clearance is due to both hepatic metabolism (25–50%) and renal excretion (50–75%). Thus, any prolongation of action of a nondepolarizing muscle relaxant from renal or hepatic insufficiency will probably be accompanied by a corresponding increase in the duration of action of a cholinesterase inhibitor.

The time required to fully reverse a nondepolarizing block depends on several

1 Applies only to physostigmine.
factors, including the choice and dose of cholinesterase inhibitor administered, the muscle relaxant being antagonized, and the extent of the blockade before reversal. Reversal with edrophonium is usually faster than with neostigmine; large doses of neostigmine lead to faster reversal than small doses; intermediate-acting relaxants reverse sooner than long-acting relaxants; and a shallow block is easier to reverse than a deep block (ie, twitch height $>10\%$). Intermediate-acting muscle relaxants therefore require a lower dose of reversal agent (for the same degree of blockade) than long-acting agents, and concurrent excretion or metabolism provides a proportionally faster reversal of the short- and intermediate-acting agents. These advantages can be lost in conditions associated with severe end-organ disease (eg, the use of vecuronium in a patient with liver failure) or enzyme deficiencies (eg, mivacurium in a patient with homozygous atypical pseudocholinesterase). Depending on the dose of muscle relaxant that has been given, spontaneous recovery to a level adequate for pharmacological reversal may take more than 1 h with long-acting muscle relaxants because of their insignificant metabolism and slow excretion. Factors associated with faster reversal are also associated with a lower incidence of residual paralysis in the recovery room and a lower risk of postoperative respiratory complications. The absence of any palpable single twitches following 5 s of tetanic stimulation at 50 Hz implies a very intensive blockade that cannot be reversed by cholinesterase inhibitors.

A reversal agent should be routinely given to patients who have received nondepolarizing muscle relaxants unless full reversal can be demonstrated or the postoperative plan includes continued intubation and ventilation. In the latter situation, adequate sedation must also be provided.

A peripheral nerve stimulator should also be used to monitor the progress and confirm the adequacy of reversal. Clinical signs of adequate reversal vary in sensitivity (sustained head lift $>$ inspiratory force $>$ vital capacity $>$ tidal volume). Newer quantitative methods for assessing recovery from neuromuscular blockade, such as acceleromyography, may further reduce the incidence of undetected residual postoperative neuromuscular paralysis.

---

**Specific Cholinesterase Inhibitors**

**NEOSTIGMINE**

**Physical Structure**
Neostigmine consists of a carbamate moiety and a quaternary ammonium group (Figure 12–4). The former provides covalent bonding to acetylcholinesterase. The latter renders the molecule lipid insoluble, so that it cannot pass through the blood–brain barrier.

**FIGURE 12–4** The molecular structures of neostigmine, pyridostigmine, edrophonium, and physostigmine.

**Dosage & Packaging**

The maximum recommended dose of neostigmine is 0.08 mg/kg (up to 5 mg in adults), but smaller amounts often suffice and larger doses have also been given safely (Table 12–3). Neostigmine is most commonly packaged as 10 mL of a 1 mg/mL solution, although 0.5 mg/mL and 0.25 mg/mL concentrations are also available.

**TABLE 12–3** The choice and dose of cholinesterase inhibitor determine the choice and dose of anticholinergic.

*Not used to reverse muscle relaxants.

**Clinical Considerations**
The effects of neostigmine (0.04 mg/kg) are usually apparent in 5 min, peak at 10 min, and last more than 1 h. In practice, some clinicians use a dose of 0.04 mg/kg (or 2.5 mg) if the preexisting blockade is mild to moderate and a dose of 0.08 mg/kg (or 5 mg) if intense paralysis is being reversed; other clinicians use the “full dose” for all patients. The duration of action is prolonged in geriatric patients. Muscarinic side effects are minimized by prior or concomitant administration of an anticholinergic agent. The onset of action of glycopyrrolate (0.2 mg glycopyrrolate per 1 mg of neostigmine) is similar to that of neostigmine and is associated with less tachycardia than is experienced with atropine (0.4 mg of atropine per 1 mg of neostigmine). It has been reported that neostigmine crosses the placenta, resulting in fetal bradycardia, but there is no evidence that the choice of atropine versus glycopyrrolate makes any difference in newborn outcomes. Neostigmine is also used to treat myasthenia gravis, urinary bladder atony, and paralytic ileus.

PYRIDOSTIGMINE

Physical Structure

Pyridostigmine is structurally similar to neostigmine except that the quaternary ammonium is incorporated into the phenol ring. Pyridostigmine shares neostigmine’s covalent binding to acetylcholinesterase and its lipid insolubility.

Dosage & Packaging

Pyridostigmine is 20% as potent as neostigmine and may be administered in doses up to 0.25 mg/kg (a total of 20 mg in adults). It is available as a solution of 5 mg/mL.

Clinical Considerations

The onset of action of pyridostigmine is slower (10–15 min) than that of neostigmine, and its duration is slightly longer (>2 h). Glycopyrrolate (0.05 mg per 1 mg of pyridostigmine) or atropine (0.1 mg per 1 mg of pyridostigmine) must also be administered to prevent bradycardia. Glycopyrrolate is preferred because its slower onset of action better matches that of pyridostigmine, again resulting in less tachycardia.
EDROPHONIUM

Physical Structure
Because it lacks a carbamate group, edrophonium must rely on noncovalent bonding to the acetylcholinesterase enzyme. The quaternary ammonium group limits lipid solubility.

Dosage & Packaging
Edrophonium is less than 10% as potent as neostigmine. The recommended dosage is 0.5 to 1 mg/kg.

Clinical Considerations
Edrophonium has the most rapid onset of action (1–2 min) and the shortest duration of effect of any of the cholinesterase inhibitors. Reduced doses should not be used, because longer-acting muscle relaxants may outlast the effects of edrophonium. Higher doses prolong the duration of action to more than 1 h. Edrophonium may not be as effective as neostigmine at reversing intense neuromuscular blockade. In equipotent doses, muscarinic effects of edrophonium are less pronounced than those of neostigmine or pyridostigmine, requiring only half the amount of anticholinergic agent. Edrophonium’s rapid onset is well matched to that of atropine (0.014 mg of atropine per 1 mg of edrophonium). Although glycopyrrolate (0.007 mg per 1 mg of edrophonium) can also be used, it should be given several minutes prior to edrophonium to avoid the possibility of bradycardia.

PHYSOSTIGMINE

Physical Structure
Physostigmine, a tertiary amine, has a carbamate group but no quaternary ammonium. Therefore, it is lipid soluble and is the only clinically available cholinesterase inhibitor that freely passes the blood–brain barrier.

Dosage & Packaging
The dose of physostigmine is 0.01–0.03 mg/kg. It is packaged as a solution
containing 1 mg/mL.

**Clinical Considerations**

The lipid solubility and central nervous system penetration of physostigmine limit its usefulness as a reversal agent for nondepolarizing blockade, but make it effective in the treatment of central anticholinergic actions of scopolamine or overdoses of atropine. In addition, it reverses some of the central nervous system depression and delirium associated with use of benzodiazepines and volatile anesthetics. Physostigmine (0.04 mg/kg) has been shown to be effective in preventing postoperative shivering. It reportedly partially antagonizes morphine-induced respiratory depression, presumably because morphine reduces acetylcholine release in the brain. These effects are transient, and repeated doses may be required. Bradycardia is infrequent in the recommended dosage range, but atropine should be immediately available. Because glycopyrrolate does not cross the blood–brain barrier, it will not reverse the central nervous system effects of physostigmine. Other possible muscarinic side effects include excessive salivation, vomiting, and convulsions. In contrast to other cholinesterase inhibitors, physostigmine is almost completely metabolized by plasma esterases, so renal excretion is not important.

**OTHER CONSIDERATIONS**

Recovery from neuromuscular blockade is influenced by the depth of block at the time of antagonism, clearance and half-life of the relaxant used, and other factors that affect neuromuscular blockade (*Table 12–4*), such as drugs and electrolyte disturbances. In addition, some specific agents with the potential of reversing the neuromuscular blocking effects of nondepolarizing muscle relaxants merit brief discussion.

NONCLASSIC REVERSAL AGENTS

Besides cholinesterase inhibitors, additional drugs (calabadion and L-cysteine) are currently under investigation, and sugammadex has been newly introduced in the United States. These agents act as selective antagonists of nondepolarizing neuromuscular blockade. Sugammadex is able to reverse aminosteroid-induced neuromuscular blockade, whereas cysteine has been shown to reverse the neuromuscular blocking effects of gantacurium and other fumarates. Calabadion prevents binding to the nicotinic receptor of both benzylisoquinolinium and steroidal nondepolarizing muscle relaxants.

SUGAMMADEX

Sugammadex is a novel selective relaxant-binding agent that has recently become available in the United States. Sugammadex is increasingly supplanting neostigmine as the preferred agent for reversal on nondepolarizing neuromuscular blockade. It is a modified γ-cyclodextrin (su refers to sugar, and gammadex refers to the structural molecule γ-cyclodextrin).

Physical Structure

Its three-dimensional structure resembles a hollow truncated cone or doughnut with a hydrophobic cavity and a hydrophilic exterior. Hydrophobic interactions trap the drug (eg, rocuronium) in the cyclodextrin cavity (doughnut hole), resulting in tight formation of a water-soluble guest–host complex in a 1:1 ratio. This terminates the neuromuscular blocking action and restrains the drug in extracellular fluid where it cannot interact with nicotinic acetylcholine.
receptors. Sugammadex is essentially eliminated unchanged via the kidneys. Sugammadex does not require coadministration of an antimuscarinic agent.

**Clinical Considerations**

Sugammadex has been administered in doses of 4 to 8 mg/kg. With an injection of 8 mg/kg, given 3 min after administration of 0.6 mg/kg of rocuronium, recovery of train-of-four ratio to 0.9 was observed within 2 min. It produces rapid and effective reversal of both shallow and profound rocuronium-induced neuromuscular blockade in a consistent manner.

Sugammadex may impair the contraceptive effect of patients using hormonal contraceptives due to its affinity for compounds with steroidal structure. An alternative, nonhormonal, contraceptive should be used for 7 days following sugammadex administration. Toremifene, an estrogen antagonist, has a high affinity for sugammadex and might delay its reversal of neuromuscular block. Because of its renal excretion, sugammadex is not recommended in patients with severe kidney dysfunction. Sugammadex may artifactually prolong the activated partial thromboplastin time.

Sugammadex is most effective in the reversal of rocuronium; however, it will bind other steroidal neuromuscular blockers. Sugammadex is not effective in reversing nondepolarizing neuromuscular blockade secondary to benzylisoquinoline relaxants. Moreover, following reversal with sugammadex, subsequent neuromuscular blockade with steroidal neuromuscular blockers may be impaired. Benzylisoquinoline relaxants can be employed as an alternative.

**CALABADION**

Calabadion is a member of the cucurbituril class of “molecular containers” and is capable of reversing both steroidal and benzylisoquinoline neuromuscular blockers. Calabadion prevents muscle relaxant binding to the nicotinic receptor. Calabadion is currently under investigation.

**L-CYSTEINE**

L-cysteine is an endogenous amino acid that is often added to total parenteral nutrition regimens to enhance calcium and phosphate solubility. The ultrashort-acting neuromuscular blocker, gantacurium, and other fumarates rapidly combine with L-cysteine in vitro to form less active degradation products (adducts). Exogenous administration of L-cysteine (10–50 mg/kg intravenously)
given to anesthetized monkeys 1 min after these neuromuscular blocking agents abolished the block within 2 to 3 min; this antagonism was found to be superior to that produced by anticholinesterases. This unique method of antagonism by adduct formation and inactivation is still in the investigative stage, especially in terms of its safety and efficacy in humans.

**CASE DISCUSSION**

**Respiratory Failure in the Recovery Room**

A 66-year-old woman weighing 85 kg is brought to the recovery room following laparoscopic cholecystectomy. The anesthetic technique included the use of isoflurane and vecuronium for muscle relaxation. At the conclusion of the procedure, the anesthesiologist administered 6 mg of morphine sulfate for postoperative pain control and 3 mg of neostigmine with 0.6 mg of glycopyrrolate to reverse any residual neuromuscular blockade. The dose of cholinesterase inhibitor was empirically based on clinical judgment. Although the patient was apparently breathing normally on arrival in the recovery room, her tidal volume progressively diminished. Arterial blood gas measurements revealed a \( \text{Pa}_2 \text{O} \) of 62 mm Hg, a \( \text{Pa}_2 \text{O} \) of 110 mm Hg, and a pH of 7.26 on a fraction of inspired oxygen (\( \text{Fi}_2 \text{O} \)) of 40%.

*Which drugs administered to this patient could explain her hypoventilation?*

Isoflurane, morphine sulfate, and vecuronium all interfere with a patient’s ability to maintain a normal ventilatory response to an elevated \( \text{Pa}_2 \text{O} \).

*Why would the patient’s breathing worsen in the recovery room?*

Possibilities include the delayed onset of action of morphine sulfate, a lack of sensory stimulation in the recovery area, fatigue of respiratory muscles, the adverse effects of hypoventilation (and hypercarbia) with neuromuscular function, and splinting as a result of upper abdominal pain.
Could the patient still have residual neuromuscular blockade?

If the dose of neostigmine was not determined by the response to a peripheral nerve stimulator, or if the recovery of muscle function was inadequately tested after the reversal drugs were given, persistent neuromuscular blockade is possible. Assume, for example, that the patient had minimal or no response to initial tetanic stimulation at 100 Hz. Even the maximal dose of neostigmine (5 mg) might not yet have adequately reversed the paralysis. Because of enormous patient variability, the response to peripheral nerve stimulation must always be monitored when muscle relaxants are administered. Even if partial reversal is achieved, paralysis may worsen if the patient hypoventilates. *Other factors (in addition to respiratory acidosis) that impair the reversal of nondepolarizing muscle relaxants include intense neuromuscular paralysis, electrolyte disturbances (hypermagnesemia, hypokalemia, and hypocalcemia), hypothermia (temperature <32°C), drug interactions (see Table 11–3), metabolic alkalosis (from accompanying hypokalemia and hypocalcemia), and coexisting diseases (see Table 11–7).*

How could the extent of reversal be tested?

Tetanic stimulation is a sensitive but uncomfortable test of neuromuscular transmission in an awake patient. Because of its shorter duration, double-burst stimulation is tolerated better than tetany by conscious patients. Quantitative measures such as acceleromyography are preferred to assess the adequacy of reversal (train of four >0.9) compared with subjective interpretations of twitch. Many other tests of neuromuscular transmission, such as vital capacity and tidal volume, are insensitive as they may still seem normal when 70% to 80% of receptors are blocked. In fact, 70% of receptors may remain blocked despite an apparently normal response to train-of-four stimulation. The ability to sustain a head lift for 5 s, however, indicates that fewer than 33% of receptors are occupied by muscle relaxant.

What treatment would you suggest?

Ventilation should be assisted to reduce the respiratory acidosis. Even if diaphragmatic function seems to be adequate, residual blockade can lead to airway obstruction and poor airway protection. More neostigmine (with an anticholinergic) could be administered up to a maximum recommended dose of 5 mg. Since vecuronium was used, sugammadex could be
administered. If this does not adequately reverse paralysis, mechanical ventilation and airway protection should be instituted and continued until neuromuscular function is fully restored.

**SUGGESTED READINGS**

Taylor P. Anticholinesterase agents. In: Brunton LL, Knollmann BC, Hilal-
The ester linkage is essential for effective binding of the anticholinergics to the acetylcholine receptors. This competitively blocks binding by acetylcholine and prevents receptor activation. The cellular effects of acetylcholine, which are mediated through second messengers, are inhibited.

Anticholinergics relax the bronchial smooth musculature, which reduces airway resistance and increases anatomic dead space.

Atropine has particularly potent effects on the heart and bronchial smooth muscle and is the most efficacious anticholinergic for treating bradyarrhythmias.

Ipratropium solution (0.5 mg in 2.5 mL) seems to be particularly effective in the treatment of acute chronic obstructive pulmonary disease when combined with a β-agonist drug (eg, albuterol).

Scopolamine is a more potent antisableagogue than atropine and causes greater central nervous system effects.

Because of its quaternary structure, glycopyrrolate cannot cross the blood–brain barrier and is almost devoid of central nervous system and ophthalmic activity.

One group of cholinergic antagonists has already been discussed: the nondepolarizing neuromuscular blocking agents. These drugs act primarily at the nicotinic receptors in skeletal muscle. This chapter presents the pharmacology of drugs that block muscarinic receptors. Although the classification anticholinergic usually refers to this latter group, a more precise term would be antimuscarinic.

In this chapter, the mechanism of action and clinical pharmacology are
introduced for three common anticholinergics: atropine, scopolamine, and glycopyrrolate. The clinical uses of these drugs in anesthesia relate to their effect on the cardiovascular, respiratory, cerebral, gastrointestinal, and other organ systems (Table 13–1).

MECHANISMS OF ACTION

Anticholinergics are esters of an aromatic acid combined with an organic base (Figure 13–1). The ester linkage is essential for effective binding of the anticholinergics to the acetylcholine receptors. This competitively blocks binding by acetylcholine and prevents receptor activation. The cellular effects of acetylcholine, which are mediated through second messengers, are inhibited. The tissue receptors vary in their sensitivity to blockade. In fact, muscarinic receptors are not homogeneous, and receptor subgroups have been identified, including central nervous system (M1,4,5), autonomic ganglia and gastric parietal cells (M1), cardiac (M2), and smooth muscle (M3) receptors.
In normal clinical doses, only muscarinic receptors are blocked by the anticholinergic drugs discussed in this chapter. The extent of the anticholinergic effect depends on the degree of baseline vagal tone.

A. Cardiovascular
Blockade of muscarinic receptors in the sinoatrial node produces tachycardia. This effect is especially useful in reversing bradycardia due to vagal reflexes (eg, baroreceptor reflex, peritoneal traction, or oculocardiac reflex). A transient slowing of heart rate in response to smaller intravenous doses of atropine (<0.4 mg) has been reported. The mechanism of this paradoxical response is unclear. Facilitation of conduction through the atrioventricular node shortens the P–R interval on the electrocardiogram and often decreases heart block caused by
vagal activity. Atrial arrhythmias and nodal (junctional) rhythms occasionally occur. Anticholinergics generally have little effect on ventricular function or peripheral vasculature because of the paucity of direct cholinergic innervation of these areas despite the presence of cholinergic receptors. Presynaptic muscarinic receptors on adrenergic nerve terminals are known to inhibit norepinephrine release, so muscarinic antagonists may modestly enhance sympathetic activity. Large doses of anticholinergic agents can produce dilation of cutaneous blood vessels (atropine flush).

B. Respiratory
The anticholinergics inhibit respiratory tract secretions, from the nose to the bronchi, a valuable property during airway endoscopic or surgical procedures. Relaxation of the bronchial smooth musculature reduces airway resistance and increases anatomic dead space. These effects are particularly pronounced in patients with chronic obstructive pulmonary disease or asthma.

C. Cerebral
Anticholinergic medications can cause a spectrum of central nervous system effects ranging from stimulation to depression, depending on drug choice and dosage. Cerebral stimulation may present as excitation, restlessness, or hallucinations. Cerebral depression, including sedation and amnesia, are prominent after scopolamine. Physostigmine, a cholinesterase inhibitor that crosses the blood–brain barrier, promptly reverses anticholinergic actions on the brain.

D. Gastrointestinal
Salivary secretions are markedly reduced by anticholinergic drugs. Gastric secretions are also decreased, but larger doses are necessary. Decreased intestinal motility and peristalsis prolong gastric emptying time. Lower esophageal sphincter pressure is reduced. Overall, the anticholinergic drugs do not prevent aspiration pneumonia.

E. Ophthalmic
Anticholinergics (particularly when dosed topically) cause mydriasis (pupillary dilation) and cycloplegia (an inability to accommodate to near vision); acute angle-closure glaucoma is unlikely but possible following systemic administration of anticholinergic drugs.
F. Genitourinary
Anticholinergics may decrease ureter and bladder tone as a result of smooth muscle relaxation and lead to urinary retention, particularly in elderly men with prostatic hypertrophy.

G. Thermoregulation
Inhibition of sweat glands may lead to a rise in body temperature (atropine fever).

Specific Anticholinergic Drugs

ATROPINE

Physical Structure
Atropine is a tertiary amine. The naturally occurring levorotatory form is active, but the commercial mixture is racemic (Figure 13–1).

Dosage & Packaging
As a premedication, atropine is administered intravenously or intramuscularly in a range of 0.01 to 0.02 mg/kg, up to the usual adult dose of 0.4 to 0.6 mg. Larger intravenous doses up to 2 mg may be required to completely block the cardiac vagal nerves in treating severe bradycardia. Atropine sulfate is available in a multitude of concentrations.

Clinical Considerations
- Atropine has particularly potent effects on the heart and bronchial smooth muscle and is the most efficacious anticholinergic for treating bradyarrhythmias. Patients with coronary artery disease may not tolerate the increased myocardial oxygen demand and decreased oxygen supply associated with the tachycardia caused by atropine. A derivative of atropine, ipratropium bromide, is available in a metered-dose inhaler for the treatment of bronchospasm. Its quaternary ammonium structure significantly limits systemic absorption. Ipratropium solution (0.5 mg in 2.5 mL) seems to be particularly effective in the treatment of acute chronic obstructive pulmonary disease when combined with a β-agonist
The central nervous system effects of atropine are minimal after the usual doses, even though this tertiary amine can rapidly cross the blood–brain barrier. Atropine has been associated with mild postoperative memory deficits, and toxic doses are usually associated with excitatory reactions. An intramuscular dose of 0.01–0.02 mg/kg reliably provides an antiallagogue effect. Atropine should be used cautiously in patients with narrow-angle glaucoma, prostatic hypertrophy, or bladder-neck obstruction.

Intravenous atropine is used in the treatment of organophosphate pesticide and nerve gas poisoning. Organophosphates inhibit acetylcholinesterase, resulting in overwhelming stimulation of nicotinic and muscarinic receptors that leads to bronchorrhea, respiratory collapse, and bradycardia. Atropine can reverse the effects of muscarinic stimulation but not the muscle weakness resulting from nicotinic receptor activation. Pralidoxime (2-PAM; 1–2 g intravenously) may reactivate acetylcholinesterase.

**SCOPOLAMINE**

**Physical Structure**

Scopolamine, a tertiary amine, differs from atropine by the addition of an epoxide to the heterocyclic ring.

**Clinical Considerations**

👀 Scopolamine is a more potent antiallagogue than atropine and causes greater central nervous system effects. Clinical dosages usually result in drowsiness and amnesia, although restlessness, dizziness, and delirium are possible. The sedative effects may be desirable for premedication but can interfere with awakening following short procedures. Scopolamine has the added virtue of preventing motion sickness. The lipid solubility allows transdermal absorption, and transdermal scopolamine (1 mg patch) has been used to prevent postoperative nausea and vomiting. Because of its pronounced mydriatic effects, scopolamine is best avoided in patients with closed-angle glaucoma.

**GLYCOPYRROLATE**

**Physical Structure**
Glycopyrrolate is a synthetic product that differs from atropine in being a quaternary amine and having both cyclopentane and pyridine moieties in the compound.

**Dosage & Packaging**

The usual dose of glycopyrrolate is one-half that of atropine. For instance, the premedication dose is 0.005 to 0.01 mg/kg up to 0.2 to 0.3 mg in adults. Glycopyrrolate for injection is packaged as a solution of 0.2 mg/mL.

**Clinical Considerations**

Because of its quaternary structure, glycopyrrolate cannot cross the blood–brain barrier and is almost devoid of central nervous system and ophthalmic activity. Potent inhibition of salivary gland and respiratory tract secretions is the primary rationale for using glycopyrrolate as a premedication. Heart rate usually increases after intravenous—but not intramuscular—administration. Glycopyrrolate has a longer duration of action than atropine (2–4 h versus 30 min after intravenous administration).

**CASE DISCUSSION**

**Central Anticholinergic Syndrome**

An elderly patient is scheduled for enucleation of a blind, painful eye. Scopolamine, 0.4 mg intramuscularly, is administered as premedication. In the preoperative holding area, the patient becomes agitated and disoriented. The only other medication the patient has received is 1% atropine eye drops.

*How many milligrams of atropine are in one drop of a 1% solution?*

A 1% solution contains 1 g dissolved in 100 mL, or 10 mg/mL. Eyedroppers vary in the number of drops formed per milliliter of solution, but average 20 drops/mL. Therefore, one drop usually contains 0.5 mg of atropine.
**How are ophthalmic drops systemically absorbed?**

Absorption by vessels in the conjunctival sac is similar to subcutaneous injection. More rapid absorption is possible by the nasolacrimal duct mucosa.

**What are the signs and symptoms of anticholinergic poisoning?**

Reactions from an overdose of anticholinergic medication involve several organ systems. The central anticholinergic syndrome refers to central nervous system changes that range from unconsciousness to hallucinations. Agitation and delirium are not unusual in elderly patients. Other systemic manifestations include dry mouth, tachycardia, atropine flush, atropine fever, and impaired vision.

**What other drugs possess anticholinergic activity that could predispose patients to the central anticholinergic syndrome?**

Tricyclic antidepressants, antihistamines, and antipsychotics have antimuscarinic properties that could potentiate the side effects of anticholinergic drugs.

**What drug is an effective antidote to anticholinergic overdosage?**

Cholinesterase inhibitors indirectly increase the amount of acetylcholine available to compete with anticholinergic drugs at the muscarinic receptor. Neostigmine, pyridostigmine, and edrophonium possess a quaternary ammonium group that prevents penetration of the blood–brain barrier. Physostigmine, a tertiary amine, is lipid soluble and effectively reverses central anticholinergic toxicity. An initial dose of 0.01 to 0.03 mg/kg may have to be repeated after 15 to 30 min.

**SUGGESTED READINGS**

Eddleston M, Chowdhury F. Pharmacological treatment of organophosphorous

Adrenergic agonists can be categorized as direct or indirect. Direct agonists bind to the receptor, whereas indirect agonists increase endogenous neurotransmitter activity.

The primary effect of phenylephrine is peripheral vasoconstriction with a concomitant rise in systemic vascular resistance and arterial blood pressure.

Clonidine decreases anesthetic and analgesic requirements and provides sedation and anxiolysis.

Dexmedetomidine has a higher affinity for $\alpha_2$-receptors than clonidine. It has sedative, analgesic, and sympatholytic effects that blunt many of the cardiovascular responses seen during the perioperative period.

Long-term use of these agents, particularly clonidine and dexmedetomidine, leads to super-sensitization and upregulation of receptors; with abrupt discontinuation of either drug, an acute withdrawal syndrome including hypertensive crisis can occur.

Ephedrine is commonly used as a vasopressor during anesthesia. As such, its administration should be viewed as a temporizing measure while the cause of hypotension is determined and remedied.

At low doses (0.5–3 mcg/kg/min), dopamine (DA) primarily activates dopaminergic receptors. Stimulation of these receptors (specifically, DA$_1$ receptors) vasodilates the renal vasculature and promotes diuresis.

Labetalol lowers blood pressure without reflex tachycardia because of its combination of $\alpha$ and $\beta$ effects.

Esmolol is an ultrashort-acting selective $\beta_1$-antagonist that reduces heart rate and, to a lesser extent, blood pressure.

Abrupt discontinuation of $\beta$-blocker therapy for 24 to 48 h may trigger a
Adrenergic agonists and antagonists produce their clinical effects by interacting with the adrenergic receptors (ie, adrenoceptors). The clinical effects of these drugs can be deduced from an understanding of the adrenoceptor physiology and a knowledge of which receptors each drug activates or blocks.

ADRENOCEPTOR PHYSIOLOGY

The term adrenergic originally referred to the effects of epinephrine (adrenaline), although norepinephrine (noradrenaline) is the primary neurotransmitter responsible for most of the adrenergic activity of the sympathetic nervous system. With the exception of eccrine sweat glands and some blood vessels, norepinephrine is released by postganglionic sympathetic fibers at end-organ tissues (Figure 14–1). In contrast, acetylcholine is released by preganglionic sympathetic fibers and all parasympathetic fibers.
Norepinephrine is synthesized in the cytoplasm of sympathetic postganglionic nerve endings and stored in the vesicles (Figure 14–2). After release by a process of exocytosis, the action of norepinephrine is primarily terminated by reuptake into the postganglionic nerve ending. Norepinephrine transporter located on neuronal cell membranes facilitates removal of norepinephrine from the synapse. Other transporters facilitate uptake of dopamine and serotonin. Tricyclic antidepressants, cocaine, and amphetamines can inhibit these transporters leading to their clinical effects. Norepinephrine may diffuse from receptor sites where it is taken up by nonneuronal cells and is metabolized by
catechol-O-methyltransferase (Figure 14–3). In neurons norepinephrine may be metabolized by monoamine oxidase or repackaged into vesicles. Prolonged adrenergic activation leads to desensitization and hyporesponsiveness to further stimulation.

**FIGURE 14–2** The synthesis of norepinephrine. Hydroxylation of tyrosine to dopa is the rate-limiting step. Dopamine is actively transported into storage vesicles. Norepinephrine can be converted to epinephrine in the adrenal medulla.
FIGURE 14–3 Sequential metabolism of norepinephrine and epinephrine. Monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT) produce a common end product, vanillylmandelic acid (VMA).

Adrenergic receptors are divided into two general categories: α and β. Each of these has been further subdivided into at least two subtypes: α₁ and α₂, and β₁, β₂, and β₃. The α-receptors have been further divided using molecular cloning techniques into α₁A, α₁B, α₁D, α₂A, α₂B, and α₂C. These receptors are linked to G proteins (Figure 14–4)—heterotrimeric receptors with α, β, and γ subunits. The different adrenoceptors are linked to specific G proteins, each with a unique effector, but each using guanosine triphosphate (GTP) as a cofactor. α₁ is linked to Gq, which activates phospholipases; α₂ is linked to Gi, which inhibits adenylate cyclase (also termed adenyl or adenylyl cyclase); and β is linked to Gs, which activates adenylate cyclase.
Activation and inhibition of adenylyl cyclase by agonists that bind to catecholamine receptors. Binding to β-adrenoceptors stimulates adenylyl cyclase by activating the stimulatory G protein, Gs, which leads to the dissociation of its α subunit charged with guanosine triphosphate (GTP). This activated αs subunit directly activates adenylyl cyclase, resulting in an increased rate of synthesis of cAMP. α2-Adrenoceptor ligands inhibit adenylyl cyclase by causing dissociation of the inhibitory G protein, Gi, into its subunits; i.e., an activated αi subunit charged with GTP and a β-γ unit. The mechanism by which these subunits inhibit adenylyl cyclase is uncertain. cAMP binds to the regulatory subunit (R) of cAMP-dependent protein kinase, leading to the liberation of active catalytic subunits (C) that phosphorylate specific protein substrates and modify their activity. These catalytic units also phosphorylate the cAMP response element binding protein (CREB), which modifies gene expression. See text for other actions of β- and α2-adrenoceptors. **α1-Receptors**

α1-Receptors are postsynaptic adrenoceptors located in smooth muscle throughout the body (in the eye, lung, blood vessels, uterus, gut, and genitourinary system). Activation of these receptors increases intracellular
calcium ion concentration, which leads to contraction of smooth muscles. Thus, $\alpha_1$-agonists are associated with mydriasis (pupillary dilation due to contraction of the radial eye muscles), bronchoconstriction, vasoconstriction, uterine contraction, and constriction of sphincters in the gastrointestinal and genitourinary tracts. Stimulation of $\alpha_1$-receptors also inhibits insulin secretion and lipolysis. The myocardium possesses $\alpha_1$-receptors that have a positive inotropic effect, which might play a role in catecholamine-induced arrhythmia. During myocardial ischemia, enhanced $\alpha_1$-receptor coupling with agonists is observed. Nonetheless, the most important cardiovascular effect of $\alpha_1$ stimulation is vasoconstriction, which increases peripheral vascular resistance, left ventricular afterload, and arterial blood pressure.

**$\alpha_2$-Receptors**

In contrast to $\alpha_1$-receptors, $\alpha_2$-receptors are located primarily on the presynaptic nerve terminals. Activation of these adrenoceptors inhibits adenylyl cyclase activity. This decreases the entry of calcium ions into the neuronal terminal, which limits subsequent exocytosis of storage vesicles containing norepinephrine. Thus, $\alpha_2$-receptors create a negative feedback loop that inhibits further norepinephrine release from the neuron. In addition, vascular smooth muscle contains postsynaptic $\alpha_2$-receptors that produce vasoconstriction. More importantly, stimulation of postsynaptic $\alpha_2$-receptors in the central nervous system causes sedation and reduces sympathetic outflow, which leads to peripheral vasodilation and lower blood pressure.

**$\beta_1$-Receptors**

$\beta$-Adrenergic receptors are classified into $\beta_1$, $\beta_2$, and $\beta_3$ receptors. Norepinephrine and epinephrine are equipotent on $\beta_1$ receptors, but epinephrine is significantly more potent than norepinephrine on $\beta_2$ receptors.

The most important $\beta_1$-receptors are located on the postsynaptic membranes in the heart. Stimulation of these receptors activates adenylyl cyclase, which converts adenosine triphosphate to cyclic adenosine monophosphate and initiates a kinase phosphorylation cascade. Initiation of the cascade has positive chronotropic (increased heart rate), dromotropic (increased conduction), and inotropic (increased contractility) effects.
**β₂-Receptors**

β₂-Receptors are primarily postsynaptic adrenoceptors located in smooth muscle and gland cells, but are also located in ventricular myocytes. Their relative contribution to the response to intravenous catecholamines increases in patients with chronic heart failure. They share a common mechanism of action with β₁-receptors: adenylyl cyclase activation. Despite this commonality, β₂ stimulation relaxes smooth muscle, resulting in bronchodilation, vasodilation, and relaxation of the uterus (tocolysis), bladder, and gut. Glycogenolysis, lipolysis, gluconeogenesis, and insulin release are stimulated by β₂-receptor activation. β₂-Agonists also activate the sodium–potassium pump.

**β₃-Receptors**

β₃-Receptors are found in the gallbladder and brain adipose tissue. Their role in gallbladder physiology is unknown, but they are thought to play a role in lipolysis, thermogenesis in brown fat, and bladder relaxation.

**Dopaminergic Receptors**

Dopamine (DA) receptors are a group of adrenergic receptors that are activated by dopamine; these receptors are classified as D₁ and D₂ receptors. Activation of D₁ receptors mediates vasodilation in the kidney, intestine, and heart. D₂ receptors are believed to play a role in the antiemetic action of droperidol.

**Adrenergic Agonists**

Adrenergic agonists interact with varying specificity (selectivity) at α- and β-adrenoceptors (Tables 14–1 and 14–2).

**TABLE 14–1** Receptor selectivity of adrenergic agonists.¹
Overlapping of activity complicates the prediction of clinical effects. For example, epinephrine stimulates $\alpha_1$-, $\alpha_2$-, $\beta_1$-, and $\beta_2$-adrenoceptors. Its net effect on arterial blood pressure depends on the dose-dependent balance between $\alpha_1$-vasoconstriction, $\alpha_2$- and $\beta_2$-vasodilation, and $\beta_1$-inotropic influences (and, to a minor degree, $\beta_2$-inotropic influences).

Adrenergic agonists can be categorized as direct or indirect. Direct agonists bind to the receptor, whereas indirect agonists increase endogenous neurotransmitter activity. Mechanisms of indirect action include increased release or decreased reuptake of norepinephrine. The differentiation between direct and indirect mechanisms of action is particularly important in patients who have abnormal endogenous norepinephrine stores, as may occur with use of some antihypertensive medications or monoamine oxidase inhibitors. Intraoperative hypotension in these patients should be treated with direct

TABLE 14–2 Effects of adrenergic agonists on organ systems. 1
agonists, as their response to indirect agonists will be unpredictable.

Another feature distinguishing adrenergic agonists from each other is their chemical structure. Adrenergic agonists that have a 3,4-dihydroxybenzene structure (Figure 14–5) are known as catecholamines. These drugs are typically short-acting because of their metabolism by monoamine oxidase and catechol-O-methyltransferase. Patients taking monoamine oxidase inhibitors or tricyclic antidepressants may therefore demonstrate an exaggerated response to catecholamines. The naturally occurring catecholamines are epinephrine, norepinephrine, and DA. Changing the side-chain structure (R₁, R₂, R₃) of naturally occurring catecholamines has led to the development of synthetic catecholamines (eg, isoproterenol and dobutamine), which tend to be more receptor specific.

![Figure 14–5 Adrenergic agonists that have a 3,4-dihydroxybenzene structure are known as catecholamines. Substitutions at the R₁, R₂, and R₃ sites affect activity and selectivity.](image)

Adrenergic agonists commonly used in anesthesiology are discussed individually below. Note that the recommended doses for continuous infusion are expressed as mcg/kg/min for some agents and mcg/min for others. In either case, these recommendations should be regarded only as guidelines, as individual responses are quite variable.

**PHENYLEPHRINE**

Phenylephrine is a noncatecholamine with selective α₁-agonist activity. The primary effect of phenylephrine is peripheral vasoconstriction with a concomitant rise in systemic vascular resistance and arterial blood pressure. Reflex bradycardia mediated by the vagus nerve can reduce cardiac output. Phenylephrine is also used topically as a decongestant and a mydriatic agent.

Small intravenous boluses of 50 to 100 mcg (0.5 to 1 mcg/kg) of phenylephrine rapidly reverse reductions in blood pressure caused by peripheral
vasodilation (eg, spinal anesthesia). The duration of action is short, lasting approximately 15 min after administration of a single dose. Tachyphylaxis may occur with phenylephrine infusions and require upward titration of the infusion. Phenylephrine must be diluted from a 1% solution (10 mg/1-mL ampule), usually to a 100 mcg/mL solution and titrated to effect.

**α₂-AGONISTS**

Clonidine is an α₂-agonist that is commonly used for its antihypertensive and negative chronotropic effects. More recently, it and other α₂-agonists are increasingly being used for their sedative properties. Various studies have examined the anesthetic effects of oral (3–5 mcg/kg), intramuscular (2 mcg/kg), intravenous (1–3 mcg/kg), transdermal (0.1–0.3 mg released per day), intrathecal (15–30 mcg), and epidural (1–2 mcg/kg) clonidine administration.

- Clonidine decreases anesthetic and analgesic requirements (decreases minimum alveolar concentration) and provides sedation and anxiolysis. During general anesthesia, clonidine reportedly enhances intraoperative circulatory stability by reducing catecholamine levels. During regional anesthesia, including peripheral nerve block, clonidine prolongs the duration of the block. Direct effects on the spinal cord may be mediated by α₂-postsynaptic receptors within the dorsal horn. Other possible benefits include decreased postoperative shivering, inhibition of opioid-induced muscle rigidity, attenuation of opioid withdrawal symptoms, and the treatment of acute postoperative pain and some chronic pain syndromes. Side effects include bradycardia, hypotension, sedation, respiratory depression, and dry mouth.

- Dexmedetomidine has a higher affinity for α₂-receptors than clonidine. Compared with clonidine, dexmedetomidine is more selective for α₂-receptors (α₂:α₁ specificity ratio is 200:1 for clonidine and 1600:1 for dexmedetomidine). Dexmedetomidine has a shorter half-life (2–3 h) than clonidine (12–24 h). It has sedative, analgesic, and sympatholytic effects that blunt many of the cardiovascular responses seen during the perioperative period. The sedative and analgesic effects are mediated by α₂-adrenergic receptors in the brain (locus ceruleus) and spinal cord. When used intraoperatively, dexmedetomidine reduces intravenous and volatile anesthetic requirements; when used postoperatively, it reduces concurrent analgesic and sedative requirements. Dexmedetomidine is useful in sedating patients in preparation for awake fiberoptic intubation. It is also a useful agent for sedating patients postoperatively in postanesthesia and
intensive care units, because it does so without significant ventilatory depression. Rapid administration may elevate blood pressure, but hypotension and bradycardia can occur during ongoing therapy. The recommended dosing of dexmedetomidine consists of a loading dose at 1 mcg/kg over 10 min followed by an infusion at 0.2 to 0.7 mcg/kg/h, although we recognize that clinicians administer this agent in a great many ways (including intranasally for sedation in children).

Although these agents are adrenergic agonists, they are also considered to be sympatholytic because sympathetic outflow is reduced. Long-term use of these agents, particularly clonidine and dexmedetomidine, leads to supersensitization and upregulation of receptors; with abrupt discontinuation of either drug, an acute withdrawal syndrome including hypertensive crisis can occur. Because of the increased affinity of dexmedetomidine for the α<sub>2</sub>-receptor, compared with that of clonidine, this syndrome may manifest after only 48 h of dexmedetomidine use when the drug is discontinued.

EPINEPHRINE

Epinephrine is an endogenous catecholamine synthesized in the adrenal medulla. Direct stimulation of β<sub>1</sub>-receptors of the myocardium by epinephrine raises blood pressure, cardiac output, and myocardial oxygen demand by increasing contractility and heart rate (increased rate of spontaneous phase IV depolarization). α<sub>1</sub> Stimulation decreases splanchnic and renal blood flow but increases coronary perfusion pressure by increasing aortic diastolic pressure. Systolic blood pressure rises, although β<sub>2</sub>-mediated vasodilation in skeletal muscle may lower diastolic pressure. β<sub>2</sub> Stimulation also relaxes bronchial smooth muscle.

Administration of epinephrine is the principal pharmacological treatment for anaphylaxis and can be used to treat ventricular fibrillation. Complications include cerebral hemorrhage, myocardial ischemia, and ventricular arrhythmias. Volatile anesthetics, particularly halothane, potentiate the arrhythmic effects of epinephrine.

In emergency situations (eg, cardiac arrest and shock), epinephrine is administered as an intravenous bolus of 0.5 to 1 mg, depending on the severity of cardiovascular compromise. In major anaphylactic reactions, epinephrine should be used at a dose of 100 to 500 mcg (repeated, if necessary) followed by infusion. To improve myocardial contractility or heart rate, a continuous infusion is prepared (1 mg in 250 mL [4 mcg/mL]) and run at a rate of 2 to 20 mcg/min
(30–300 ng/kg/min). Epinephrine local infiltration is also used to reduce bleeding from the operative sites. Some local anesthetic solutions containing epinephrine at a concentration of 1:200,000 (5 mcg/mL) or 1:400,000 (2.5 mcg/mL) are characterized by less systemic absorption and a longer duration of action. Epinephrine is available in vials at a concentration of 1:1000 (1 mg/mL) and prefilled syringes at a concentration of 1:10,000 (0.1 mg/mL [100 mcg/mL]). A 1:100,000 (10 mcg/mL) concentration is available for pediatric use.

**EPHEDRINE**

The cardiovascular effects of ephedrine, a noncatecholamine sympathomimetic, are similar to those of epinephrine: increase in blood pressure, heart rate, contractility, and cardiac output. Likewise, ephedrine is also a bronchodilator. There are important differences, however: Ephedrine has a longer duration of action, is much less potent, has both indirect and direct actions, and stimulates the central nervous system (it raises minimum alveolar concentration). The indirect agonist properties of ephedrine may be due to peripheral postsynaptic norepinephrine release or inhibition of norepinephrine reuptake.

Ephedrine is commonly used as a vasopressor during anesthesia. As such, its administration should be viewed as a temporizing measure while the cause of hypotension is determined and remedied. Unlike direct-acting $\alpha_1$-agonists, ephedrine in sheep experiments did not decrease uterine blood flow; thus, for many years it was the preferred vasopressor in obstetric anesthesia. Currently phenylephrine is widely used in obstetric patients undergoing neuroaxial anesthesia due its faster onset, shorter duration of action, easier titration, and lack of adverse effects on fetal pH relative to ephedrine.

In adults, ephedrine is administered as a bolus of 2.5 to 10 mg; in children, it is given as a bolus of 0.1 mg/kg. Subsequent doses are increased to offset the development of tachyphylaxis, which is probably due to depletion of norepinephrine stores. Ephedrine is available in 1-mL ampules containing 25 or 50 mg of the agent.

**NOREPINEPHRINE**

Direct $\alpha_1$ stimulation with limited $\beta_2$ activity (at the doses used clinically) induces intense vasoconstriction of arterial and venous vessels. Increased myocardial contractility from $\beta_1$ effects, along with peripheral vasoconstriction, contributes to a rise in arterial blood pressure. Both systolic and diastolic
pressures usually rise, but increased afterload and reflex bradycardia may prevent any elevation in cardiac output. Decreased renal and splanchnic blood flow and increased myocardial oxygen requirements are concerns, yet norepinephrine is the agent of choice in the management of refractory (particularly septic) shock. Extravasation of norepinephrine at the site of intravenous administration can cause tissue necrosis.

Norepinephrine is administered usually as a continuous infusion due to its short half-life at a rate of 2 to 20 mcg/min (30–300 ng/kg/min). Ampules contain 4 mg of norepinephrine in 4 mL of solution.

**DOPAMINE**

The clinical effects of DA, an endogenous nonselective direct and indirect adrenergic and dopaminergic agonist, vary markedly with the dose. At low doses (0.5–3 mcg/kg/min), DA primarily activates dopaminergic receptors (specifically, DA\(_1\) receptors); stimulation of these receptors vasodilates the renal vasculature and promotes diuresis and natriuresis. Although this action increases renal blood flow, use of this “renal dose” does not impart any beneficial effect on kidney function. When used in moderate doses (3–10 mcg/kg/min), \(\beta_1\) stimulation increases myocardial contractility, heart rate, systolic blood pressure, and cardiac output. Myocardial oxygen demand typically increases more than supply. The \(\alpha_1\) effects become prominent at higher doses (10–20 mcg/kg/min), causing an increase in peripheral vascular resistance and a fall in renal blood flow. The exact dose–response curve for dopamine and these several actions is far more unpredictable than the preceding paragraph would suggest! The indirect effects of DA are due to release of norepinephrine from presynaptic sympathetic nerve ganglion.

DA was formerly a first-line treatment for shock to improve cardiac output, support blood pressure, and maintain renal function. The chronotropic and proarrhythmic effects of DA limit its usefulness in some patients, and it has been replaced by norepinephrine for many situations in critical illness. DA is administered as a continuous infusion at a rate of 1 to 20 mcg/kg/min. It is most commonly supplied in 5 to 10 mL vials containing 200 or 400 mg of DA.

**ISOPROTERENOL**

Isoproterenol is of interest because it is a pure \(\beta\)-agonist. \(\beta_1\) effects increase heart rate, contractility, and cardiac output. Systolic blood pressure may increase or
remain unchanged, but $\beta_2$ stimulation decreases peripheral vascular resistance and diastolic blood pressure. Myocardial oxygen demand increases while oxygen supply falls, making isoproterenol or any pure $\beta$-agonist a poor inotropic choice in most situations.

**DOBUTAMINE**

Dobutamine is a racemic mixture of two isomers with affinity for both $\beta_1$- and $\beta_2$-receptors, with relatively higher selectivity for $\beta_1$-receptors. Its primary cardiovascular effect is a rise in cardiac output as a result of increased myocardial contractility. A decline in peripheral vascular resistance caused by $\beta_2$ activation usually prevents much of a rise in arterial blood pressure. Left ventricular filling pressure decreases, whereas coronary blood flow increases.

Dobutamine increases myocardial oxygen consumption and should not be routinely used without specific indications to facilitate separation from cardiopulmonary bypass. It is often employed in pharmacological stress testing. Dobutamine is administered as an infusion at a rate of 2 to 20 mcg/kg/min. It is supplied in 20-mL vials containing 250 mg.

**FENOLDOPAM**

Fenoldopam is a selective $D_1$-receptor agonist that has many of the benefits of DA but with little or no $\alpha$- or $\beta$-adrenoceptor or $D_2$-receptor agonist activity. Fenoldopam has been shown to exert hypotensive effects characterized by a decrease in peripheral vascular resistance, along with an increase in renal blood flow, diuresis, and natriuresis. It is indicated for patients undergoing cardiac surgery and aortic aneurysm repair with potential risk of perioperative kidney impairment. Fenoldopam exerts an antihypertensive effect, but helps to maintain renal blood flow. It is also indicated for patients who have severe hypertension, particularly those with renal impairment. Along with its recommended use in hypertensive emergencies, fenoldopam is also indicated in the prevention of contrast media-induced nephropathy. Fenoldopam has a fairly rapid onset of action and is easily titratable because of its short elimination half-life. The ability of fenoldopam to “protect” the kidney perioperatively remains the subject of ongoing debate, but there is no good evidence for efficacy.

Fenoldopam is supplied in 1-, 2-, and 5-mL ampules, 10 mg/mL. It is started as a continuous infusion of 0.1 mcg/kg/min, increased by increments of 0.1 mcg/kg/min at 15- to 20-min intervals until target blood pressure is achieved.
Lower doses have been associated with less reflex tachycardia.

**Adrenergic Antagonists**

Adrenergic antagonists bind but do not activate adrenoceptors. They act by preventing adrenergic agonist activity. Like the agonists, the antagonists differ in their spectrum of receptor interaction.

**α-BLOCKERS: PHENTOLAMINE**

Phentolamine produces a competitive (reversible) blockade of both α₁- and α₂-receptors. α₁ Antagonism and direct smooth muscle relaxation are responsible for peripheral vasodilation and a decline in arterial blood pressure. The drop in blood pressure provokes reflex tachycardia. This tachycardia is augmented by antagonism of presynaptic α₂-receptors in the heart because α₂ blockade promotes norepinephrine release by eliminating negative feedback. These cardiovascular effects are usually apparent within 2 min and last up to 15 min. As with all of the adrenergic antagonists, the extent of the response to receptor blockade depends on the degree of existing sympathetic tone. Reflex tachycardia and postural hypotension limit the usefulness of phentolamine to the treatment of hypertension caused by excessive α stimulation (eg, pheochromocytoma, clonidine withdrawal). Prazosin and phenoxybenzamine are examples of other α-antagonists.

Phentolamine is administered intravenously as intermittent boluses (1–5 mg in adults) or as a continuous infusion. To prevent or minimize tissue necrosis following extravasation of intravenous fluids containing an α-agonist (eg, norepinephrine), 5 to 10 mg of phentolamine in 10 mL of normal saline can be locally infiltrated. Phentolamine has been used in combination with norepinephrine for inotropic support in heart surgery, to block excessive hypertension during resection of pheochromocytoma, and to facilitate cooling prior to circulatory arrest in children undergoing repair of congenital heart lesions.

**MIXED ANTAGONISTS: LABETALOL**

Labetalol blocks α₁-, β₁-, and β₂-receptors. The ratio of α blockade to β blockade has been estimated to be approximately 1:7 following intravenous
administration. This mixed blockade reduces peripheral vascular resistance and arterial blood pressure. Heart rate and cardiac output are usually slightly depressed or unchanged. Thus, labetalol lowers blood pressure without reflex tachycardia because of its combination of α and β effects, which is beneficial to patients with coronary artery disease. Peak effect usually occurs within 5 min after an intravenous dose. Left ventricular failure, paradoxical hypertension, and bronchospasm have been reported.

The initial recommended dose of labetalol is 2.5 to 10 mg administered intravenously over 2 min. After the initial dose, and depending on the response, 5 to 20 mg may be given at 10-min intervals until the desired blood pressure response is obtained.

**β-BLOCKERS**

β-Receptor blockers have variable degrees of selectivity for the β₁-receptors. Those that are more β₁ selective have less influence on bronchopulmonary and vascular β₂-receptors (Table 14–3). Theoretically, a selective β₁-blocker would have less of an inhibitory effect on β₂-receptors and, therefore, might be preferred in patients with chronic obstructive lung disease or peripheral vascular disease. Patients with peripheral vascular disease could potentially have a decrease in blood flow if β₂-receptors, which dilate the arterioles, are blocked. β-Receptor blocking agents also reduce intraocular pressure in patients with glaucoma.

ISA, intrinsic sympathomimetic activity; +, mild effect; 0, no effect.

β-Blockers are also classified by the amount of intrinsic sympathomimetic activity (ISA) they have. Many of the β-blockers have some agonist activity; although they would not produce effects similar to full agonists (such as epinephrine).
β-Blockers can be further classified as those that are eliminated by hepatic metabolism (such as metoprolol), those that are excreted by the kidneys unchanged (such as atenolol), or those that are hydrolyzed in the blood (such as esmolol).

**ESMOLOL**

Esmolol is an ultrashort-acting selective β₁-antagonist that reduces heart rate and, to a lesser extent, blood pressure. It is used to prevent or minimize tachycardia and hypertension in response to perioperative stimuli, such as intubation, surgical stimulation, and emergence. For example, esmolol (0.5–1 mg/kg) attenuates the rise in blood pressure and heart rate that usually accompanies electroconvulsive therapy, without significantly affecting seizure duration. Esmolol is useful in controlling the ventricular rate of patients with atrial fibrillation or flutter. Although esmolol is considered to be cardioselective, at higher doses it inhibits β₂-receptors in bronchial and vascular smooth muscle.

The short duration of action of esmolol is due to rapid redistribution (distribution half-life is 2 min) and hydrolysis by red blood cell esterase (elimination half-life is 9 min). Side effects can be reversed within minutes by discontinuing its infusion. As with all β₁-antagonists, esmolol should be avoided in patients with sinus bradycardia, heart block greater than first degree, cardiogenic shock, or uncompensated, low ejection fraction heart failure.

Esmolol is administered as a bolus (0.2–0.5 mg/kg) for short-term therapy, such as attenuating the cardiovascular response to laryngoscopy and intubation. Long-term treatment is typically initiated with a loading dose of 0.5 mg/kg administered over 1 min, followed by a continuous infusion of 50 mcg/kg/min to maintain therapeutic effect. If this fails to produce a sufficient response within 5 min, the loading dose may be repeated and the infusion increased by increments of 50 mcg/kg/min every 5 min to a maximum of 200 mcg/kg/min.

Esmolol is supplied as multidose vials for bolus administration containing 10 mL of drug (10 mg/mL). Ampules for continuous infusion (2.5 g in 10 mL) are also available but must be diluted prior to administration to a concentration of 10 mg/mL.

**METOPROLOL**

Metoprolol is a selective β₁-antagonist with no intrinsic sympathomimetic activity. It is available for both oral and intravenous use. It can be administered
intravenously in 1 to 5 mg increments every 2 to 5 min, titrated to blood pressure and heart rate.

**PROPRANOLOL**

Propranolol nonselectively blocks β₁- and β₂-receptors. Arterial blood pressure is lowered by several mechanisms, including decreased myocardial contractility, lowered heart rate, and diminished renin release. Cardiac output and myocardial oxygen demand are reduced. Propranolol slows atrioventricular conduction and slows the ventricular response to supraventricular tachycardia.

Side effects of propranolol include bronchospasm (β₂ antagonism), acute congestive heart failure, bradycardia, and atrioventricular heart block (β₁ antagonism). Concomitant administration of propranolol and verapamil (a calcium channel blocker) can synergistically depress heart rate, contractility, and atrioventricular node conduction.

Propranolol’s elimination half-life of 100 min is quite long compared with that of esmolol. Generally, propranolol is titrated to effect in 0.5 mg increments every 3 to 5 min. Total doses rarely exceed 0.15 mg/kg. Propranolol is supplied in 1-mL ampules containing 1 mg.

**NEBIVOLOL**

Nebivolol is a newer generation β-blocker with high affinity for β₁-receptors. The drug is unique in its ability to cause direct vasodilation via its stimulatory effect on endothelial nitric oxide synthase.

**CARVEDILOL**

Carvedilol is a mixed β- and α-blocker used in the management of chronic heart failure secondary to cardiomyopathy, left ventricular dysfunction following acute myocardial infarction, and hypertension. Carvedilol dosage is individualized and gradually increased up to 25 mg twice daily, as required and tolerated. Bisoprolol and sustained-release metoprolol are also used in long-term therapy to reduce mortality in patients with reduced ejection fraction heart failure.

**PERIOPERATIVE β-BLOCKER THERAPY**

Management of β-blockers perioperatively has been a key anesthesia
performance indicator and is closely monitored by various “quality management” agencies. Although studies regarding the perioperative administration of β-blockers have yielded conflicting results as to benefit versus harm, maintenance of β-blockers in patients already being treated with them is essential, unless contraindicated by other clinical concerns. Initial small trials did not demonstrate adverse outcomes from initiation of perioperative β-blocker therapy. Subsequent studies either demonstrated no benefit or actual harm (eg, stroke) when β blockade was begun perioperatively. Consequently, guidelines continue to be revised as new evidence is evaluated.

The 2014 American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend continuation of β-blocker therapy during the perioperative period in patients who are receiving them chronically (class I benefit >>> risk). β-Blocker therapy postoperatively should be guided by clinical circumstances (class IIa benefit >> risk). Irrespective of when β-blocker therapy was started, therapy may need to be temporarily discontinued (eg, bleeding, hypotension, bradycardia). The ACC/AHA guidelines suggest that it may be reasonable to begin perioperative β-blockers in patients at intermediate or high risk for myocardial ischemia (class IIb benefit ≥ risk). Other conditions such as risk of stroke or uncompensated heart failure should be considered in discerning if β-blockade should be initiated perioperatively. Additionally, in patients with three or more Revised Cardiac Risk Index risk factors (see Chapter 21), it may be reasonable to begin β-blocker therapy before surgery (class IIb). Lacking these risk factors, it is unclear whether preoperative β-blocker therapy is effective or safe. Should it be decided to begin β-blocker therapy, the ACC/AHA guidelines suggest that it is reasonable to start therapy sufficiently in advance of the surgical procedure to assess safety and tolerability of treatment (class IIb).

Lastly, β-blockers should not be initiated in β-blocker naïve patients on the day of surgery (class III: harm).

Abrupt discontinuation of β-blocker therapy for 24 to 48 h may trigger a withdrawal syndrome characterized by rebound hypertension, tachycardia, and angina pectoris. This effect seems to be caused by an increase in the number of β-adrenergic receptors (upregulation).

CASE DISCUSSION

Pheochromocytoma
A 45-year-old man with a history of paroxysmal attacks of headache, hypertension, sweating, and palpitations is scheduled for resection of an abdominal pheochromocytoma.

What is a pheochromocytoma?

A pheochromocytoma is a vascular tumor of chromaffin tissue (most commonly the adrenal medulla) that produces and secretes norepinephrine and epinephrine. The diagnosis and management of pheochromocytoma are based on the effects of abnormally high circulating levels of these endogenous adrenergic agonists.

How is the diagnosis of pheochromocytoma made in the laboratory?

Urinary excretion of vanillylmandelic acid (an end product of catecholamine metabolism), norepinephrine, and epinephrine is often markedly increased. Elevated levels of urinary catecholamines and metanephrines (Figure 14–3) provide a highly accurate diagnosis. Fractionated plasma-free metanephrine levels may be superior to urinary studies in making the diagnosis. The location of the tumor can be determined by magnetic resonance imaging or computed tomographic scan with or without contrast.

What pathophysiology is associated with chronic elevations of norepinephrine and epinephrine?

\( \alpha_1 \) Stimulation increases peripheral vascular resistance and arterial blood pressure. Hypertension can lead to intravascular volume depletion (increasing hematocrit), renal failure, and cerebral hemorrhage. Elevated peripheral vascular resistance also increases myocardial work, which predisposes patients to myocardial ischemia, ventricular hypertrophy, and congestive heart failure. Prolonged exposure to epinephrine and norepinephrine may lead to a catecholamine-induced cardiomyopathy. Hyperglycemia results from decreased insulin secretion in the face of increased glycogenolysis and gluconeogenesis. \( \beta_1 \) Stimulation increases automaticity and ventricular ectopy.

Which adrenergic antagonists might be helpful in controlling the effects of norepinephrine and epinephrine hypersecretion?
Phenoxybenzamine, an $\alpha_1$-antagonist, effectively reverses the vasoconstriction, resulting in a drop in arterial blood pressure and an increase in intravascular volume (hematocrit drops). Glucose intolerance is often corrected. Phenoxybenzamine can be administered orally and is longer acting than phentolamine, another $\alpha_1$-antagonist. For these reasons, phenoxybenzamine is often administered preoperatively to control symptoms.

Intravenous phentolamine has been used intraoperatively to control hypertensive episodes. Compared with some other hypotensive agents, however, phentolamine has a slow onset and long duration of action; furthermore, the agent no longer is widely available. Other vasodilators can be used in this circumstance.

$\beta_1$ Blockade is recommended after initiation of $\alpha$ blockade for patients with tachycardia or ventricular arrhythmias.

*Why should $\alpha_1$-receptors be blocked with phenoxybenzamine before administration of a $\beta$-antagonist?*

If $\beta$-receptors are blocked first, norepinephrine and epinephrine will produce unopposed $\alpha$ stimulation. $\beta_2$-Mediated vasodilation will not be able to offset $\alpha_1$ vasoconstriction, and peripheral vascular resistance would increase. This may explain the paradoxical hypertension that has been reported in a few patients with pheochromocytoma treated only with labetalol. Finally, the myocardium might not be able to handle its already elevated workload without the inotropic effects of $\beta_1$ stimulation.

*Which anesthetic agents should be specifically avoided?*

Ketamine is a sympathomimetic and might exacerbate the effects of adrenergic agonists. Halothane sensitizes the myocardium to the arrhythmogenic effects of epinephrine. Vagolytic drugs (eg, anticholinergics and pancuronium) may contribute to tachycardia. Because histamine provokes catecholamine secretion by the tumor, drugs associated with histamine release (eg, atracurium) are best avoided. Vecuronium and rocuronium are probably the neuromuscular blocking agents of choice.

*Would an epidural or spinal technique effectively block sympathetic hyperactivity?*
A major regional block—such as an epidural or spinal anesthetic—could block sensory (afferent) nerves and sympathetic (efferent) discharge in the area of the surgical field. However, the catecholamines released from a pheochromocytoma during surgical manipulation would still be able to bind and activate adrenergic receptors throughout the body.

GUIDELINES

SUGGESTED READINGS

Inhaled nitric oxide is a selective pulmonary vasodilator that is used in the treatment of reversible pulmonary hypertension.

Acute cyanide toxicity is characterized by metabolic acidosis, cardiac arrhythmias, and increased venous oxygen content (as a result of the inability to utilize oxygen). Another early sign of cyanide toxicity is the acute resistance to the hypotensive effects of increasing doses of sodium nitroprusside (tachyphylaxis).

By dilating pulmonary vessels, sodium nitroprusside may prevent the normal vasoconstrictive response of the pulmonary vasculature to hypoxia (hypoxic pulmonary vasoconstriction).

Preload reduction makes nitroglycerin an excellent drug for the relief of cardiogenic pulmonary edema.

Hydralazine relaxes arteriolar smooth muscle in multiple ways, including dilation of precapillary resistance vessels via increased cyclic guanosine 3’,5’-monophosphate.

The body reacts to a hydralazine-induced fall in blood pressure by increasing heart rate, myocardial contractility, and cardiac output. These compensatory responses can be detrimental to patients with coronary artery disease and are minimized by the concurrent administration of a β-adrenergic antagonist.

Fenoldopam (infusion rates studied in clinical trials range from 0.01 to 1.6 mcg/kg/min) reduces systolic and diastolic blood pressure in patients with malignant hypertension to an extent comparable to nitroprusside.

Dihydropyridine calcium channel blockers preferentially dilate arterial vessels, often preserving or increasing cardiac output.
A multitude of drugs are capable of lowering blood pressure, including volatile anesthetics, sympathetic antagonists and agonists, calcium channel blockers, β-blockers, and angiotensin-converting enzyme inhibitors. This chapter examines agents that may be useful to the anesthesiologist for perioperative control of arterial blood pressure.

As patients age, so too does their vasculature. When a pulse wave is generated by ventricular contraction, it is propagated through the arterial system. At branch points of the aorta, the wave is reflected back toward the heart. In younger patients, the reflected wave tends to augment diastole, improving diastolic pressure. In older patients, the wave arrives sooner, being conducted back by the noncompliant vasculature during late systole, which causes an increase in cardiac workload and a decrease in diastolic pressure (Figure 15–1). Thus, older patients develop increased systolic pressure and decreased diastolic pressure. Widened pulse pressures (the difference between systolic and diastolic pressures) have been associated with both increased incidence of postoperative kidney dysfunction and increased risk of cerebral events in patients undergoing coronary bypass surgery.
FIGURE 15–1 Illustration of the influence of increased vascular stiffness on peripheral (radial) and central (aortic) pressures. Note the similarity of peripheral radial pressures in individuals with normal (lower left panel) and increased (upper left panel) vascular stiffness. In young individuals with normal vascular stiffness, central aortic pressures are lower than radial pressures (lower panels). In contrast, in older individuals with increased vascular stiffness, central aortic pressures are increased and can approach or equal peripheral pressures as a result of wave reflection and central wave augmentation during systole (top panels).

β-Blocker therapy should be maintained perioperatively in patients who are being treated with β-blockers as a part of their routine medical regimen. The American College of Cardiology/American Heart Association guidelines for β-blocker use perioperatively should be followed (see Chapter 14). β-Blockers (esmolol, metoprolol, and others) were previously discussed for the treatment of
transient perioperative hypertension and are routinely used during anesthesia. This chapter discusses antihypertensive agents other than adrenergic antagonists that are used perioperatively. Antihypertensive agents are critically important for managing hypertensive emergencies (blood pressure >180/120 mm Hg) with signs of organ injury (eg, encephalopathy). Excepting patients with acute aortic dissection, mean arterial pressure should be reduced gradually to prevent organ hypoperfusion (eg, 20% decrease in mean arterial pressure or a diastolic blood pressure of 100–110 mm Hg initially). Prompt treatment of hypertension is also advisable following cardiac and intracranial surgery and other procedures where excessive bleeding is a major concern. Perioperative hypertension is often secondary to pain, anxiety, hypoxemia, hypercapnia, distended bladder, and failure to continue baseline antihypertensive medications. These primary etiologies should be considered and addressed when treating perioperative hypertension.

Blood pressure is the product of cardiac output and systemic vascular resistance. Agents that lower blood pressure reduce myocardial contractility or produce vasodilatation of the arterial and venous capacitance vessels, or both. Agents other than β-adrenergic blockers used to lower blood pressure include nitrovasodilators, calcium antagonists, adrenergic agonists, anesthetic agents, and angiotensin-converting enzyme inhibitors.

**SODIUM NITROPRUSSIDE**

**Mechanism of Action**

Sodium nitroprusside (and other nitrovasodilators) relax both arteriolar and venous smooth muscle. Its primary mechanism of action is shared with other nitrates (eg, hydralazine and nitroglycerin). As nitrovasodilators are metabolized, they release nitric oxide, which activates guanylyl cyclase. This enzyme is responsible for the synthesis of cyclic guanosine 3’,5’-monophosphate (cGMP), which controls the phosphorylation of several proteins, including some involved in the control of free intracellular calcium and smooth muscle contraction.

Nitric oxide, a naturally occurring potent vasodilator released by endothelial cells (endothelium-derived relaxing factor), plays an important role in regulating vascular tone throughout the body. Its ultrashort half-life (<5 s) provides nimble endogenous control of regional blood flow. Inhaled nitric oxide is a selective pulmonary vasodilator that is used in the treatment of reversible pulmonary
hypertension.

**Clinical Uses**

Sodium nitroprusside is a potent and reliable antihypertensive. It is usually diluted to a concentration of 100 mcg/mL and administered as a continuous intravenous infusion (0.25–5 mcg/kg/min). Its extremely rapid onset of action (1–2 min) and fleeting duration of action allow precise titration of arterial blood pressure. The potency of this drug requires frequent blood pressure measurements—or, preferably, intraarterial monitoring—and the use of mechanical infusion pumps. Solutions of sodium nitroprusside must be protected from light because of photodegradation.

**Metabolism**

After parenteral injection, sodium nitroprusside enters red blood cells, where it receives an electron from the iron (Fe^{2+}) of oxyhemoglobin. This nonenzymatic electron transfer results in an unstable nitroprusside radical and methemoglobin (Hgb Fe^{3+}). The former moiety spontaneously decomposes into five cyanide ions and the active nitroso (N ≡ O) group.

The cyanide ions can be involved in one of three possible reactions: (1) binding to methemoglobin to form cyanmethemoglobin; (2) undergoing a reaction in the liver and kidney catalyzed by the enzyme rhodanase (thiosulfate + cyanide → thiocyanate); or (3) binding to tissue cytochrome oxidase, which interferes with normal oxygen utilization (Figure 15–2).

**FIGURE 15–2** The metabolism of sodium nitroprusside.

The last of these reactions underlies the development of acute cyanide
toxicity, characterized by metabolic acidosis, cardiac arrhythmias, and increased venous oxygen content (as a result of the inability to utilize oxygen). Another early sign of cyanide toxicity is the acute resistance to the hypotensive effects of increasing doses of sodium nitroprusside (tachyphylaxis). Cyanide toxicity is more likely if the cumulative daily dose of sodium nitroprusside is greater than 500 mcg/kg or if the drug is administered at infusion rates greater than 2 mcg/kg/min for more than a few hours. Patients with cyanide toxicity should be mechanically ventilated with 100% oxygen to maximize oxygen availability. The pharmacological treatment of cyanide toxicity depends on providing alternative binding sites for cyanide ions by administering sodium thiosulfate (150 mg/kg over 15 min) or 3% sodium nitrite (5 mg/kg over 5 min), which oxidizes hemoglobin to methemoglobin. A methemoglobin concentration of 10% to 20% is the aim of nitrite administration. Caution should be exercised when inducing methemoglobinemia in patients experiencing cyanide toxicity secondary to combustion as carboxyhemoglobinemia from carbon monoxide poisoning might also be present. Additionally, hydroxocobalamin combines with cyanide to form cyanocobalamin (vitamin B_{12}) and likewise can be administered to treat cyanide poisoning. Cyanocobalamin is excreted by the kidney.

Thiocyanate is slowly cleared by the kidney. Accumulation of large amounts of thiocyanate (eg, in patients with kidney failure) may result in a milder toxic reaction that includes thyroid dysfunction, muscle weakness, nausea, hypoxia, and an acute toxic psychosis. The risk of cyanide toxicity is not increased by kidney failure, however. Methemoglobinemia from excessive doses of sodium nitroprusside or sodium nitrite can be treated with methylene blue (1–2 mg/kg of a 1% solution over 5 min), which reduces methemoglobin to hemoglobin.

**Effects on Organ Systems**

The combined dilation of venous and arteriolar vascular beds by sodium nitroprusside results in reductions of preload and afterload. Arterial blood pressure falls due to the decrease in peripheral vascular resistance. Although cardiac output is usually unchanged in normal patients, the reduction in afterload may increase cardiac output in patients with congestive heart failure, mitral regurgitation, or aortic regurgitation. In opposition to any favorable changes in myocardial oxygen requirements are reflex-mediated responses to the fall in arterial blood pressure. These include tachycardia and increased myocardial contractility. In addition, dilation of coronary arterioles by sodium nitroprusside may result in an **intracoronary steal** of blood flow away from ischemic areas.
that are already maximally dilated.

Sodium nitroprusside dilates cerebral vessels and abolishes cerebral autoregulation. Cerebral blood flow is maintained or increases unless arterial blood pressure is markedly reduced. The resulting increase in cerebral blood volume tends to increase intracranial pressure, particularly in patients with reduced intracranial compliance (eg, brain tumors). This intracranial hypertension can be minimized by slow administration of sodium nitroprusside and institution of hypocapnia.

The pulmonary vasculature also dilates in response to sodium nitroprusside infusion. Reductions in pulmonary artery pressure may decrease the perfusion of some normally ventilated alveoli, increasing physiological dead space. By dilating pulmonary vessels, sodium nitroprusside may prevent the normal vasoconstrictive response of the pulmonary vasculature to hypoxia (hypoxic pulmonary vasoconstriction). Both of these effects tend to mismatch pulmonary ventilation to perfusion, increase venous admixture, and decrease arterial oxygenation.

In response to decreased arterial blood pressure, renin and catecholamines are released during administration of nitroprusside. Renin release can be inhibited with β-blockers. Kidney function is fairly well maintained during sodium nitroprusside infusion, despite moderate drops in arterial blood pressure and renal perfusion.

**NITROGLYCERIN**

**Mechanism of Action**

Nitroglycerin relaxes vascular smooth muscle, with venous dilation predominating over arterial dilation. Its mechanism of action is similar to that of sodium nitroprusside: metabolism to nitric oxide, which activates guanylyl cyclase, leading to increased cGMP, decreased intracellular calcium, and vascular smooth muscle relaxation.

**Clinical Uses**

Nitroglycerin relieves myocardial ischemia, hypertension, and ventricular failure. Like sodium nitroprusside, nitroglycerin is commonly diluted to a concentration of 100 mcg/mL and administered as a continuous intravenous infusion (0.5–5 mcg/kg/min). In the past glass containers and special intravenous
tubing were recommended because of the adsorption of nitroglycerin to polyvinylchloride, but these are now rarely used. Nitroglycerin can also be administered by a sublingual (peak effect in 4 min) or transdermal (sustained release for 24 h) route.

**Metabolism**

Nitroglycerin undergoes rapid reductive hydrolysis in the liver and blood by glutathione-organic nitrate reductase. One metabolic product is nitrite, which can convert hemoglobin to methemoglobin. Significant methemoglobinemia is rare and can be treated with intravenous methylene blue (1–2 mg/kg over 5 min).

Nitroglycerin reduces myocardial oxygen demand and increases myocardial oxygen supply by several mechanisms:

- The pooling of blood in the large-capacitance vessels reduces the effective circulating blood volume and preload. The accompanying decrease in ventricular end-diastolic pressure reduces myocardial oxygen demand and increases endocardial perfusion.
- Any afterload reduction from arteriolar dilation will decrease both end-systolic pressure and oxygen demand. Of course, a fall in diastolic pressure may lower coronary perfusion pressure and actually decrease myocardial oxygen supply.
- Nitroglycerin redistributes coronary blood flow to ischemic areas of the subendocardium.
- Coronary artery spasm may be relieved.

The beneficial effect of nitroglycerin in patients with coronary artery disease contrasts with the coronary steal phenomenon seen with sodium nitroprusside. Preload reduction makes nitroglycerin an excellent drug for the relief of cardiogenic pulmonary edema. Heart rate is unchanged or minimally increased. Rebound hypertension is less likely after discontinuation of nitroglycerin than following discontinuation of sodium nitroprusside. The prophylactic administration of low-dose nitroglycerin to high-risk patients undergoing surgery and anesthesia has no proven benefit.

The effects of nitroglycerin on cerebral blood flow and intracranial pressure are similar to those of sodium nitroprusside. Headache from dilation of cerebral vessels is a common side effect of nitroglycerin. In addition to the dilating effects on the pulmonary vasculature (previously described for sodium nitroprusside), nitroglycerin relaxes bronchial smooth muscle.
Nitroglycerin (50–100 mcg boluses) has been demonstrated to be an effective (but transient) uterine relaxant that can be beneficial during certain obstetrical procedures if the placenta is still present in the uterus (eg, retained placenta, uterine inversion, uterine tetany, breech extraction, and external version of the second twin). Nitroglycerin therapy has been shown to diminish platelet aggregation.

**HYDRAZINE**

Hydralazine relaxes arteriolar smooth muscle in multiple ways, including dilation of precapillary resistance vessels via increased cGMP.

Intraoperative hypertension is sometimes controlled with an intravenous dose of 5 to 20 mg of hydralazine. The onset of action is within 15 min, and the antihypertensive effect usually lasts 2 to 4 h. The delayed onset and prolonged duration have made this agent much less attractive than others for perioperative use. Hydralazine can be used to control pregnancy-induced hypertension.

Hydralazine undergoes acetylation and hydroxylation in the liver.

**Effects on Organ Systems**

The lowering of peripheral vascular resistance causes a drop in arterial blood pressure. The body reacts to a hydralazine-induced fall in blood pressure by increasing heart rate, myocardial contractility, and cardiac output. These compensatory responses can be detrimental to patients with coronary artery disease and are minimized by the concurrent administration of a β-adrenergic antagonist. Conversely, the decline in afterload often proves beneficial to patients in congestive heart failure.

Hydralazine is a potent cerebral vasodilator and inhibitor of cerebral blood flow autoregulation. Unless blood pressure is markedly reduced, cerebral blood flow and intracranial pressure will rise.

Renal blood flow is usually maintained or increased by hydralazine.

**FENOLDOPAM**

**Mechanism of Action**

Fenoldopam causes rapid vasodilation by selectively activating D₁-dopamine receptors. The R-isomer is responsible for the racemic mixture’s biological
activity due to its much greater receptor affinity, compared with the S-isomer.

**Clinical Uses**

Fenoldopam (infusion rates studied in clinical trials range from 0.01 to 1.6 mcg/kg/min) reduces systolic and diastolic blood pressure in patients with malignant hypertension to an extent comparable to nitroprusside. Side effects include headache, flushing, nausea, tachycardia, hypokalemia, and hypotension. The onset of the hypotensive effect occurs within 15 min, and discontinuation of an infusion quickly reverses this effect without rebound hypertension. Some degree of tolerance may develop 48 h after the infusion. Studies are mixed regarding fenoldopam’s ability to “protect” and “maintain” kidney function in perioperative patients with hypertension at risk of perioperative kidney injury.

**Metabolism**

Fenoldopam undergoes conjugation without participation of the cytochrome P-450 enzymes, and its metabolites are inactive. Clearance of fenoldopam remains unaltered despite the presence of kidney or hepatic failure, and no dosage adjustments are necessary for these patients.

**Effects on Organ Systems**

Fenoldopam decreases systolic and diastolic blood pressure. Heart rate typically increases. Low initial doses (0.03–0.1 mcg/kg/min) titrated slowly have been associated with less reflex tachycardia than higher doses. Tachycardia decreases over time but remains substantial at higher doses.

Fenoldopam can lead to rises in intraocular pressure and should be administered with caution or avoided in patients with a history of glaucoma or intraocular hypertension.

As would be expected from a D1-dopamine receptor agonist, fenoldopam markedly increases kidney blood flow. Despite a drop in arterial blood pressure, the glomerular filtration rate is well maintained. Fenoldopam increases urinary flow rate, urinary sodium extraction, and creatinine clearance compared with sodium nitroprusside.

**CALCIUM ANTAGONISTS**

Dihydropyridine calcium channel blockers (nicardipine, clevidipine) are
arterial selective vasodilators routinely used for perioperative blood pressure control in patients undergoing cardiothoracic surgery. Clevidipine, prepared as a lipid emulsion, has a short half-life secondary to rapid metabolism by blood esterases, which facilitates its rapid titration. Clevidipine is infused initially at a rate of 1 to 2 mg/h, with the dose doubled until the desired effect is obtained, up to 16 mg/h. Because of its formulation as a lipid emulsion it is contraindicated in patients with soy or egg allergies and those with impaired lipid metabolism. Unlike verapamil and diltiazem, the dihydropyridine calcium channel blockers have minimal effects on cardiac conduction and ventricular contractility. These calcium channel blockers bind to L-type calcium channel and impair calcium entry into the vascular smooth muscle. L-type receptors are more prevalent on arterial than venous capacitance vessels. Consequently, cardiac filling and preload are less affected by these agents than by nitrates, which might dilate both arterial and venous systems. With preload maintained, cardiac output often increases when vascular tone is reduced by use of dihydropyridine calcium blockers. Nicardipine infusion is titrated to effect (5–15 mg/h).

Another intravenous agent that can produce hypotension perioperatively is the intravenous angiotensin-converting enzyme inhibitor enalaprilat (0.625–1.25 mg). The role of enalaprilat as a nondirect-acting agent in the acute treatment of a hypertensive crisis is limited.

**CASE DISCUSSION**

**Controlled Hypotension**

A 59-year-old man is scheduled for total hip arthroplasty under general anesthesia. The surgeon requests a controlled hypotensive technique.

**What is controlled hypotension, and what are its advantages?**

Controlled hypotension is the elective lowering of arterial blood pressure. The primary advantages of this technique are minimization of surgical blood loss and better surgical visualization.

**How is controlled hypotension achieved?**

The primary methods of electively lowering blood pressure are use of hypotensive anesthetic techniques (eg, neuraxial anesthesia) and the administration of hypotensive drugs. Elevation of the surgical site can
selectively reduce the blood pressure at the wound. During general anesthesia the increase in intrathoracic pressure that accompanies positive-pressure ventilation impedes venous return to the heart, lowering cardiac output and mean arterial pressure. Numerous pharmacological agents effectively lower blood pressure: volatile anesthetics, spinal and epidural anesthesia, sympathetic antagonists, calcium channel blockers, and the peripheral vasodilators discussed in this chapter.

**Which surgical procedures might benefit most from a controlled hypotensive technique?**

Controlled hypotension has been successfully used during cerebral aneurysm repair, brain tumor resection, total hip arthroplasty, radical neck dissection, radical cystectomy, major spine surgery, and other operations associated with significant blood loss. Controlled hypotension may allow safer surgery of patients whose religious beliefs prohibit blood transfusions (eg, Jehovah’s Witnesses).

**What are some relative contraindications to controlled hypotension?**

Some patients have predisposing illnesses that decrease the margin of safety for adequate organ perfusion: severe anemia, hypovolemia, atherosclerotic cardiovascular disease, renal or hepatic insufficiency, cerebrovascular disease, or uncontrolled glaucoma.

**What are the possible complications of controlled hypotension?**

As the preceding list of contraindications suggests, the risks of low arterial blood pressure include cerebral thrombosis, hemiplegia (due to decreased spinal cord perfusion), acute tubular necrosis, massive hepatic necrosis, myocardial infarction, cardiac arrest, and blindness (from retinal artery thrombosis or ischemic optic neuropathy). These complications are more likely in patients with coexisting anemia. Consequently, the use of induced or controlled hypotension continues to decline. Patients requiring beach chair positioning for shoulder surgery or sitting position are at particular risk for cerebral hypoperfusion and perioperative cerebral infarction.

**What is a safe level of hypotension?**

This depends on the patient. Healthy young individuals may tolerate
mean arterial pressures as low as 50 to 60 mm Hg without complications. On the other hand, chronically hypertensive patients have altered autoregulation of cerebral blood flow and may tolerate a mean arterial pressure of no more than 20% to 30% lower than baseline. Patients with a history of transient ischemic attacks may not tolerate any decline in cerebral perfusion. Recent studies suggest that the lower limit of cerebral autoregulation may be at a much higher mean arterial pressure than long has been assumed.

**What special monitoring is indicated during controlled hypotension?**

Intraarterial blood pressure monitoring correctly positioned to determine mean arterial pressure at the brain is suggested. Likewise, cerebral oximetry can be employed if hypotensive anesthesia techniques are to be considered.

**SUGGESTED READINGS**

Voltage-gated sodium (Na) channels are membrane-associated proteins that comprising one large α subunit, through which Na ions pass, and one or two smaller β subunits. Na channels exist in (at least) three states—resting (nonconducting), open (conducting), and inactivated (nonconducting). Local anesthetics bind and inhibit a specific region of the α subunit, preventing channel activation and the Na influx associated with membrane depolarization.

Sensitivity of nerve fibers to inhibition by local anesthetics is influenced by axonal diameter, myelination, and other factors.

Clinical local anesthetic potency correlates with octanol solubility and the ability of the local anesthetic molecule to permeate lipid membranes. Potency is increased by adding large alkyl groups to a parent molecule. There is no clinical measurement of local anesthetic potency that is analogous to the minimum alveolar concentration (MAC) of inhalation anesthetics.

Onset of action depends on many factors, including lipid solubility and the relative concentration of the nonionized, more lipid-soluble free-base form (B) and the ionized more water-soluble form (BH\(^+\)), expressed by the pK\(_a\). The pK\(_a\) is the pH at which there is an equal fraction of ionized and nonionized drug. Less potent, less lipid-soluble agents (eg, lidocaine or mepivacaine) generally have a faster onset than more potent, more lipid-soluble agents (eg, ropivacaine or bupivacaine).

Duration of action correlates with potency and lipid solubility. Highly lipid-soluble local anesthetics have a longer duration of action, presumably because they more slowly diffuse from a lipid-rich environment to the aqueous bloodstream.
In regional anesthesia local anesthetics are typically applied close to their intended site of action; thus their pharmacokinetic profiles in blood are important determinants of elimination and toxicity and have very little to do with the duration of their desired clinical effect.

The rates of local anesthetic systemic absorption and rise of local anesthetic concentrations in blood are related to the vascularity of the site of injection, and generally follow this rank order: intravenous (or intraarterial) > tracheal > intercostal > paracervical > epidural > brachial plexus > sciatic > subcutaneous.

Ester local anesthetics are metabolized predominantly by pseudocholinesterase. Amide local anesthetics are metabolized (N-dealkylation and hydroxylation) by microsomal P-450 enzymes in the liver.

In awake patients rising local anesthetic concentrations in the central nervous system produce the premonitory signs of local anesthetic intoxication.

Major cardiovascular toxicity usually requires about three times the local anesthetic concentration in blood as that required to produce seizures.

Unintended intravascular injection of bupivacaine during regional anesthesia may produce severe cardiovascular toxicity, including left ventricular depression, atrioventricular heart block, and life-threatening arrhythmias such as ventricular tachycardia and fibrillation.

True hypersensitivity reactions (due to IgG or IgE antibodies) to local anesthetics—as distinct from systemic toxicity caused by excessive plasma concentrations—are uncommon. Esters appear more likely to induce an allergic reaction, especially if the compound is a derivative (eg, procaine or benzocaine) of p-aminobenzoic acid, a known allergen.

Local and regional anesthesia and analgesia techniques depend on a group of drugs—local anesthetics—that transiently inhibit some or all of sensory, motor, or autonomic nerve function when the drugs are applied near neural tissue. This chapter presents the mechanism of action, structure–activity relationships, and clinical pharmacology of local anesthetic drugs. The more commonly used regional anesthetic techniques are presented elsewhere (see Chapters 45 and 46).

**MECHANISMS OF LOCAL ANESTHETIC**
**ACTION**

Neurons (and all other living cells) maintain a resting membrane potential of −60 to −70 mV. The electrogenic, energy-consuming sodium–potassium pump (Na\(^+\)-K\(^+\)-ATPase) couples the transport of three sodium (Na) ions out of the cell for every two potassium (K) ions it moves into the cell. This creates a concentration gradient that favors the movement of K ions from an intracellular to an extracellular location, and the movement of Na ions in the opposite direction. The cell membrane is normally much more “leaky” to K ions than to Na ions, so a relative excess of negatively charged ions (anions) accumulates intracellularly. This accounts for the negative resting membrane potential.

Excitable cells (e.g., neurons or cardiac myocytes) have the unusual capability of generating action potentials. Membrane-associated, voltage-gated Na channels in peripheral nerve axons can produce and transmit membrane depolarizations following chemical, mechanical, or electrical stimuli. Activation of voltage-gated Na channels causes a very brief (roughly 1 ms) change in the conformation of the channel, allowing an influx of Na ions and generating an action potential (Figure 16–1). The increase in Na permeability causes temporary depolarization of the membrane potential to +35 mV. The Na current is brief and is terminated by inactivation of voltage-gated Na channels, which do not conduct Na ions. When there is no Na ion flux the membrane returns to its resting potential. When a stimulus is sufficient to depolarize a patch of membrane, the signal can be transmitted as a wave of depolarization along the nerve membrane (an impulse). Baseline concentration gradients are maintained by the sodium–potassium pump, and only a minuscule number of Na ions pass into the cell during an action potential.
FIGURE 16-1 Compound Aα, Aδ, and C fiber action potentials recorded after supramaximal stimulation of a rat sciatic nerve. Note the differing time scale of the recordings. In peripheral nerves, Aδ and C fibers have much slower conduction velocities, and their compound action potentials are longer and of less amplitude when compared with those from Aα fibers. (Reproduced with permission from Butterworth JF 4th, Strichartz GR. The alpha2-adrenergic agonists clonidine and guanfacine produce tonic and phasic block of conduction in rat sciatic nerve fibers. Anesth Analg. 1993 Feb;76(2):295-301.)

The previously mentioned, voltage-gated Na channels are membrane-associated proteins comprising one large α subunit, through which Na ions pass, and one or two smaller β subunits. Na channels exist in (at least) three states—resting (nonconducting), open (conducting), and inactivated (nonconducting) (Figure 16–2). When local anesthetics bind a specific region of the α subunit, they prevent channel activation and Na influx through the individual channels. Local anesthetic binding to Na channels does not alter the resting membrane potential. With increasing local anesthetic concentrations, an increasing fraction of the Na channels in the membrane bind a local anesthetic molecule and cannot conduct Na ions. As a consequence of more channels binding a local anesthetic, the threshold for excitation and impulse conduction in the nerve increases, the rate of rise and the magnitude of the action potential decreases, and impulse conduction velocity slows. At great enough local anesthetic concentrations (when a sufficient fraction of Na channels has bound a local anesthetic), action potentials can no longer be generated and impulse propagation is abolished. Local anesthetics have a greater affinity for the Na channel in the open or inactivated state than in the resting state. Depolarizations lead to open and
inactivated channels; therefore, depolarization favors local anesthetic binding. The fraction of Na channels that bind a local anesthetic increases with frequent depolarization (eg, during trains of impulses). This phenomenon is termed use-dependent block. Put another way, local anesthetic inhibition of Na channels is both voltage (membrane potential) and frequency dependent. Local anesthetic binding is greater when nerve fibers are firing and depolarizing frequently than with infrequent depolarizations.

**FIGURE 16–2** Voltage-gated sodium (Na<sub>v</sub>) channels exist in at least three states—resting, open (activated), and inactivated. Resting Na<sub>v</sub> channels activate and open when they are depolarized, briefly allowing Na ions to pass into the cell down their concentration gradient, then rapidly inactivate. Inactivated Na<sub>v</sub> channels return to the resting state as the cell membrane repolarizes. In the figure, Na ions are shown on the extracellular side of the cell membrane. Extracellular Na ions conduct only through open Na<sub>v</sub> channels that have not bound a local anesthetic molecule. The Na<sub>v</sub> channel binding site for local anesthetics is nearer to the cytoplasmic than the extracellular side of the channel.

Local anesthetics may also bind and inhibit calcium (Ca), K, transient receptor potential vanilloid-1 (TRPV1), and many other channels and receptors. Conversely, other classes of drugs, notably tricyclic antidepressants (amitriptyline), meperidine, volatile anesthetics, Ca channel blockers, α<sub>2</sub>-receptor agonists, and nerve toxins also may inhibit Na channels. Tetrodotoxin and saxitoxin are poisons that specifically bind Na channels at a site on the exterior of the plasma membrane. Human studies are under way with similar toxins to determine whether they might provide effective, prolonged analgesia after local infiltration, particularly when coadministered with local anesthetics.
Sensitivity of nerve fibers to inhibition by local anesthetics is influenced by axonal diameter, myelination, and other factors. Table 16–1 lists the most commonly used classification for nerve fibers. In comparing nerve fibers of the same type (myelinated versus unmyelinated), smaller diameter associates with increased sensitivity to local anesthetics. Thus, larger, faster-conducting Aα fibers are less sensitive to local anesthetics than smaller, slower-conducting Aδ fibers. Larger unmyelinated fibers are less sensitive than smaller unmyelinated fibers. On the other hand, small unmyelinated C fibers are relatively resistant to inhibition by local anesthetics as compared with larger myelinated fibers. In a human peripheral nerve the onset of local anesthetic inhibition generally follow this sequence: autonomic before sensory before motor. But at steady state, if sensory anesthesia is present, usually all modalities are inhibited.

### STRUCTURE–ACTIVITY RELATIONSHIPS

Local anesthetics consist of a lipophilic group (usually an aromatic benzene ring) separated from a hydrophilic group (usually a tertiary amine) by an intermediate chain that includes an ester or amide linkage. The nature of the intermediate chain is the basis of the classification of local anesthetics as either esters or amides (Table 16–2). Articaine, a popular local anesthetic for dentistry in several European countries, is an amide but it contains a thiophene ring rather than a benzene ring. Local anesthetics are weak bases that at physiological pH usually carry a positive charge at the tertiary amine group. Physicochemical properties of local anesthetics depend on the substitutions in the aromatic ring, the type of linkage in the intermediate chain, and the alkyl groups attached to the amine nitrogen.

Clinical local anesthetic potency correlates with octanol solubility and the ability of the local anesthetic molecule to permeate lipid membranes. Potency is increased by adding large alkyl groups to a parent molecule (compare tetracaine with procaine, or bupivacaine with mepivacaine). There is no clinical measurement of local anesthetic potency that is analogous to the minimum alveolar concentration (MAC) of inhalation anesthetics. The minimum concentration of local anesthetic that will block nerve impulse conduction is affected by several factors, including fiber size, type, and myelination; pH (an
acidic environment antagonizes clinical nerve block; frequency of nerve stimulation; and electrolyte concentrations (hypokalemia and hypercalcemia antagonize blockade).

Onset of local anesthetic action depends on many factors, including lipid solubility and the relative concentration of the nonionized, more lipid-soluble free-base form (B) and the ionized water-soluble form (BH⁺), expressed by the pKₐ. The pKₐ is the pH at which there is an equal fraction of ionized and nonionized drug. Less potent, less lipid-soluble agents (eg, lidocaine or mepivacaine) generally have a faster onset than more potent, more lipid-soluble agents (eg, ropivacaine or bupivacaine).

Local anesthetics with a pKₐ closest to physiological pH will have (at physiological pH) a greater fraction of nonionized base that more readily permeates the nerve cell membrane, generally facilitating a more rapid onset of action. It is the lipid-soluble free-base form that more readily diffuses across the neural sheath (epineurium) and through the nerve membrane. Curiously, once the local anesthetic molecule gains access to the cytoplasmic side of the Na channel, it is the charged cation (rather than the nonionized base) that more avidly binds the Na channel. For instance, the pKₐ of lidocaine exceeds physiological pH. Thus, at physiological pH (7.40), more than half the lidocaine will exist as the charged cation form (BH⁺).

The importance of pKₐ in understanding differences among local anesthetics is often overstated. It has been asserted that the onset of action of local anesthetics directly correlates with pKₐ. This is not supported by data; in fact, the agent of fastest onset (2-chloroprocaine) has the greatest pKₐ of all clinically used agents. Other factors, such as ease of diffusion through connective tissue, can affect the onset of action in vivo. Moreover, not all local anesthetics exist in a charged form (eg, benzocaine).

The importance of the ionized and nonionized forms has many clinical implications for those agents that exist in both forms. Local anesthetic solutions are prepared commercially as water-soluble hydrochloride salts (pH 6–7). Because epinephrine is unstable in alkaline environments, commercially formulated local anesthetic solutions containing epinephrine are generally more acidic (pH 4–5) than the comparable “plain” solutions lacking epinephrine. As a direct consequence, these commercially formulated, epinephrine-containing preparations may have a lower fraction of free base and a slower onset than solutions to which the epinephrine is added by the clinician immediately prior to use. Similarly, the extracellular base-to-cation ratio is decreased and onset is
delayed when local anesthetics are injected into acidic (eg, infected) tissues. Some researchers have found that alkanization of local anesthetic solutions (particularly commercially prepared, epinephrine-containing ones) by the addition of sodium bicarbonate (eg, 1 mL 8.4% sodium bicarbonate per 10 mL local anesthetic) speeds the onset and improves the quality of the block. presumably by increasing the fraction of free-base local anesthetic. Interestingly, alkanization also decreases pain during subcutaneous infiltration.

Duration of action correlates with potency and lipid solubility. Highly lipid-soluble local anesthetics have a longer duration of action, presumably because they more slowly diffuse from a lipid-rich environment to the aqueous bloodstream. Lipid solubility of local anesthetics is correlated with plasma protein binding. In blood local anesthetics are mostly bound by $\alpha_1$-acid glycoprotein and to a lesser extent to albumin. Sustained-release systems using liposomes or microspheres can significantly prolong local anesthetic duration of action. Liposomal bupivacaine is approved for local infiltration and analgesia after surgery and has been investigated for prolonged transverse abdominis plane (TAP) and peripheral nerve blocks.

Differential block of sensory but not motor function would be desirable. Unfortunately, only bupivacaine and ropivacaine display some clinically useful selectivity (mostly during onset and offset of block) for sensory nerves; however, the concentrations required for surgical anesthesia almost always result in some motor blockade.

**CLINICAL PHARMACOLOGY**

**Pharmacokinetics**

In regional anesthesia local anesthetics are typically applied close to their intended site of action; thus their pharmacokinetic profiles in blood are important determinants of elimination and toxicity and have very little to do with the duration of their desired clinical effect.

**A. Absorption**

Absorption after topical application depends on the site. Most mucous membranes (eg, tracheal or oropharyngeal mucosa) provide a minimal barrier to local anesthetic penetration, leading to a rapid onset of action. Intact skin, on the other hand, requires topical application of a high concentration of lipid-soluble local anesthetic base to ensure permeation and analgesia. EMLA™ (Eutectic
Mixture of Local Anesthetics) cream was formulated to overcome the obstacles presented by intact skin. It consists of a mixture of lidocaine and prilocaine bases in an emulsion. Depth of analgesia (usually <0.5 cm), duration of action (usually <2 h), and amount of drug absorbed depend on application time, dermal blood flow, and total dose administered. Typically, 1 to 2 g of cream is applied per 10-cm² area of skin. Dermal analgesia sufficient for inserting an intravenous catheter requires about 1 h under an occlusive dressing. EMLA cream should not be used on mucous membranes, broken skin, infants younger than 1 month of age, or patients with a contraindication to either lidocaine or prilocaine.

**Systemic absorption of injected local anesthetics depends on blood flow,** which is determined by the following factors.

1. **Site of injection**—The rates of local anesthetic systemic absorption and rise of local anesthetic concentrations in blood are related to the vascularity of the site of injection and generally follow this rank order: intravenous (or intraarterial) > tracheal > intercostal > paracervical > epidural > brachial plexus > sciatic > subcutaneous.

2. **Presence of additives**—Addition of epinephrine—or less commonly phenylephrine—causes vasoconstriction at the site of administration. The consequent decreased absorption reduces the peak local anesthetic concentration in blood, facilitates neuronal uptake, enhances the quality of analgesia, prolongs the duration of analgesia, and limits toxic side effects. Vasoconstrictors have more pronounced effects on duration of shorter-acting than on longer-acting agents. For example, addition of epinephrine to lidocaine usually extends the duration of anesthesia by at least 50%, but epinephrine has limited effect on the duration of bupivacaine peripheral nerve blocks. Epinephrine and clonidine can also augment analgesia through activation of α₂-adrenergic receptors. Coadministration of dexamethasone or other steroids with local anesthetics can prolong blocks by up to 50%. Mixtures of local anesthetics (eg, ropivacaine and mepivacaine) produce nerve blocks with onset and duration that are intermediate between the two parent compounds.

3. **Local anesthetic agent**—More lipid-soluble local anesthetics that are highly tissue bound are also more slowly absorbed than less lipid-soluble agents. The agents also vary in their intrinsic vasodilator properties.

**B. Distribution**
Distribution depends on organ uptake, which is determined by the following factors.

1. **Tissue perfusion**—The highly perfused organs (brain, lung, liver, kidney, and heart) are responsible for the initial rapid removal of local anesthetics from blood, which is followed by a slower redistribution to a wider range of tissues. In particular, the lung extracts significant amounts of local anesthetic during the “first pass”; consequently, patients with right-to-left cardiac shunts are more susceptible to toxic side effects of lidocaine injected as an antiarrhythmic agent.

2. **Tissue/blood partition coefficient**—Increasing lipid solubility is associated with greater plasma protein binding and also greater tissue uptake of local anesthetics from an aqueous compartment.

3. **Tissue mass**—Muscle provides the greatest reservoir for distribution of local anesthetic agents in the bloodstream because of its large mass.

C. **Biotransformation and Excretion**

The biotransformation and excretion of local anesthetics is defined by their chemical structure. For all compounds very little nonmetabolized local anesthetic is excreted by the kidneys.

1. **Esters**—Ester local anesthetics are predominantly metabolized by pseudocholinesterase (also termed butyrylcholinesterase). Ester hydrolysis is rapid, and the water-soluble metabolites are excreted in the urine. Procaine and benzocaine are metabolized to p-aminobenzoic acid (PABA), which has been associated with rare anaphylactic reactions. Patients with genetically deficient pseudocholinesterase would theoretically be at increased risk for toxic side effects from ester local anesthetics, as metabolism is slower, but clinical evidence for this is lacking, most likely because alternative metabolic pathways are available in the liver. In contrast to other ester anesthetics, cocaine is primarily metabolized (ester hydrolysis) in the liver.

2. **Amides**—Amide local anesthetics are metabolized (N-dealkylation and hydroxylation) by microsomal P-450 enzymes in the liver. The rate of amide metabolism depends on the specific agent (prilocaine > lidocaine > mepivacaine > ropivacaine > bupivacaine) but overall is consistently slower than ester hydrolysis of ester local anesthetics. Decreases in hepatic function (eg, with cirrhosis) or in liver blood flow (eg, congestive heart failure, β-blockers, or H₂-
receptor blockers) will reduce the rate of amide metabolism and potentially predispose patients to having greater blood concentrations and a greater risk of systemic toxicity. Water-soluble local anesthetic metabolites are dependent on renal clearance.

Prilocaine is the only local anesthetic that is metabolized to o-toluidine, which produces methemoglobinemia in a dose-dependent fashion. Classical teaching was that a defined dose of prilocaine (in the range of 10 mg/kg) must be exceeded to produce clinically consequential methemoglobinemia; however, recent studies have shown that younger, healthier patients develop medically important methemoglobinemia after lower doses of prilocaine (and at lower doses than needed in older, sicker patients). Prilocaine currently has limited use in North America, but is more commonly used in other regions. Benzocaine, a common ingredient in topical local anesthetic sprays, can also cause dangerous levels of methemoglobinemia. For this reason, many hospitals no longer permit benzocaine spray during endoscopic procedures. Treatment of medically important methemoglobinemia includes intravenous methylene blue (1–2 mg/kg of a 1% solution over 5 min). Methylene blue reduces methemoglobin (Fe\(^{3+}\)) to hemoglobin (Fe\(^{2+}\)).

**Effects on Organ Systems**

Because voltage-gated Na channels underlie action potentials in neurons throughout the body as well as impulse generation and conduction in the heart, it is not surprising that local anesthetics in high circulating concentrations could produce systemic toxicity. Although organ system effects are discussed for these drugs as a group, individual drugs differ.

Potency at most toxic side effects correlates with local anesthetic potency at nerve blocks. “Maximum safe doses” are listed in **Table 16–3**, but it must be recognized that the maximum safe dose depends on the patient, the specific nerve block, the rate of injection, and a long list of other factors. In other words, tables of purported maximal safe doses are nearly nonsensical. Mixtures of local anesthetics should be considered to have additive toxic effects; therefore, injecting a solution combining 50% of a toxic dose of lidocaine and 50% of a toxic dose of bupivacaine likely will produce toxic effects.

**TABLE 16–3  Clinical use of local anesthetic agents.**
## A. Neurological

The central nervous system is vulnerable to local anesthetic systemic toxicity and there are premonitory signs and symptoms of rising local anesthetic concentrations in blood in awake patients. Such symptoms include circumoral numbness, tongue paresthesia, dizziness, tinnitus, blurred vision, and a feeling of impending doom. Such signs include restlessness, agitation, nervousness, and garrulousness. Muscle twitching precedes tonic–clonic seizures. Still higher blood concentrations may produce central nervous system depression (e.g., coma and respiratory arrest). The excitatory reactions are thought to be the result of selective blockade of inhibitory pathways. Potent, highly lipid-soluble local anesthetics produce seizures at lower blood concentrations than less potent agents. Benzodiazepines, propofol, and hyperventilation raise the threshold of local anesthetic-induced seizures. Both respiratory and metabolic acidosis reduce the seizure threshold. Propofol (0.5–2 mg/kg) quickly and reliably terminates seizure activity (as do comparable doses of benzodiazepines or barbiturates). Some clinicians use intravenous lipid to terminate local anesthetic-induced seizures (see below). Maintaining a clear airway with adequate ventilation and oxygenation is most important.

$^1$Wide variation depending on concentration, location, technique, and whether combined with a vasoconstrictor (epinephrine). Generally, the shortest duration is with spinal anesthesia and the longest with peripheral nerve blocks.

$^2$No longer recommended for topical anesthesia.

$^3$NA, not applicable or not defined.

$^4$Recent literature describes this agent for short-duration spinal anesthetics.

---

The table above provides information on local anesthetics, including their techniques, concentrations available, maximum doses, and typical durations of nerve blocks. However, the focus here is on the neurological aspects, especially the signs and symptoms of local anesthetic toxicity, and the management strategies such as the use of benzodiazepines, propofol, and hyperventilation. It is crucial to maintain a clear airway and ensure adequate ventilation and oxygenation to prevent complications.
Infused local anesthetics have a variety of actions. Lidocaine infusions have been used to inhibit ventricular arrhythmias. Systemically administered local anesthetics such as lidocaine (1.5 mg/kg) can decrease cerebral blood flow and attenuate the rise in intracranial pressure that may accompany intubation in patients with decreased intracranial compliance. Infusions of lidocaine and procaine have been used to supplement general anesthetic techniques, as they are capable of reducing the MAC of volatile anesthetics by up to 40%. Infusions of lidocaine inhibit inflammation and reduce postoperative pain. In some studies infused lidocaine reduces postoperative opioid requirements sufficiently to reduce length of stay after surgery.

Cocaine stimulates the central nervous system and at moderate doses usually causes a sense of euphoria. An overdose is heralded by restlessness, emesis, tremors, convulsions, arrhythmias, respiratory failure, and cardiac arrest.

In the past, unintentional injection of large volumes of chloroprocaine into the subarachnoid space (during attempts at epidural anesthesia) produced total spinal anesthesia, marked hypotension, and prolonged neurological deficits. The cause of this neural toxicity may be direct neurotoxicity or a combination of the low pH of chloroprocaine and a preservative, sodium bisulfite. Chloroprocaine has also been occasionally associated with unexplained severe back pain following epidural administration. Chloroprocaine is available in a preservative (bisulfite)-free formulation that has been used safely and successfully for many thousands of brief spinal anesthetics.

Administration of 5% lidocaine has been associated with neurotoxicity (cauda equina syndrome) after use in continuous spinal anesthesia. This may be due to pooling of drug around the cauda equina. In animal experiments undiluted 5% lidocaine can produce permanent neuronal damage. Transient neurological symptoms (including dysesthesias, burning pain, and aching in the lower extremities and buttocks) have been reported following spinal anesthesia with a variety of local anesthetic agents, but most commonly after use of lidocaine 5% for male outpatients undergoing surgery in the lithotomy position. These symptoms (sometimes referred to as “radicular irritation”) typically resolve within 4 weeks. Many clinicians have abandoned lidocaine and substituted 2-chloroprocaine, mepivacaine, or small doses of bupivacaine for spinal anesthesia in the hope of avoiding these transient symptoms.

B. Respiratory
Lidocaine depresses the ventilatory response to low PaO$_2$ (hypoxic drive). Apnea can result from phrenic and intercostal nerve paralysis (eg, from “high” spinals)
or depression of the medullary respiratory center following direct exposure to local anesthetic agents (eg, after retrobulbar blocks; see Chapter 36). However, apnea after administration of a “high” spinal or epidural anesthetic is nearly always the result of hypotension and brain ischemia, rather than phrenic block. Local anesthetics relax bronchial smooth muscle. Intravenous lidocaine (1.5 mg/kg) may block the reflex bronchoconstriction sometimes associated with intubation.

C. Cardiovascular

Signs of cardiovascular stimulation (tachycardia and hypertension) may occur with local anesthetic concentrations that produce central nervous system excitation or from injection or absorption of epinephrine (often compounded with local anesthetics). Myocardial contractility and conduction velocity are also depressed at higher blood concentrations. All local anesthetics depress myocardial automaticity (spontaneous phase IV depolarization). These effects result from direct actions on cardiac muscle membrane (ie, cardiac Na channel inhibition) and in intact organisms from inhibition of the autonomic nervous system. At low concentrations all local anesthetics inhibit nitric oxide, causing vasoconstriction. All local anesthetics except cocaine produce smooth muscle relaxation and arterial vasodilation at higher concentrations, including arteriolar vasodilation. At increased blood concentrations the combination of arrhythmias, heart block, depression of ventricular contractility, and hypotension may culminate in cardiac arrest. Major cardiovascular toxicity usually requires about three times the local anesthetic concentration in blood as that required to produce seizures. Cardiac arrhythmias or circulatory collapse are the usual presenting signs of local anesthetic intoxication during general anesthesia.

The hypertension associated with laryngoscopy and intubation is often attenuated by intravenous administration of lidocaine (1.5 mg/kg) 1–3 min prior to instrumentation. Overdoses of lidocaine can lead to marked left ventricular contractile dysfunction.

Unintended intravascular injection of bupivacaine during regional anesthesia may produce severe cardiovascular toxicity, including left ventricular depression, atroventricular heart block, and life-threatening arrhythmias such as ventricular tachycardia and fibrillation. Pregnancy, hypoxemia, and respiratory acidosis are predisposing risk factors. Young children may also be at increased risk of toxicity. Multiple studies have demonstrated that bupivacaine is associated with more pronounced changes in conduction and a greater risk of terminal arrhythmias than comparable doses of lidocaine. Mepivacaine,
ropivacaine, and bupivacaine each have a chiral carbon and therefore can exist in either of two optical isomers (enantiomers). The R(+) optical isomer of bupivacaine blocks more avidly and dissociates more slowly from cardiac Na channels than does the S(−) optical isomer (levobupivacaine or ropivacaine). Resuscitation from bupivacaine-induced cardiac toxicity is often difficult and resistant to standard resuscitation drugs. Multiple clinical reports suggest that bolus administration of nutritional lipid emulsions at 1.5 mL/kg can resuscitate bupivacaine-intoxicated patients who do not respond to standard therapy. We advocate that lipid be a first-line treatment for local anesthetic cardiovascular toxicity and we are concerned that case reports indicate persisting delayed use of this nearly risk-free treatment despite an American Society of Regional Anesthesia and Pain Medicine (ASRA) guideline on local anesthetic systemic toxicity being available in print, online, and in a mobile app.

Ropivacaine shares many physicochemical properties with bupivacaine. Onset time and duration of action are similar, but ropivacaine produces less motor block when injected at the same volume and concentration as bupivacaine (which may reflect an overall lower potency as compared with bupivacaine). Ropivacaine appears to have a greater therapeutic index than racemic bupivacaine. This improved safety profile likely reflects its formulation as a pure S(−) isomer—that is, having no R(+) isomer—as opposed to racemic bupivacaine. Levobupivacaine, the S(−) isomer of bupivacaine, was reported to have fewer cardiovascular and cerebral side effects than the racemic mixture, but it is no longer available in the United States.

Cocaine’s cardiovascular reactions are unlike those of any other local anesthetic. Cocaine inhibits the normal reuptake of norepinephrine by adrenergic nerve terminals, thereby potentiating the effects of adrenergic stimulation. Cardiovascular responses to cocaine include hypertension and ventricular ectopy. Initial treatment of systemic cocaine toxicity should include benzodiazepines to reduce the central stimulation. Cocaine-induced arrhythmias have been successfully treated with α-adrenergic antagonists and amiodarone. Cocaine produces vasoconstriction when applied topically and is a useful agent to reduce pain and epistaxis related to nasal intubation in awake patients.

D. Immunological

True hypersensitivity reactions (due to IgG or IgE antibodies) to local anesthetics—as distinct from systemic toxicity caused by excessive plasma concentrations—are uncommon. Esters appear more likely to induce an allergic reaction, especially if the compound is a derivative (eg, procaine or benzocaine)
of PABA, a known allergen. Commercial multidose preparations of amides often contain **methylparaben**, which has a chemical structure vaguely similar to that of PABA. As a consequence, generations of anesthesiologists have speculated whether this preservative may be responsible for most of the apparent allergic responses to amide agents, particularly when skin testing fails to confirm true allergy to the local anesthetic.

**E. Musculoskeletal**
When directly injected into skeletal muscle either intentionally (eg, trigger-point injection treatment of myofascial pain) or unintentionally, local anesthetics are mildly myotoxic. Regeneration usually occurs within 4 weeks after the injection. Compounding the local anesthetic with steroid or epinephrine worsens the myonecrosis. When infused into joints for prolonged periods, local anesthetics can produce severe chondromalacia.

**F. Hematological**
Lidocaine mildly depresses normal blood coagulation (reduced thrombosis and decreased platelet aggregation) and enhances fibrinolysis of whole blood as measured by thromboelastography. These actions could underlie the lower incidence of thromboembolic events in patients receiving epidural anesthetics (in older studies of patients not receiving prophylaxis against deep vein thrombosis).

**Drug Interactions**
Local anesthetics potentiate nondepolarizing muscle relaxant blockade in laboratory experiments, but this likely has no clinical importance.

As noted earlier, both succinylcholine and ester local anesthetics depend on pseudocholinesterase for metabolism. There is no evidence that this potential competition between ester local anesthetics and succinylcholine for the enzyme has any clinical importance. Dibucaine, an amide local anesthetic, inhibits pseudocholinesterase, and the extent of inhibition by dibucaine defines one form of genetically abnormal pseudocholinesterases (see Chapter 11). Pseudocholinesterase inhibitors (eg, organophosphate poisons) can prolong the metabolism of ester local anesthetics (see Table 11–2).

As noted earlier, drugs that decrease hepatic blood flow (eg, H₂-receptor blockers and β-blockers) decrease amide local anesthetic clearance. Opioids potentiate analgesia produced by epidural and spinal local anesthetics. Similarly α₂-adrenergic agonists (eg, clonidine) potentiate local anesthetic analgesia.
produced after epidural or peripheral nerve block injections. Epidural chloroprocaine may interfere with the analgesic actions of neuraxial morphine, notably after cesarean delivery.

CASE DISCUSSION

Local Anesthetic Overdose

An 18-year-old woman in the active stage of labor requests an epidural anesthetic. Immediately following injection of 2 mL and 5 mL test doses of 1.5% lidocaine with 1:200,000 epinephrine through the epidural catheter, the patient complains of lip numbness and becomes very apprehensive. Her heart rate has increased from 85 to 105 beats/min.

What is your presumptive diagnosis?

Circumoral numbness and apprehension immediately following administration of lidocaine suggest an intravascular injection of local anesthetic. Abrupt tachycardia strongly suggests intravascular injection of epinephrine. These symptoms and signs after relatively small test doses typically will not be followed by a seizure.

What measures should be immediately undertaken?

The patient should receive supplemental oxygen. She should be closely observed for a possible (but unlikely) seizure and be reassured that the symptoms and signs will soon lapse.

What treatment should be initiated for a generalized seizure?

The laboring patient is always considered to be at increased risk for aspiration (see Chapter 41); therefore, the airway should be protected by immediate administration of succinylcholine and tracheal intubation (see Case Discussion, Chapter 17). The succinylcholine will eliminate tonic–clonic activity but will not address the underlying cerebral hyperexcitability. We favor administering an anticonvulsant such as midazolam (1–2 mg) or propofol (20–50 mg) with or before succinylcholine. Thus, wherever conduction anesthetics are administered resuscitation drugs and equipment must be available just as for a general anesthetic.
**What could have been expected if a large dose of bupivacaine (eg, 15 mL 0.5% bupivacaine)—instead of lidocaine—had been given intravascularly?**

When administered at “comparably anesthetizing” doses, bupivacaine is more likely to produce cardiac toxicity than lidocaine. Acute acidosis (nearly universal after a seizure) tends to potentiate local anesthetic toxicity. Ventricular arrhythmias and conduction disturbances may lead to cardiac arrest and death. Cardiac Na channels unbind bupivacaine more slowly than lidocaine. Amiodarone may be given as treatment for local anesthetic-induced ventricular tachyarrhythmias, but we favor immediate administration of lipid emulsion with the onset of seizures and most certainly at the first signs of cardiac toxicity from bupivacaine. Vasopressors may be required. We recommend incremental small (0.5-1 mcg/kg) doses of epinephrine. The reason for the apparent greater susceptibility to local anesthetic cardiotoxicity during pregnancy is unclear. Although total dose (regardless of concentration) of local anesthetic determines toxicity, the Food and Drug Administration recommends against use of 0.75% bupivacaine in pregnant and elderly patients, and in any case this concentration is not needed.

**What could have prevented the toxic reaction described?**

The risk from accidental intravascular injections during attempted epidural anesthesia is reduced by using test doses and administering the local anesthetic dose in smaller, safer aliquots. Finally, one should administer only the minimum required dose for a given regional anesthetic.

This web site provides up-to-date information about the use of lipid for rescue from local anesthetic toxicity. [http://www.lipidrescue.org](http://www.lipidrescue.org)

The American Society of Regional Anesthesia and Pain Medicine (ASRA) website provides access to all ASRA guidelines (all of which are related to local anesthetics, regional anesthesia, or pain medicine). [http://www.asra.com](http://www.asra.com)
Adjuncts to Anesthesia

KEY CONCEPTS

1. Diphenhydramine is one of a diverse group of drugs that competitively blocks H₁ receptors. Many drugs with H₁-receptor antagonist properties have considerable antimuscarinic, or atropine-like, activity (eg, dry mouth), or antiserotonergic activity (antiemetic).

2. H₂ blockers reduce the perioperative risk of aspiration pneumonia by decreasing gastric fluid volume and raising the pH of gastric contents.

3. Metoclopramide increases lower esophageal sphincter tone, speeds gastric emptying, and lowers gastric fluid volume by enhancing the stimulatory effects of acetylcholine on intestinal smooth muscle.

4. Ondansetron, granisetron, tropisetron, and dolasetron selectively block serotonin 5-HT₃ receptors, with little or no effect on dopamine receptors. Located peripherally and centrally, 5-HT₃ receptors appear to play an important role in the initiation of the vomiting reflex.

5. Ketorolac is a parenteral nonsteroidal antiinflammatory drug that provides analgesia by inhibiting prostaglandin synthesis.

6. Clonidine is a commonly used antihypertensive agent but in anesthesia it is used as an adjunct for epidural, caudal, and peripheral nerve block anesthesia and analgesia. It is often used in the management of patients with chronic neuropathic pain to increase the efficacy of epidural opioid infusions.

7. Dexmedetomidine is a parenteral selective α₂-agonist with sedative properties. It appears to be more selective for the α₂-receptor than clonidine.

8. Selective activation of carotid chemoreceptors by low doses of doxapram stimulates hypoxic drive, producing an increase in tidal
volume and a slight increase in respiratory rate. Doxapram is not a specific reversal agent and should not replace standard supportive therapy (ie, mechanical ventilation).

Naloxone reverses the agonist activity associated with endogenous or exogenous opioid compounds.

Flumazenil is useful in the reversal of benzodiazepine sedation and the treatment of benzodiazepine overdose.

Aspiration does not necessarily result in aspiration pneumonia. The seriousness of the lung damage depends on the volume and composition of the aspirate. Patients are at risk if their gastric volume is greater than 25 mL (0.4 mL/kg) and their gastric pH is less than 2.5.

Many drugs are routinely administered perioperatively to protect against aspiration pneumonitis, to prevent or reduce the incidence of perianesthetic nausea and vomiting, or to reverse respiratory depression secondary to narcotics or benzodiazepines. This chapter discusses these agents along with other unique classes of drugs that are often administered as adjuvants during anesthesia or analgesia. Additionally, many nonanesthetic agents are increasingly prescribed perioperatively to provide for enhanced recovery following surgery (see Chapter 48).

Aspiration

Aspiration of gastric contents is a rare and potentially fatal event that can complicate anesthesia. Based on an animal study, it is often stated that aspiration of 25 mL of volume at a pH of less than 2.5 will be sufficient to produce aspiration pneumonia. Many factors place patients at risk for aspiration, including “full” stomach, intestinal obstruction, hiatal hernia, obesity, pregnancy, reflux disease, emergency surgery, and inadequate depth of anesthesia.

Many approaches are employed to reduce the potential for aspiration perioperatively. Many of these interventions, such as the holding of cricoid pressure (Sellick maneuver) and rapid sequence induction, may only offer limited protection. Cricoid pressure can be applied incorrectly and fail to occlude the esophagus. Whether it has any beneficial effect on outcomes even when it is applied correctly remains unproven. Anesthetic agents can decrease lower esophageal sphincter tone and decrease or obliterate the gag reflex, theoretically increasing the risk for passive aspiration. Additionally, inadequately anesthetized
patients can vomit; if the airway is unprotected, aspiration of gastric contents may occur. Different combinations of premedications have been advocated to reduce gastric volume, increase gastric pH, or augment lower esophageal sphincter tone. These agents include antihistamines, antacids, and metoclopramide.

**HISTAMINE-RECEPTOR ANTAGONISTS**

**Histamine Physiology**

Histamine is found in the central nervous system, in the gastric mucosa, and in other peripheral tissues. It is synthesized by decarboxylation of the amino acid histidine. Histaminergic neurons are primarily located in the posterior hypothalamus but have wide projections in the brain. Histamine also normally plays a major role in the secretion of hydrochloric acid by parietal cells in the stomach (Figure 17–1). The greatest concentrations of histamine are found in the storage granules of circulating basophils and mast cells. Mast cells tend to be concentrated in connective tissue just beneath epithelial (mucosal) surfaces. Histamine release (degranulation) from these cells can be triggered by chemical, mechanical, or immunological stimulation.
Secretion of hydrochloric acid is normally mediated by gastrin-induced histamine release from enterochromaffin-like cells (ECL) in the stomach. Note that acid secretion by gastric parietal cells can also be increased indirectly by acetylcholine (AC) via stimulation of M₃ receptors and directly by gastrin through an increase in intracellular Ca²⁺ concentration. Prostaglandin E₂ (PGE₂) can inhibit acid secretion by decreasing cyclic adenosine monophosphate (cAMP) activity. ATP, adenosine triphosphate; Gᵢ, G inhibitory protein; Gₛ, G stimulatory protein.

Multiple receptors (H₁–H₄) mediate the effects of histamine. The H₁ receptor activates phospholipase C, whereas the H₂ receptor increases intracellular cyclic adenosine monophosphate (cAMP). The H₃ receptor is primarily located on histamine-secreting cells and mediates negative feedback, inhibiting the
synthesis and release of additional histamine. The H₄ receptors are present on hematopoietic cells, mast cells, and eosinophils and are active in allergy and inflammation. Histamine-N-methyltransferase metabolizes histamine to inactive metabolites that are excreted in the urine.

A. Cardiovascular
Histamine reduces arterial blood pressure but increases heart rate and myocardial contractility. H₁-Receptor stimulation increases capillary permeability and enhances ventricular irritability, whereas H₂-receptor stimulation increases heart rate and increases contractility. Both types of receptors mediate peripheral arteriolar dilation and some coronary vasodilation.

B. Respiratory
Histamine constricts bronchiolar smooth muscle via the H₁ receptor. H₂-Receptor stimulation may produce mild bronchodilation. Histamine has variable effects on the pulmonary vasculature; the H₁ receptor appears to mediate some pulmonary vasodilation, whereas the H₂ receptor may be responsible for histamine-mediated pulmonary vasoconstriction.

C. Gastrointestinal
Activation of H₂ receptors in parietal cells increases gastric acid secretion. Stimulation of H₁ receptors leads to contraction of intestinal smooth muscle.

D. Dermal
The classic wheal-and-flare response of the skin to histamine results from increased capillary permeability and vasodilation, primarily via H₁-receptor activation.

E. Immunological
Histamine is a major mediator of type 1 hypersensitivity reactions. H₁-Receptor stimulation attracts leukocytes and induces synthesis of prostaglandin. In contrast, the H₂ receptor appears to activate suppressor T lymphocytes.

1. H₁-Receptor Antagonists
Mechanism of Action

Diphenhydramine (an ethanolamine) is one of a diverse group of drugs that competitively blocks \( H_1 \) receptors (Table 17–1). Many drugs with \( H_1 \)-receptor antagonist properties have considerable antimuscarinic, or atropine-like, activity (eg, dry mouth), or antiserotonergic activity (antiemetic). Promethazine is a phenothiazine derivative with \( H_1 \)-receptor antagonist activity as well as antidopaminergic and \( \alpha \)-adrenergic–blocking properties.

Clinical Uses

Like other \( H_1 \)-receptor antagonists, diphenhydramine has a multitude of therapeutic uses: suppression of allergic reactions and symptoms of upper respiratory tract infections (eg, urticaria, rhinitis, conjunctivitis); vertigo, nausea, and vomiting (eg, motion sickness, Ménière disease); sedation; suppression of cough; and dyskinesia (eg, parkinsonism, drug-induced extrapyramidal side effects). Some of these actions are predictable from an understanding of histamine physiology, whereas others are the result of the drugs’ antimuscarinic and antiserotonergic effects (Table 17–1). Although \( H_1 \) blockers prevent the bronchoconstrictive response to histamine, they are ineffective in treating bronchial asthma, which is primarily due to other mediators. Likewise, \( H_1 \) blockers will not completely prevent the hypotensive effect of histamine unless an \( H_2 \) blocker is administered concomitantly.

Although many \( H_1 \) blockers cause significant sedation, ventilatory drive is
usually unaffected in the absence of other sedative medications. Promethazine and hydroxyzine were often combined with opioids to potentiate analgesia. Newer (second-generation) antihistamines tend to produce little or no sedation because of limited penetration across the blood–brain barrier. This group of drugs is used primarily for allergic rhinitis and urticaria. They include loratadine, fexofenadine, and cetirizine. Many preparations for allergic rhinitis often also contain vasoconstrictors such as pseudoephedrine. Meclizine and dimenhydrinate are used primarily as an antiemetic, particularly for motion sickness, and in the management of vertigo. Cyproheptadine, which also has significant serotonin antagonist activity, has been used in the management of Cushing disease, carcinoid syndrome, and vascular (cluster) headaches.

**Dosage**

The usual adult dose of diphenhydramine is 25 to 50 mg (0.5–1.5 mg/kg) orally, intramuscularly, or intravenously every 3 to 6 h. The doses of other H₁-receptor antagonists are listed in Table 17–1.

**Drug Interactions**

The sedative effects of H₁-receptor antagonists can potentiate other central nervous system depressants such as barbiturates, benzodiazepines, and opioids.

**2. H₂-Receptor Antagonists**

**Mechanism of Action**

H₂-Receptor antagonists include cimetidine, famotidine, nizatidine, and ranitidine (Table 17–2). These agents competitively inhibit histamine binding to H₂ receptors, thereby reducing gastric acid output and raising gastric pH.

**TABLE 17–2  Pharmacology of aspiration pneumonia prophylaxis.**

[^1]
Clinical Uses

All H₂-receptor antagonists are equally effective in the treatment of peptic duodenal and gastric ulcers, hypersecretory states (Zollinger–Ellison syndrome), and gastroesophageal reflux disease (GERD). Intravenous preparations are also used to prevent stress ulceration in critically ill patients. Duodenal and gastric ulcers are usually associated with *Helicobacter pylori* infection, which is treated with combinations of bismuth, tetracycline, and metronidazole. By decreasing gastric fluid volume and hydrogen ion content, H₂ blockers reduce the perioperative risk of aspiration pneumonia. These drugs affect the pH of only those gastric secretions that occur after their administration.

The combination of H₁- and H₂-receptor antagonists provides some protection against drug-induced allergic reactions (eg, intravenous radiocontrast, chymopapain injection for lumbar disk disease, protamine, vital blue dyes used for sentinel node biopsy). Although pretreatment with these agents does not reduce histamine release, it may decrease subsequent hypotension.

Side Effects

Rapid intravenous injection of cimetidine or ranitidine has been rarely associated with hypotension, bradycardia, arrhythmias, and cardiac arrest. H₂-Receptor antagonists change the gastric flora by virtue of their pH effects. Complications of long-term cimetidine therapy include hepatotoxicity (elevated serum transaminases), interstitial nephritis (elevated serum creatinine), granulocytopenia, and thrombocytopenia. Cimetidine also binds to androgen receptors, occasionally causing gynecomastia and impotence. Finally, cimetidine has been associated with changes in mental status ranging from lethargy and

hallucinations to seizures, particularly in elderly patients. In contrast, ranitidine, nizatidine, and famotidine do not affect androgen receptors and penetrate the blood–brain barrier poorly.

**Dosage**

As a premedication to reduce the risk of aspiration pneumonia, H$_2$-receptor antagonists should be administered at bedtime and again at least 2 h before surgery. Because all four drugs are eliminated primarily by the kidneys, the dose should be reduced in patients with significant renal dysfunction.

**Drug Interactions**

Cimetidine may reduce hepatic blood flow and binds to the cytochrome P-450 mixed-function oxidases. These effects slow the metabolism of a multitude of drugs, including lidocaine, propranolol, diazepam, theophylline, phenobarbital, warfarin, and phenytoin. Ranitidine is a weak inhibitor of the cytochrome P-450 system, and no significant drug interactions have been demonstrated. Famotidine and nizatidine do not appear to affect the cytochrome P-450 system.

**ANTACIDS**

**Mechanism of Action**

Antacids neutralize the acidity of gastric fluid by providing a base (usually hydroxide, carbonate, bicarbonate, citrate, or trisilicate) that reacts with hydrogen ions to form water.

**Clinical Uses**

Common uses of antacids include the treatment of peptic ulcers and GERD. In anesthesiology, antacids provide protection against the harmful effects of aspiration pneumonia by raising the pH of gastric contents. Unlike H$_2$-receptor antagonists, antacids have an immediate effect. Unfortunately, they increase intragastric volume. Aspiration of particulate antacids (aluminum or magnesium hydroxide) produces abnormalities in lung function comparable to those that occur following acid aspiration. Nonparticulate antacids (sodium citrate or sodium bicarbonate) are much less damaging to lung alveoli if aspirated. Furthermore, nonparticulate antacids mix with gastric contents better than
particulate solutions. Timing is critical, as nonparticulate antacids lose their effectiveness 30 to 60 min after ingestion.

**Dosage**

The usual adult dose of a 0.3 M solution of sodium citrate—Bicitra (sodium citrate and citric acid) or Polycitra (sodium citrate, potassium citrate, and citric acid)—is 15 to 30 mL orally, 15 to 30 min prior to induction (Table 17–2).

**Drug Interactions**

Because antacids alter gastric and urinary pH, they change the absorption and elimination of many drugs. The rate of absorption of digoxin, cimetidine, and ranitidine is slowed, whereas the rate of phenobarbital elimination is quickened.

**METOCLOPRAMIDE**

**Mechanism of Action**

Metoclopramide acts peripherally as a cholinomimetic (ie, facilitates acetylcholine transmission at selective muscarinic receptors) and centrally as a dopamine receptor antagonist. Its action as a prokinetic agent in the upper gastrointestinal (GI) tract is not dependent on vagal innervation but is abolished by anticholinergic agents. It does not stimulate secretions.

**Clinical Uses**

- By enhancing the stimulatory effects of acetylcholine on intestinal smooth muscle, metoclopramide increases lower esophageal sphincter tone, speeds gastric emptying, and lowers gastric fluid volume (Table 17–2). These properties account for its efficacy in the treatment of patients with diabetic gastroparesis and GERD, as well as prophylaxis for those at risk for aspiration pneumonia. Metoclopramide does not affect the secretion of gastric acid or the pH of gastric fluid.

  Metoclopramide produces an antiemetic effect by blocking dopamine receptors in the chemoreceptor trigger zone of the central nervous system. However, at doses used clinically during the perioperative period, the drug’s ability to reduce postoperative nausea and vomiting is negligible.
**Side Effects**

Rapid intravenous injection may cause abdominal cramping, and metoclopramide is contraindicated in patients with complete intestinal obstruction. It can induce a hypertensive crisis in patients with pheochromocytoma by releasing catecholamines from the tumor. Sedation, nervousness, and extrapyramidal signs from dopamine antagonism (eg, akathisia) are uncommon and reversible. Nonetheless, metoclopramide is best avoided in patients with Parkinson disease. Prolonged treatment with metoclopramide can lead to tardive dyskinesia. Metoclopramide-induced increases in aldosterone and prolactin secretion are probably inconsequential during short-term therapy. Metoclopramide may rarely result in hypotension and arrhythmias.

**Dosage**

An adult dose of 10 to 15 mg of metoclopramide (0.25 mg/kg) is effective orally, intramuscularly, or intravenously (injected over 5 min). Larger doses (1–2 mg/kg) have been used to prevent emesis during chemotherapy. The onset of action is much more rapid following parenteral (3–5 min) than oral (30–60 min) administration. Because metoclopramide is excreted in the urine, its dose should be decreased in patients with kidney dysfunction.

**Drug Interactions**

Antimuscarinic drugs (eg, atropine, glycopyrrolate) block the GI effects of metoclopramide. Metoclopramide decreases the absorption of orally administered cimetidine. Concurrent use of phenothiazines or butyrophenones (droperidol) increases the likelihood of extrapyramidal side effects.

**PROTON PUMP INHIBITORS**

**Mechanism of Action**

These agents, including omeprazole (Prilosec), lansoprazole (Prevacid), rabeprazole (AcipHex), esomeprazole (Nexium), and pantoprazole (Protonix), bind to the proton pump of parietal cells in the gastric mucosa and inhibit secretion of hydrogen ions.
Clinical Uses

Proton pump inhibitors (PPIs) are indicated for the treatment of peptic ulcer, GERD, and Zollinger–Ellison syndrome. They may promote healing of peptic ulcers and erosive GERD more quickly than H₂-receptor blockers. There are ongoing questions regarding the safety of PPIs in patients taking clopidogrel (Plavix). These concerns relate to inadequate antiplatelet therapy when these drugs are combined due to inadequate activation of clopidogrel by hepatic enzyme CYP2C19, which is inhibited to varying degrees by PPIs.

Side Effects

PPIs are generally well tolerated, causing few side effects. Adverse side effects primarily involve the GI system (nausea, abdominal pain, constipation, diarrhea). On rare occasions, these drugs have been associated with myalgias, anaphylaxis, angioedema, and severe dermatological reactions. Long-term use of PPIs has also been associated with gastric enterochromaffin-like cell hyperplasia and an increased risk of pneumonia secondary to bacterial colonization in the higher-pH environment.

Dosage

Recommended oral doses for adults are omeprazole, 20 mg; lansoprazole, 15 mg; rabeprazole, 20 mg; and pantoprazole, 40 mg. Because these drugs are primarily eliminated by the liver, repeat doses should be decreased in patients with severe liver impairment.

Drug Interactions

PPIs can interfere with hepatic P-450 enzymes, potentially decreasing the clearance of diazepam, warfarin, and phenytoin. Concurrent administration can decrease clopidogrel (Plavix) effectiveness, as the latter medication is dependent on hepatic enzymes for activation.

Postoperative Nausea & Vomiting (PONV)

Without any prophylaxis, PONV occurs in approximately 30% or more of the general surgical population and up to 70% to 80% in patients with predisposing
risk factors. The Society for Ambulatory Anesthesia (SAMBA) provides extensive guidelines for the management of PONV. Table 17–3 identifies risks factors for PONV and scores the evidence for assessing risk. When PONV risk is sufficiently great, prophylactic antiemetic medications are administered and strategies to reduce its incidence are initiated. The Apfel score provides a simplified assessment tool to predict risk of PONV (Figures 17–2 and 17–3). (Obesity, anxiety, and reversal of neuromuscular blockade are not independent risk factors for PONV.)

5-HT$_3$ RECEPTOR ANTAGONISTS

**Serotonin Physiology**

Serotonin, 5-hydroxytryptamine (5-HT), is present in large quantities in platelets and the GI tract (enterochromaffin cells and the myenteric plexus). It is also an important neurotransmitter in multiple areas of the central nervous system. Serotonin is formed by hydroxylation and decarboxylation of tryptophan. Monoamine oxidase inactivates serotonin into 5-hydroxyindoleacetic acid (5-HIAA). The physiology of serotonin is very complex because there are at least seven receptor types, most with multiple subtypes. The 5-HT$_3$ receptor mediates vomiting and is found in the GI tract and the brain (area postrema). The 5-HT$_{2A}$ receptors are responsible for smooth muscle contraction and platelet aggregation, the 5-HT$_4$ receptors in the GI tract mediate secretion and peristalsis, and the 5-HT$_6$ and 5-HT$_7$ receptors are located primarily in the limbic system where they appear to play a role in depression. All except the 5-HT$_3$ receptor are coupled to G proteins and affect either adenylyl cyclase or phospholipase C; effects of the 5-HT$_3$ receptor are mediated via an ion channel.

**A. Cardiovascular**

Except in the heart and skeletal muscle, serotonin is a powerful vasoconstrictor of arterioles and veins. Its vasodilator effect in the heart is endothelium dependent. When the myocardial endothelium is damaged following injury, serotonin produces vasoconstriction. The pulmonary and kidney vasculatures are very sensitive to the arterial vasoconstrictive effects of serotonin. Modest and transient increases in cardiac contractility and heart rate may occur immediately following serotonin release; reflex bradycardia often follows. Vasodilation in skeletal muscle can subsequently cause hypotension. Excessive serotonin can produce *serotonin syndrome*, characterized by hypertension, hyperthermia, and agitation.

**B. Respiratory**

Contraction of smooth muscle increases airway resistance. Bronchoconstriction from released serotonin is often a prominent feature of carcinoid syndrome.
C. Gastrointestinal
Direct smooth muscle contraction (via 5-HT_{2} receptors) and serotonin-induced release of acetylcholine in the myenteric plexus (via 5-HT_{3} receptors) greatly augment peristalsis. Secretions are unaffected.

D. Hematological
Activation of 5-HT_{2} receptors causes platelet aggregation.

Mechanism of Action
- Ondansetron, granisetron, tropisetron, and dolasetron selectively block serotonin 5-HT_{3} receptors, with little or no effect on dopamine receptors (5-HT_{3} receptors, which are located peripherally (abdominal vagal afferents) and centrally (chemoreceptor trigger zone of the area postrema and the nucleus tractus solitarius), appear to play an important role in the initiation of the vomiting reflex. The 5-HT_{3} receptors of the chemoreceptor trigger zone in the area postrema reside outside the blood–brain barrier (Figure 17–5). The chemoreceptor trigger zone is activated by substances such as anesthetics and opioids and signals the nucleus tractus solitarius, resulting in PONV. Emetogenic stimuli from the GI tract similarly stimulate the development of PONV.
Clinical Uses

5-HT<sub>3</sub>-Receptor antagonists are generally administered at the end of surgery. All these agents are effective antiemetics in the postoperative period. A new agent, palonosetron has an extended duration of action and may reduce the incidence of postdischarge nausea and vomiting (PDNV). SAMBA guidelines suggest risk factors for PDNV include:

- Female sex
- History of PONV
- Age 50 years or younger
- Use of opioids in the postanesthesia care unit (PACU)
- Nausea in the PACU
Side Effects

5-HT<sub>3</sub>-Receptor antagonists are essentially devoid of serious side effects, even in amounts several times the recommended dose. They do not appear to cause sedation, extrapyramidal signs, or respiratory depression. The most commonly reported side effect is headache. All three drugs can slightly prolong the QT interval on the electrocardiogram. This effect may be more frequent with dolasetron (no longer available in the United States). Nonetheless, these drugs, should be used cautiously in patients who are taking antiarrhythmic drugs or who have a prolonged QT interval.

Ondansetron undergoes extensive metabolism in the liver via hydroxylation and conjugation by cytochrome P-450 enzymes. Liver failure impairs clearance several-fold, and the dose should be reduced accordingly.

BUTYROPHENONES

Droperidol (0.625–1.25 mg) was previously used routinely for PONV prophylaxis. Given at the end of the procedure, it blocks dopamine receptors that contribute to the development of PONV. Despite its effectiveness, many practitioners no longer routinely administer this medication because of a U.S. Food and Drug Administration (FDA) black box warning related to concerns that doses described in the product labeling (“package insert”) may lead to QT prolongation and development of torsades des pointes arrhythmia. However, the doses relevant to the FDA warning, as acknowledged by the FDA, were those used for neurolept anesthesia (5–15 mg), not the much smaller doses employed for PONV. Cardiac monitoring is warranted when large doses of the drug are used. There is no evidence that use of droperidol at the doses routinely employed for PONV management increases the risk of sudden cardiac death in the perioperative population.

As with other drugs that antagonize dopamine, droperidol use in patients with Parkinson disease and in other patients manifesting extrapyramidal signs should be carefully considered.

The phenothiazine, prochlorperazine (Compazine), which affects multiple receptors (histaminergic, dopaminergic, muscarinic), may be used for PONV management. It may cause extrapyramidal and anticholinergic side effects. Promethazine (Phenergan) works primarily as an anticholinergic agent and antihistamine and likewise can be used to treat PONV. As with other agents of this class, anticholinergic effects (sedation, delirium, confusion, vision changes) can complicate the postoperative period.
**DEXAMETHASONE**

Dexamethasone (Decadron) in doses as small as 4 mg has been shown to be as effective as ondansetron in reducing the incidence of PONV. Dexamethasone should be given at induction as opposed to the end of surgery, and its mechanism of action is unclear. It may provide analgesic and mild euphoric effects. Dexamethasone can increase postoperative blood glucose concentration, and some practitioners have suggested that dexamethasone could increase the risk of postoperative infection. Nonetheless, most studies have not demonstrated any increase in wound infections following dexamethasone administration for PONV prophylaxis.

**NEUROKININ-1 RECEPTOR ANTAGONIST**

*Substance P* is a neuropeptide that interacts at neurokinin-1 (NK1) receptors. NK1 antagonists inhibit substance P at central and peripheral receptors. Aprepitant, an NK1 antagonist, has been found to reduce PONV perioperatively and is additive with ondansetron for this indication.

**OTHER PONV STRATEGIES**

Several other agents and techniques have been employed to reduce the incidence of PONV. Transdermal scopolamine has been used effectively, although it may produce central anticholinergic effects (confusion, blurred vision, and dry mouth). Acupuncture, acupressure, and transcutaneous electrical stimulation of the P6 acupuncture point can reduce PONV incidence and medication requirements.

As no single agent will both treat and prevent PONV, perioperative management centers on identifying patients at greatest risk so that prophylaxis, often with multiple agents, may be initiated. Since systemic opioid administration is associated with PONV, opioid-sparing strategies (eg, use of regional anesthetics and nonopioid analgesics) can markedly reduce the risk of PONV.

---

**Other Drugs Used as Adjuvants to Anesthesia**

**KETOROLAC**
Mechanism of Action

Ketorolac is a parenteral nonsteroidal antiinflammatory drug (NSAID) that provides analgesia by inhibiting prostaglandin synthesis. A peripherally acting drug, it has become a popular alternative to opioids for postoperative analgesia because of its minimal central nervous system side effects.

Clinical Uses

Ketorolac is indicated for the short-term (<5 days) management of pain, and appears to be particularly useful in the immediate postoperative period. A standard dose of ketorolac provides analgesia equivalent to 6 to 12 mg of morphine administered by the same route. Its time to onset is also similar to morphine, but ketorolac has a longer duration of action (6–8 h).

Ketorolac does not cause respiratory depression, sedation, or nausea and vomiting. In fact, ketorolac does not cross the blood–brain barrier to any significant degree. Numerous studies have shown that oral and parenteral NSAIDs have an opioid-sparing effect. They may be most beneficial in patients at increased risk for postoperative respiratory depression or emesis.

Side Effects

As with other NSAIDs, ketorolac inhibits platelet aggregation and prolongs bleeding time. It and other NSAIDs should therefore be used with caution in patients at risk for postoperative hemorrhage. Long-term administration may lead to renal toxicity (eg, papillary necrosis) or GI tract ulceration with bleeding and perforation. Because ketorolac depends on kidney elimination, it should not be given to patients with kidney disease. Ketorolac is contraindicated in patients allergic to aspirin or NSAIDs. Patients with asthma have an increased incidence of aspirin sensitivity (approximately 10%), particularly if they also have a history of nasal polyps (approximately 20%).

Dosage

Ketorolac has been approved for administration as either a 60 mg intramuscular or 30 mg intravenous loading dose; a maintenance dose of 15 to 30 mg every 6 h is recommended. Elderly patients clear ketorolac more slowly and should receive reduced doses.
Drug Interactions

Aspirin decreases the protein binding of ketorolac, increasing the amount of active unbound drug. Ketorolac does not affect minimum alveolar concentration of inhalation anesthetic agents, and its administration does not alter the hemodynamics of anesthetized patients. It decreases the postoperative requirement for opioid analgesics.

Other NSAID Adjuvant Drugs

Other NSAID agents are used perioperatively. Ketorolac and other NSAIDs inhibit cyclooxygenase (COX) isoenzymes. COX-1 maintains gastric mucosa and stimulates platelet aggregation. COX-2 is expressed during inflammation. Diclofenac and ibuprofen are now available for intravenous administration. Whereas ketorolac, diclofenac, and ibuprofen are nonselective COX inhibitors, other agents such as celecoxib are specific for COX-2. COX-2 inhibitors spare both the gastric mucosa and platelet function. However, their use is associated with an increased risk of hypertension, stroke, and cardiovascular events. Indeed, the FDA warns that all non-aspirin nonsteroidal antiinflammatory drugs increase the risk of myocardial infarction or stroke.

Intravenous acetaminophen (Ofirmev) is available for perioperative use in the United States. Acetaminophen is a centrally acting analgesic with likely central COX inhibition and with weak peripheral COX effects. Its exact mechanism of action remains controversial; nevertheless it does not cause gastric irritation and clotting abnormalities. A maximal adult (>50 kg weight) dose of 1 g is infused to a maximum total dose of 4 g/d. Patients weighing 50 kg or less should receive a maximal dose of 15 mg/kg and a maximal total dose of 75 mg/kg/d. Hepatotoxicity is a known risk of overdosage, and the drug should be used with caution in patients with hepatic disease or undergoing hepatic surgery. Oral and rectal acetaminophen are as effective as the intravenous form and orders of magnitude less expensive.

CLONIDINE

Mechanism of Action

Clonidine is an imidazoline derivative with predominantly \( \alpha_2 \)-adrenergic agonist activity. It is highly lipid soluble and readily penetrates the blood–brain barrier and the placenta. Studies indicate that binding of clonidine to receptors is highest
in the rostral ventrolateral medulla in the brainstem (the final common pathway for sympathetic outflow), where it activates inhibitory neurons. The overall effect is to decrease sympathetic activity, enhance parasympathetic tone, and reduce circulating catecholamines. There is also evidence that some of clonidine’s antihypertensive action may occur via binding to a nonadrenergic (imidazoline) receptor. In contrast, its analgesic effects, particularly in the spinal cord, are mediated entirely via pre- and possibly postsynaptic α₂-adrenergic receptors that block nociceptive transmission. Clonidine also has local anesthetic effects when applied to peripheral nerves and is frequently added to local anesthetic solutions to increase duration of action.

**Clinical Uses**

Clonidine is a commonly used antihypertensive agent that reduces sympathetic tone, decreasing systemic vascular resistance, heart rate, and blood pressure. In anesthesia, clonidine is used as an adjunct for epidural, caudal, and peripheral nerve block anesthesia and analgesia. It is often used in the management of patients with chronic neuropathic pain to increase the efficacy of epidural opioid infusions. When given epidurally, the analgesic effect of clonidine is segmental, being localized to the level at which it is injected or infused. When added to local anesthetics of intermediate duration (eg, mepivacaine or lidocaine) administered for epidural or peripheral nerve block, clonidine will markedly prolong both the anesthetic and analgesic effects.

Unlabeled/investigational uses of clonidine include serving as an adjunct in premedication, control of withdrawal syndromes (nicotine, opioids, alcohol, and vasomotor symptoms of menopause), and treatment of glaucoma as well as various psychiatric disorders.

**Side Effects**

Sedation, dizziness, bradycardia, and dry mouth are common side effects. Less commonly, orthostatic hypotension, nausea, and diarrhea may be observed. Abrupt discontinuation of clonidine following long-term administration (>1 month) can produce a withdrawal phenomenon characterized by rebound hypertension, agitation, and sympathetic overactivity.

**Dosage**

Epidural clonidine is usually started at 30 mcg/h in a mixture with an opioid or a
local anesthetic. Oral clonidine is readily absorbed, has a 30 to 60 min onset, and lasts 6 to 12 h. In the initial treatment of hypertension, 0.1 mg can be given two times a day and adjusted until the blood pressure is controlled. The maintenance dose typically ranges from 0.1 to 0.3 mg twice daily. Transdermal preparations of clonidine can also be used for maintenance therapy. They are available as 0.1, 0.2, and 0.3 mg/d patches that are replaced every 7 days. Clonidine is metabolized by the liver and excreted by the kidney. Dosages should be reduced for patients with kidney disease.

**Drug Interactions**

Clonidine enhances and prolongs sensory and motor blockade from local anesthetics. Additive effects with hypnotic agents, general anesthetics, and sedatives can potentiate sedation, hypotension, and bradycardia. The drug should be used cautiously, if at all, in patients who take β-adrenergic blockers and in those with significant cardiac conduction system abnormalities. Lastly, clonidine can mask the symptoms of hypoglycemia in diabetic patients.

**DEXMEDETOMIDINE**

**Mechanism of Action**

Dexmedetomidine is a parenteral selective α₂ agonist with sedative properties. It appears to be more selective for the α₂ receptor than clonidine. At higher doses, it loses its selectivity and also stimulates α₁-adrenergic receptors.

**Clinical Uses**

Dexmedetomidine causes dose-dependent sedation, anxiolysis, some analgesia, and blunting of the sympathetic response to surgery and to other stress. Most importantly, it has an opioid-sparing effect and does not significantly depress respiratory drive; excessive sedation, however, may cause airway obstruction. The drug can be used for short-term (<24 h), intravenous sedation of mechanically ventilated patients. Discontinuation after more prolonged use can potentially cause a withdrawal phenomenon similar to that of clonidine. It is also used for intraoperative sedation and as an adjunct to general anesthetics.

**Side Effects**
The principal side effects are bradycardia, heart block, and hypotension. It may also cause nausea.

**Dosage**

The recommended initial loading dose is 1 mcg/kg intravenously over 10 min with a maintenance infusion rate of 0.2 to 0.7 mcg/kg/h. Dexmedetomidine has a rapid onset and terminal half-life of 2 h. The drug is metabolized in the liver and its metabolites are eliminated in the urine. Dosage should be reduced in patients with liver or kidney disease.

**Drug Interactions**

Caution should be used when dexmedetomidine is administered with vasodilators, cardiac depressants, and drugs that decrease heart rate. Reduced requirements of hypnotics/anesthetic agents should prevent excessive hypotension.

**GABAPENTIN & PREGABALIN**

Gabapentin was initially employed as an anticonvulsant. Gabapentin and pregabalin act by blocking voltage-gated calcium channels, resulting in diminished release of glutamate. Various studies have demonstrated that both drugs may reduce perioperative opioid consumption when included in multimodal pain management. Gabapentin may be given to adults as a 600 mg preemptive dose prior to surgery and continued postoperatively (1200 mg/d in divided doses). These agents are also commonly used for management of chronic (particularly neuropathic) pain syndromes.

**CAPSAICIN**

Capsaicin is a TRPV1-receptor agonist. It depletes substance P and inhibits pain signal transmission. Infiltration of capsaicin in surgical wounds reduces opioid consumption and improves perioperative analgesia.

**DOXAPRAM**

**Mechanism of Action**
Doxapram is a peripheral and central nervous system stimulant. Selective activation of carotid chemoreceptors by low doses of doxapram stimulates hypoxic drive, producing an increase in tidal volume and a slight increase in respiratory rate. At larger doses, respiratory centers in the medulla are stimulated.

**Clinical Uses**
Doxapram is not a specific reversal agent and should not replace standard supportive therapy (ie, mechanical ventilation). Drug-induced respiratory and central nervous system depression, including that seen immediately postoperatively, can be *temporarily* overcome. Doxapram will not reverse paralysis caused by muscle relaxants and will not alleviate airway obstruction.

**Side Effects**
Stimulation of the central nervous system leads to a variety of possible side effects: changes in mental status (confusion, dizziness, seizures), cardiac abnormalities (tachycardia, dysrhythmias, hypertension), and pulmonary dysfunction (wheezing, tachypnea). Vomiting and laryngospasm are of particular concern to the anesthesiologist in the postoperative period. Doxapram should not be used in patients with a history of epilepsy, cerebrovascular disease, acute head injury, coronary artery disease, hypertension, or bronchial asthma.

**Dosage**
Bolus intravenous administration (0.5–1 mg/kg) results in transient increases in minute ventilation (the onset of action is 1 min; the duration of action is 5–12 min). Continuous intravenous infusions (1–3 mg/min) provide longer-lasting effects (the maximum dose is 4 mg/kg).

**Drug Interactions**
The sympathetic stimulation produced by doxapram may exaggerate the cardiovascular effects of monoamine oxidase inhibitors or adrenergic agents.
Naloxone is a competitive opioid receptor antagonist. Its affinity for opioid µ receptors appears to be much greater than for opioid κ or δ receptors. Naloxone has no significant agonist activity.

**Clinical Uses**

- Naloxone reverses the agonist activity associated with endogenous (enkephalins, endorphins) or exogenous opioid compounds. A dramatic example is the reversal of unconsciousness that occurs in a patient with opioid overdose who has received naloxone. Thus, naloxone is widely available for first responders and relatives of those who abuse opioids. Perioperative respiratory depression caused by opioids is rapidly antagonized (1–2 min). Some degree of opioid analgesia can often be spared if the dose of naloxone is limited to the minimum required to maintain adequate ventilation (40–80 mcg intravenously in adults, repeated as needed). Small doses of intravenous naloxone reverse the side effects of spinal or epidural opioids without necessarily reversing the analgesia.

**Side Effects**

Abrupt, complete reversal of opioid analgesia can result in a surge of sympathetic stimulation (tachycardia, ventricular irritability, hypertension, pulmonary edema) caused by severe, acute pain, and an acute withdrawal syndrome in patients who are opioid-dependent.

**Dosage**

In postoperative patients experiencing respiratory depression from excessive opioid administration, intravenous naloxone (0.4 mg/mL vial diluted in 9 mL saline to 0.04 mg/mL) can be titrated in increments of 0.5 to 1 mcg/kg every 3 to 5 min until adequate ventilation and alertness are achieved. Doses in excess of 200 mcg are rarely needed. The brief duration of action of intravenous naloxone (30–45 min) is due to rapid redistribution from the central nervous system. A more prolonged effect will be necessary to prevent the recurrence of respiratory depression from longer-acting opioids. Therefore, intramuscular naloxone (twice the required intravenous dose) or a continuous naloxone infusion is recommended. Naloxone may precipitate symptoms of withdrawal in infants of opioid-exposed mothers.
**Drug Interactions**

The effect of naloxone on nonopioid anesthetic agents such as nitrous oxide or clonidine is insignificant.

**NALTREXONE**

Naltrexone is also a pure opioid antagonist with a high affinity for the μ receptor, but with a significantly longer half-life than naloxone. Naltrexone is used orally for maintenance treatment of addiction. Chapter 48 reviews the use of the peripherally acting opioid receptor antagonists alvimopan and methylnaltrexone in the management and prevention of postoperative ileus as an element of enhanced perioperative recovery.

**FLUMAZENIL**

**Mechanism of Action**

Flumazenil, an imidazobenzodiazepine, is a specific and competitive antagonist of benzodiazepines at benzodiazepine receptors.

**Clinical Uses**

Flumazenil is useful in the reversal of benzodiazepine sedation and the treatment of benzodiazepine overdose. Although it promptly (onset <1 min) reverses the hypnotic effects of benzodiazepines, amnesia has proved to be less reliably prevented. Some evidence of respiratory depression may linger despite an alert and awake appearance. Specifically, tidal volume and minute ventilation return to normal, but the slope of the carbon dioxide response curve remains depressed. Effects in elderly patients appear to be particularly difficult to reverse fully, and these patients are more prone to relapse of sedation.

**Side Effects & Drug Interactions**

Rapid administration of flumazenil may cause anxiety reactions in previously sedated patients and symptoms of withdrawal in those on long-term benzodiazepine therapy. Flumazenil reversal has been associated with increases in intracranial pressure in patients with head injuries and abnormal intracranial compliance. Flumazenil may induce seizure activity if benzodiazepines have
been given as anticonvulsants or in conjunction with an overdose of tricyclic antidepressants. Flumazenil reversal following a midazolam–ketamine anesthetic technique may increase the incidence of emergence dysphoria and hallucinations. Nausea and vomiting are not uncommon following administration of flumazenil. The reversal effect of flumazenil is based on its strong antagonist affinity for benzodiazepine receptors. Flumazenil does not affect the minimum alveolar concentration of inhalation anesthetics.

**Dosage**

Gradual titration of flumazenil is usually accomplished by intravenous administration of 0.2 mg/min until reaching the desired degree of reversal. The usual total dose is 0.6 to 1.0 mg. Because of flumazenil’s rapid hepatic clearance, repeat doses may be required after 1 to 2 h to avoid re-sedation and premature recovery room or outpatient discharge. Liver failure prolongs the clearance of flumazenil and benzodiazepines.

**CASE DISCUSSION**

**Management of Patients at Risk for Aspiration Pneumonia**

A 58-year-old man is scheduled for elective laparoscopic cholecystectomy. His past history reveals a persistent problem with heartburn and passive regurgitation of gastric contents into the pharynx. He has been told by his internist that these symptoms are due to a hiatal hernia.

*Why would a history of hiatal hernia concern the anesthesiologist?*

Perioperative aspiration of gastric contents (Mendelson syndrome) is a potentially fatal complication of anesthesia. Hiatal hernia is commonly associated with symptomatic GERD, which is considered a predisposing factor for aspiration. Mild or occasional heartburn may not significantly increase the risk of aspiration. In contrast, symptoms related to passive reflux of gastric fluid, such as acid taste or sensation of refluxing liquid into the mouth, should alert the clinician to a high risk of pulmonary aspiration. Paroxysms of coughing or wheezing, particularly at night or when the
Which patients are predisposed to aspiration?

Patients with altered airway reflexes (eg, drug intoxication, general anesthesia, encephalopathy, neuromuscular disease) or abnormal pharyngeal or esophageal anatomy (eg, large hiatal hernia, Zenker diverticulum, scleroderma, pregnancy, obesity, history of esophagectomy) are prone to pulmonary aspiration.

Does aspiration consistently result in aspiration pneumonia?

Not necessarily. The seriousness of the lung damage depends on the volume and composition of the aspirate. Traditionally, patients are considered to be at risk if their gastric volume is greater than 25 mL (0.4 mL/kg) and their gastric pH is less than 2.5. Some investigators believe that controlling acidity is more important than volume and that the criteria should be revised to a pH less than 3.5 with a volume greater than 50 mL.

Patients who have eaten immediately prior to emergency surgery are obviously at risk. Traditionally, “NPO after midnight” implied a preoperative fast of at least 6 h. Current opinion allows clear liquids until 2 h before induction of anesthesia. According to the American Society of Anesthesiologists (ASA) guideline, breast milk is permitted up to 4 h before anesthesia. Infant formula, nonhuman milk and a light meal are permitted up to 6 h before induction. Patients consuming a heavy meal including meat, fats, and fried foods should fast for 8 h. Certain patient populations are particularly likely to have large volumes of acidic gastric fluid: patients with an acute abdomen or peptic ulcer disease, children, the elderly, diabetic patients, pregnant women, and obese patients. Furthermore, pain, anxiety, or opioids may delay gastric emptying. Note that pregnancy and obesity place patients in double jeopardy by increasing the chance of aspiration (increased intraabdominal pressure and distortion of the lower esophageal sphincter) and the risk of aspiration pneumonia (increased acidity and volume of gastric contents). Aspiration is more common in patients undergoing esophageal, upper abdominal, or emergency laparoscopic surgery.

Which drugs lower the risk of aspiration pneumonia?

H₂-Receptor antagonists decrease gastric acid secretion. Although they
will not affect gastric contents already in the stomach, they will inhibit further acid production. Both gastric pH and volume are affected. In addition, the long duration of action of ranitidine and famotidine may provide protection in the recovery room.

Metoclopramide shortens gastric emptying time and increases lower esophageal sphincter tone. It does not affect gastric pH, and it cannot clear large volumes of food in a few hours. Nonetheless, metoclopramide with ranitidine is a good combination for most at-risk patients. Antacids usually raise gastric fluid pH, but, at the same time, they increase gastric volume. Although antacid administration technically removes a patient from the at-risk category, aspiration of a substantial volume of particulate matter will lead to serious physiological damage. For this reason, clear antacids (eg, sodium citrate) are employed. In contrast to H₂ antagonists, antacids are immediately effective and alter the acidity of existing gastric contents. Thus, they are useful in emergency situations and in patients who have recently eaten.

Anticholinergic drugs, particularly glycopyrrolate, decrease gastric secretions if large doses are administered; however, lower esophageal sphincter tone is reduced. Overall, anticholinergic drugs do not reliably reduce the risk of aspiration pneumonia and can reverse the protective effects of metoclopramide. Proton pump inhibitors are generally as effective as H₂ antagonists.

The ASA guideline recommends that prophylaxis against gastric content aspiration be undertaken only in at-risk patients.

**What anesthetic techniques are used in full-stomach patients?**

If the full stomach is due to recent food intake and the surgical procedure is elective, the operation should be postponed. If the risk factor is not reversible (eg, large hiatal hernia) or the case is emergent, proper anesthetic technique can minimize the risk of aspiration pneumonia. Regional anesthesia with minimal sedation should be considered in patients at increased risk for aspiration pneumonia. If local anesthetic techniques are impractical, the patient’s airway must be protected. Delivering anesthesia by mask or laryngeal mask airway is contraindicated. As in every anesthetic case, the availability of suction must be confirmed before induction. A rapid-sequence induction (or, depending upon airway examination, an awake intubation) is indicated.
**How does a rapid-sequence induction differ from a routine induction?**

- The patient is always preoxygenated prior to induction. Patients with lung disease require 3 to 5 min of preoxygenation.
- A wide assortment of blades, video laryngoscopes, intubation bougies, and endotracheal tubes are prepared in advance and immediately available.
- An assistant may apply firm pressure over the cricoid cartilage prior to induction (Sellick maneuver). Because the cricoid cartilage forms an uninterrupted and incompressible ring, pressure over it is transmitted to underlying tissue. The esophagus is collapsed, and passively regurgitated gastric fluid cannot reach the hypopharynx. Excessive cricoid pressure (beyond what can be tolerated by a conscious person) applied during active regurgitation has been associated with rupture of the posterior wall of the esophagus. The effectiveness of Sellick maneuver has been questioned.
- A propofol induction dose is given as a bolus. Obviously, this dose must be modified if there is any indication that the patient’s cardiovascular system is unstable. Other rapid-acting induction agents can be substituted (eg, etomidate, ketamine).
- Succinylcholine (1.5 mg/kg) or rocuronium (0.9–1.2 mg/kg) is administered immediately following the induction dose, even if the patient has not yet lost consciousness.
- The patient is not artificially ventilated, to avoid filling the stomach with gas and thereby increasing the risk of emesis. Once spontaneous efforts have ceased or muscle response to nerve stimulation has disappeared, the patient is rapidly intubated. Cricoid pressure is maintained until the endotracheal tube cuff is inflated and tube position is confirmed. A modification of the classic rapid-sequence induction allows gentle ventilation as long as cricoid pressure is maintained.
- If the intubation proves difficult, cricoid pressure is maintained and the patient is gently ventilated with oxygen until another intubation attempt can be performed. If intubation is still unsuccessful, spontaneous ventilation should be allowed to return and an awake intubation performed. Sugammadex can be administered to reverse rocuronium-induced muscle relaxation.
- After surgery, the patient should remain intubated until airway reflexes
and consciousness have returned.

**What are the relative contraindications to rapid-sequence inductions?**

Rapid-sequence inductions are often associated with increases in intracranial pressure, arterial blood pressure, and heart rate.

**Describe the pathophysiology and clinical findings associated with aspiration pneumonia.**

The pathophysiological changes depend on the composition of the aspirate. Acid solutions cause atelectasis, alveolar edema, and loss of surfactant. Particulate aspirate will also result in small-airway obstruction and alveolar necrosis. Granulomas may form around food or antacid particles. The earliest physiological change following aspiration is intrapulmonary shunting, resulting in hypoxia. Other changes may include pulmonary edema, pulmonary hypertension, and hypercapnia.

Wheezing, rhonchi, tachycardia, and tachypnea are common physical findings. Decreased lung compliance can make ventilation difficult. Hypotension signals significant fluid shifts into the alveoli and is associated with diffuse bilateral lung injury. Chest roentgenography may not demonstrate diffuse bilateral infiltrates for several hours after the event. Arterial blood gases reveal hypoxemia, hypercapnia, and respiratory acidosis.

**What is the treatment for aspiration pneumonia?**

As soon as regurgitation is suspected, the patient should be placed in a head-down position so that gastric contents drain out of the mouth instead of into the trachea. The pharynx and, if possible, the trachea should be thoroughly suctioned. The mainstay of therapy in patients who subsequently become hypoxic is positive-pressure ventilation. Intubation and the institution of positive end-expiratory pressure, or noninvasive ventilation, may be required. Bronchoscopy and pulmonary lavage are usually indicated when particulate aspiration has occurred. Use of corticosteroids is generally not recommended, and antibiotics are administered depending upon culture results.

Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: Application to healthy patients undergoing elective procedures. An updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology.* 2011;114:495.

**SUGGESTED READINGS**

Preoperative Assessment, Premedication, & Perioperative Documentation

KEY CONCEPTS

1. The cornerstones of an effective preoperative or preprocedure evaluation are the history and physical examination, which should include a complete and up-to-date listing of all medications taken by the patient in the recent past, all pertinent allergies, and responses and reactions to previous anesthetics.

2. The anesthesiologist should not be expected to provide the risk-versus-benefit discussion for the proposed surgery or procedure; this is the responsibility and purview of the responsible surgeon or “proceduralist.”

3. By convention physicians in many countries use the American Society of Anesthesiologists’ classification to identify relative risk prior to conscious sedation and surgical anesthesia.

4. In general, the indications for cardiovascular investigations are the same in elective surgical patients as in any other patient with a similar medical condition.

5. Adequacy of long-term blood glucose control can be easily and rapidly assessed by measurement of hemoglobin A\(_{1c}\).

6. In patients deemed at high risk for thrombosis (eg, those with certain mechanical heart valve implants or with atrial fibrillation and a prior thromboembolic stroke), chronic anticoagulants should be replaced by intramuscular low-molecular-weight heparins or by intravenous unfractionated heparin.
Current guidelines recommend postponing all but mandatory emergency surgery until at least 1 month after any coronary intervention and suggest that treatment options other than a drug-eluting stent (which will require prolonged dual antiplatelet therapy) be used in patients expected to undergo a surgical procedure within 12 months after the intervention.

There are no good data to support restricting fluid intake (of any kind or any amount) more than 2 h before induction of general anesthesia in healthy patients undergoing elective procedures; moreover, there is strong evidence that nondiabetic patients who drink fluids containing carbohydrates and protein up to 2 h before induction of anesthesia suffer less perioperative nausea and dehydration than those who are fasted longer.

To be valuable, preoperative testing must discriminate: There must be an avoidable increased perioperative risk when the results are abnormal (and the risk will remain unknown if the test is not performed), and when testing fails to detect the abnormality (or it has been corrected), there must be reduced risk.

The utility of a test depends on its sensitivity and specificity. Sensitive tests have a low rate of false-negative results and rarely fail to identify an abnormality when one is present, whereas specific tests have a low rate of false-positive results and rarely identify an abnormality when one is not present.

Premedication should be given purposefully, not as a mindless routine.

Incomplete, inaccurate, or illegible records unnecessarily complicate defending a physician against otherwise unjustified allegations of malpractice.

PREOPERATIVE EVALUATION

The cornerstones of an effective preoperative or preprocedure evaluation are the medical history and physical examination, which should include a complete and up-to-date listing of all medications taken by the patient in the recent past, all pertinent allergies, and responses and reactions to previous anesthetics. Additionally, this evaluation may include diagnostic tests, imaging procedures, or consultations from other physicians when indicated. A patient’s initial contact with a perioperative surgical home or enhanced recovery after surgery (ERAS)
program ideally will occur at the time of the preoperative evaluation visit. An enhanced recovery may require “prehabilitation” with one or more of the following: smoking cessation, nutritional supplementation, an exercise regimen, and adjustment of medications. The preoperative evaluation will often guide the anesthetic plan. Inadequate preoperative planning and incomplete patient preparation commonly lead to avoidable delays, cancellations, complications, and costs.

The preoperative evaluation serves multiple purposes. One purpose is to identify those patients whose outcomes likely will be improved by implementation of a specific medical treatment (which rarely may require that planned surgery be rescheduled). For example, a 60-year-old patient scheduled for elective total hip arthroplasty who also has unstable angina from left main coronary artery disease would more likely survive if coronary artery bypass grafting is performed before rather than after the elective orthopedic procedure. Another purpose of the preoperative evaluation is to identify patients whose condition is so poor that the proposed surgery might only hasten death without improving the quality of life. For example, a patient with severe chronic lung disease, end-stage kidney disease, liver failure, and chronic heart failure likely would not survive to derive benefit from an 8-h, complex, multilevel spinal fusion with instrumentation. A patient’s preoperative evaluation can uncover findings that will change the anesthetic plan (Table 18–1). For example, the anesthetic plan may need to be adjusted for a patient whose trachea appears difficult to intubate, one with a family history of malignant hyperthermia, or one with an infection near where a proposed regional anesthetic would be administered.

**TABLE 18–1** The anesthetic plan.
Another purpose of the preoperative evaluation is to provide the patient with an estimate of anesthetic risk. However, the anesthesiologist should not be expected to provide the risk-versus-benefit discussion for the proposed surgery or procedure; this is the responsibility and purview of the responsible surgeon or “proceduralist.” For example, a discussion of the risks and benefits of robot-assisted laparoscopic prostatectomy versus “open” prostatectomy, radiation therapy, or “watchful waiting” requires detailed knowledge of the current medical literature and the capabilities of an individual surgeon. Finally, the preoperative evaluation presents an opportunity for the anesthesiologist to describe the proposed anesthetic plan in the context of the overall surgical and postoperative plan, provide the patient with psychological support, and obtain informed consent for the proposed anesthetic plan from the surgical patient.

By convention, physicians in many countries use the American Society of Anesthesiologists’ (ASA) physical status classification to define relative risk.
prior to conscious sedation or surgical anesthesia (Table 18–2). The ASA physical status classification has many advantages: it is time tested, simple, and reproducible, and, most importantly, it has been shown to be strongly associated with perioperative risk. However, many other risk assessment tools are available, particularly in the area of cardiovascular risk assessment (see Chapter 21).

**Elements of the Preoperative History**

Patients presenting for elective surgery and anesthesia typically require the recording of a focused medical history emphasizing abnormalities of exercise tolerance; nutritional and functional status; cardiac, pulmonary, endocrine, kidney, or liver function; electrolytes or metabolism; and anatomic issues relevant to airway management or regional anesthesia. How the patient responded to and recovered from previous anesthetics can be helpful. The ASA
and other societies publish and periodically update general guidelines for preoperative assessment (see Guidelines at end of chapter).

A. Cardiovascular Issues
Guidelines for preoperative cardiac assessment are regularly updated and available from the American College of Cardiology/American Heart Association and from the European Society of Cardiology (see Guidelines). A more complete discussion of cardiovascular assessment is provided in Chapter 21. The focus of preoperative cardiac assessment should be on determining whether the patient would benefit from further cardiac evaluation or interventions prior to the scheduled surgery. However, the same approach is not appropriate for all patients. The prudent approach to a patient undergoing elective knee arthroplasty will differ from that for a patient needing resection of pancreatic cancer, given the benign results of a delay in the former procedure and the possible deadly effects of a delay in the latter procedure. In general, the indications for cardiovascular investigations are the same in elective surgical patients as in any other patient with a similar medical condition. Put another way, the fact that a patient is scheduled to undergo elective surgery does not change the indications for testing to diagnose coronary artery disease.

B. Pulmonary Issues
Perioperative pulmonary complications, most notably postoperative respiratory depression and respiratory failure, are vexing problems associated with obesity and obstructive sleep apnea. A guideline developed by the American College of Physicians identifies patients 60 years of age or older and those with chronic obstructive lung disease, with markedly reduced exercise tolerance, with functional dependence, or with heart failure as potentially requiring preoperative and postoperative interventions to avoid respiratory complications. The risk of postoperative respiratory complications is closely associated with these factors, and with the following: ASA physical status 3 and 4, cigarette smoking, surgeries lasting longer than 4 h, certain types of surgery (abdominal, thoracic, aortic aneurysm, head and neck, and emergency surgery), and general anesthesia (compared with cases in which general anesthesia was not used).

Efforts at prevention of respiratory complications in patients at risk should include cessation of cigarette smoking several weeks before surgery and lung expansion techniques (eg, incentive spirometry) after surgery. Patients with asthma, particularly those receiving suboptimal medical management, have a greater risk for bronchospasm during airway manipulation. Appropriate use of
analgesia and monitoring are key strategies for avoiding postoperative respiratory depression in patients with obstructive sleep apnea. Further discussion of this topic appears in Chapter 44.

C. Endocrine and Metabolic Issues

The appropriate target blood glucose concentration has been the subject of several celebrated clinical trials. “Tight” control of blood glucose, with a target concentration in the “normal” range, was shown in the Diabetes Control and Complications Trial to improve outcomes in ambulatory patients with type 1 diabetes mellitus. Other more recent trials conducted in subjects with critical illness have shown that blood glucose should not be so tightly controlled.

The usual practice is to obtain a blood glucose measurement in diabetic patients on the morning of elective surgery. Unfortunately, many diabetic patients presenting for elective surgery do not maintain blood glucose within the desired range. Other patients, who may be unaware that they have type 2 diabetes, present with blood glucose measurements above the normal range. Adequacy of long-term blood glucose control can be easily and rapidly assessed by measurement of hemoglobin A\textsubscript{1c}. In patients with abnormally elevated hemoglobin A\textsubscript{1c}, referral to a diabetology service for education about the disease and adjustment of diet and medications to improve metabolic control may be beneficial. Elective surgery should be delayed in patients presenting with marked hyperglycemia; in an otherwise well-managed patient with type 1 diabetes, this delay might consist only of rearranging the order of scheduled cases to allow insulin infusion to bring the blood glucose concentration closer to the normal range before surgery. A more complete discussion of diabetes mellitus and other perioperative endocrine concerns is provided in Chapter 35.

D. Coagulation Issues

Three important coagulation issues that must be addressed during the preoperative evaluation are (1) how to manage patients who are taking warfarin or other long-acting anticoagulants on a long-term basis; (2) how to manage patients with coronary artery disease who are taking clopidogrel or related agents; and (3) whether one can safely provide neuraxial anesthesia to patients who either are receiving long-term anticoagulation therapy or who will receive anticoagulation perioperatively. In the first circumstance, most patients undergoing anything more involved than minor surgery will require discontinuation of anticoagulation in advance of surgery to avoid excessive blood loss. The key issues to be addressed are how far in advance the drug
should be discontinued and whether the patient will require “bridging” therapy with another, shorter-acting, agent. In patients deemed at high risk for thrombosis (eg, those with certain mechanical heart valve implants or with atrial fibrillation and a prior thromboembolic stroke), chronic anticoagulants should be replaced by intramuscular low molecular weight heparins (eg, enoxaparin) or by intravenous unfractionated heparin. The prescribing physician and surgeon may need to be consulted regarding discontinuation of these agents and whether bridging will be required. In patients with a high risk of thrombosis who receive bridging therapy, the risk of death from excessive bleeding is an order of magnitude lower than the risk of death or disability from stroke if the bridging therapy is omitted. Patients at lower risk for thrombosis may have their anticoagulant drug discontinued preoperatively and then reinitiated after successful surgery.

Clopidogrel and similar agents are often administered with aspirin (so-called dual antiplatelet therapy) to patients with coronary artery disease who have received intracoronary stenting. Immediately after stenting, such patients are at increased risk of acute myocardial infarction if clopidogrel (or related agents) and aspirin are abruptly discontinued. Therefore, current guidelines recommend postponing all but mandatory surgery until at least 1 month after any coronary intervention and suggest that treatment options other than a drug-eluting stent (which will require prolonged dual antiplatelet therapy) be used in patients expected to undergo a surgical procedure within 12 months after the intervention (eg, a patient with coronary disease who also has resectable colon cancer). As the drugs, treatment options, and consensus guidelines are updated frequently, when we are in doubt we consult with a cardiologist when patients receiving these agents require a surgical procedure.

The third issue—when it may be safe to perform regional (particularly neuraxial) anesthesia in patients who are or will be receiving anticoagulation therapy—has also been the subject of debate. The American Society of Regional Anesthesia and Pain Medicine publishes a regularly updated consensus guideline on this topic, and other prominent societies (eg, the European Society of Anaesthesiologists) also provide guidance on this topic (see Chapter 45).

E. Gastrointestinal Issues
Since Mendelson’s 1946 report, aspiration of gastric contents has been recognized as a potentially disastrous pulmonary complication of surgical anesthesia. It has also been long recognized that the risk of aspiration is increased in certain groups of patients: pregnant women in the second and third
trimesters, those whose stomachs have not emptied after a recent meal, and those with serious gastroesophageal reflux disease (GERD).

Although there is consensus that pregnant women and those who have recently (within 6 h) consumed a full meal should be treated as if they have “full” stomachs, there is less consensus as to the necessary period of time in which patients must fast before elective surgery. Proof of the lack of consensus is the fact that the ASA’s guideline on this topic was voted down by the ASA House of Delegates several years in a row before it was presented in a form that received majority approval. The guideline as approved is more permissive of fluid intake than many anesthesiologists would prefer, and many medical centers have policies that are more restrictive than the ASA guideline on this topic. The truth is that there are no good data to support restricting fluid intake (of any kind or any amount) more than 2 h before induction of general anesthesia in healthy patients undergoing elective procedures; moreover, there is strong evidence that nondiabetic patients who drink fluids containing carbohydrates and protein up to 2 h before induction of anesthesia suffer less perioperative nausea and dehydration than those who are fasted longer.

Patients claiming a history of GERD present vexing problems. Some of these patients will be at increased risk for aspiration; others may carry this “self-diagnosis” based on advertisements or internet searches, or may have been given this diagnosis by a physician who did not follow the standard diagnostic criteria. Our approach is to treat patients who have only occasional symptoms like any other patient without GERD, and to treat patients with consistent symptoms (multiple times per week) with medications (eg, nonparticulate antacids such as sodium citrate) and techniques (eg, tracheal intubation rather than laryngeal mask airway) as if they were at increased risk for aspiration.

**Elements of the Preoperative Physical Examination**

The preoperative history and physical examination complement one another: The physical examination may detect abnormalities not apparent from the history, and the history helps focus the physical examination. Examination of healthy asymptomatic patients should include measurement of vital signs (blood pressure, heart rate, respiratory rate, and temperature) and examination of the airway, heart, and lungs using standard techniques of inspection, palpation, percussion, and auscultation. Before administering regional anesthetics or inserting invasive monitors, one should examine the relevant anatomy; infection or anatomic abnormalities near the site may contraindicate the planned procedure (see Chapters 5, 45, and 46). An abbreviated, focused neurological
examination serves to document whether any neurological deficits may be present before a regional anesthesia procedure is performed.

The anesthesiologist should examine the patient’s airway before every anesthetic is administered. Any loose or chipped teeth, caps, bridges, or dentures should be noted. Poor fit of the anesthesia mask should be expected in edentulous patients and those with significant facial abnormalities. Micrognathia (a short distance between the chin and the hyoid bone), prominent upper incisors, a large tongue, limited range of motion of the temporomandibular joint or cervical spine, or a short or thick neck suggest that difficulty may be encountered in direct laryngoscopy for tracheal intubation (see Chapter 19). The Mallampati score is often recorded.

**Preoperative Laboratory Testing**

Routine laboratory testing is not recommended for fit and asymptomatic patients. “Routine” testing is avoidably expensive and rarely alters perioperative management; moreover, inconsequential abnormal values may result in further unnecessary testing, delays, and costs. Nonetheless, despite no evidence of benefit, some physicians request blood tests, an electrocardiogram, and a chest radiograph for all patients, perhaps in the misplaced hope of reducing their exposure to litigation.

Ideally, testing should be guided by the history and physical examination. To be valuable, preoperative testing must discriminate: There must be an avoidable increased perioperative risk when the results are abnormal (and the risk will remain unknown if the test is not performed), and when testing fails to detect the abnormality (or it has been corrected), there must be reduced risk. Useful tests have a low rate of false-positive and false-negative results (Table 18–3). The utility of a test depends on its sensitivity and specificity. Sensitive tests have a low rate of false-negative results and rarely fail to identify an abnormality when one is present, whereas specific tests have a low rate of false-positive results and rarely identify an abnormality when one is not present.

**TABLE 18–3** Calculation of sensitivity and specificity based on presence or absence of disease in the population being tested.
The prevalence of a disease or of an abnormal test result varies with the population tested. Testing is therefore most effective when sensitive and specific tests are used in patients in whom the abnormality will be detected frequently enough to justify the expense and inconvenience of the test procedure. Accordingly, laboratory testing should be based on the history and physical examination and the nature of the proposed surgery or procedure. Thus, a baseline hemoglobin or hematocrit measurement is desirable in any patient about to undergo a procedure in which extensive blood loss and transfusion are likely, particularly when there is sufficient time to correct anemia preoperatively (eg, with iron supplements).

Testing fertile women and girls for pregnancy is controversial (but done routinely in many centers) and should not be done without the permission of the patient; pregnancy testing involves detection of chorionic gonadotropin in urine or serum. Routine testing for HIV and routine coagulation studies are not indicated. Urinalysis is not cost-effective in asymptomatic healthy patients; nevertheless, a preoperative urinalysis is required by state law in at least one U.S. jurisdiction.

**PREMEDICATION**

A classic study showed that a preoperative visit from an anesthesiologist resulted in greater reduction in patient anxiety than preoperative sedative drugs. Yet, there was a time when virtually every patient received premedication before
arriving in the preoperative area in anticipation of surgery. The belief was that all patients benefitted from preoperative sedation and anticholinergics, often combined with an opioid. With the move to outpatient surgery and “same-day” hospital admission, preoperative sedative-hypnotics or opioids are now almost never administered before patients arrive in the preoperative holding area for elective surgery. Children, especially those aged 2 to 10 years who (along with their parents) likely will experience separation anxiety may benefit from premedication administered in the preoperative holding area. This topic is discussed in Chapter 42. Oral or intravenous midazolam or nasal dexamethomidine are common methods. Adults often receive intravenous midazolam (2–5 mg) once an intravenous line has been established. If a painful procedure (eg, regional block or a central venous line) will be performed while the patient remains awake, small doses of opioid (typically fentanyl) will often be given. Patients who will undergo airway surgery or extensive airway manipulations benefit from preoperative administration of an anticholinergic agent (glycopyrrolate or atropine) to reduce airway secretions before and during surgery. Patients who are expected to have significant amounts of postoperative pain will often be given “multimodal” analgesia, including various combinations of nonsteroidal antiinflammatory drugs, acetaminophen, gabapentinoids, and anti-nausea drugs in the preoperative holding area. The fundamental message here is that premedication should be given purposefully, not as a mindless routine.

**DOCUMENTATION**

Physicians should provide high-quality, safe, and cost-efficient medical care. But they also must document the care that they provide. Adequate documentation provides guidance to those who will encounter the patient in the future. It permits others to assess the quality of the care that was given and to provide risk adjustment of outcomes. Without documentation a physician will not be paid for his or her services; incomplete documentation may not justify the otherwise appropriate “full” payment. Incomplete documentation may render it difficult for a hospital system to recover its costs and may incorrectly lead to the conclusion that a patient’s hospitalization was inappropriately prolonged. Finally, adequate and organized documentation (as opposed to inadequate and disorganized documentation) supports a potential defense case should a claim for medical malpractice be filed.
Preoperative Assessment Note

The preoperative assessment note should appear in the patient’s permanent medical record and should describe pertinent findings, including the medical history, anesthetic history, current medications (and whether they were taken on the day of surgery), physical examination, ASA physical status, laboratory results, interpretation of imaging, electrocardiograms, and pertinent recommendations of any consultants. A comment is particularly important when a consultant’s recommendation will not be followed.

The preoperative note should identify the anesthetic plan, indicating whether regional or general anesthesia (or sedation) will be used, and whether invasive monitoring or other advanced techniques will be employed. It should include a statement regarding the informed consent discussion with the patient (or guardian). Documentation of the informed consent discussion may take the form of a narrative indicating that the plan, alternative plans, and their advantages and disadvantages (including their relative risks) were presented, understood, and accepted by the patient. Some centers include consent for anesthesia within the consent for surgery (or the procedure). Alternatively, the patient may be asked to read and sign a separate anesthesia consent form that contains the same information.

In the United States, the Joint Commission (TJC) requires an immediate preanesthetic “reevaluation” to determine whether the patient’s status has changed in the time since the preoperative evaluation was performed. This reevaluation might include a review of the medical record to search for any new laboratory results or consultation reports if the patient was last seen on another date. However, even when the elapsed time is less than a minute, the bureaucracy will not be denied: the “box” must be checked to document that there has been no interval change.

Intraoperative Anesthesia Record

The intraoperative anesthesia record serves many purposes. It functions as documentation of intraoperative monitoring, a reference for future anesthetics for that patient, and a source of data for quality assurance. This record should be terse, pertinent, and accurate. Increasingly, parts of the anesthesia record are generated automatically and recorded electronically. Such anesthesia information management systems (commonly abbreviated AIMS) have many theoretical and practical advantages over the traditional paper record but also introduce all the common pitfalls of computerization, including the potential for unrecognized
recording of artefactual data, the possibility that practitioners will find attending
to the computer more interesting than attending to the patient, and the inevitable
occurrence of device and software shutdowns. Regardless of whether the record
is on paper or electronic it should document the anesthetic care in the operating
room by including the following elements:

• That there has been a preoperative check of the anesthesia machine and other
  relevant equipment
• That there has been a reevaluation of the patient immediately prior to
  induction of anesthesia (a TJC requirement)
• Time of administration, dosage, and route of drugs given intraoperatively
• Intraoperative estimates of blood loss and urinary output
• Results of laboratory tests obtained during the operation (when there is an
  AIMS linked to an electronic medical record, such testing may be recorded
  elsewhere)
• Intravenous fluids and any blood products administered
• Pertinent procedure notes (eg, for tracheal intubation or insertion of invasive
  monitors)
• Any specialized intraoperative techniques such as hypotensive anesthesia,
  one-lung ventilation, high-frequency jet ventilation, or cardiopulmonary
  bypass
• Timing and conduct of intraoperative events such as induction, positioning,
  surgical incision, and extubation
• Unusual events or complications (eg, cardiac arrest)
• Condition of the patient at the time of “handoff” to the postanesthesia or
  intensive care unit nurse

By tradition and convention (and, in the United States, according to practice
guidelines) arterial blood pressure and heart rate are recorded graphically at no
less than 5 min intervals. Data from other monitors are also usually entered
graphically, whereas descriptions of techniques or complications are described in
text.

Unfortunately, the conventional, handwritten anesthetic record is ill suited for
documenting critical incidents, such as a cardiac arrest. In such cases, a separate
text note inserted in the patient’s medical record may be necessary. Careful
recording of the timing of events is needed to avoid discrepancies between
multiple simultaneous records (anesthesia record, nurses’ notes,
cardiopulmonary resuscitation record, and other physicians’ entries in the medical record). Such discrepancies are frequently targeted by malpractice attorneys as evidence of incompetence, inaccuracy, or deceit. Incomplete, inaccurate, or illegible records unnecessarily complicate defending a physician against otherwise unjustified allegations of malpractice.

**Postoperative Notes**

After accompanying the patient to the postanesthesia care unit (PACU), the anesthesia provider should remain with the patient until normal vital signs have been measured and the patient’s condition is deemed stable. An unstable patient may require being “handed off” to another physician. Before discharge from the PACU, a note should be written by an anesthesiologist to document the patient’s recovery from anesthesia, any apparent anesthesia-related complications, the immediate postoperative condition of the patient, and the patient’s disposition (discharge to an outpatient area, an inpatient ward, an intensive care unit, or home). In the United States, as of 2009, the Centers for Medicare and Medicaid Services require that certain elements be included in all postoperative notes (Table 18–4). Recovery from anesthesia should be assessed at least once within 48 h after discharge from the PACU in all inpatients. Postoperative notes should document the general condition of the patient, the presence or absence of any anesthesia-related complications, and any measures undertaken to treat such complications. The anesthesiologist’s involvement with the patient may continue through the early stages of postoperative recovery when the anesthesiologist is involved in a functioning perioperative surgical home or is providing treatment of postoperative pain (see Chapters 48, 59).

**TABLE 18–4** Elements required by the Center for Medicare and Medicaid Services in all postoperative notes.¹
A healthy 45-year-old man has a cardiac arrest during an elective laparoscopic inguinal hernia repair. Although cardiopulmonary resuscitation is successful, the patient is left with permanent neuropsychological deficits that preclude his return to work. One year later, the patient files a complaint against the anesthesiologist, surgeon, and hospital.

**What four elements must be proved by the plaintiff (patient) to establish negligence on the part of the defendant (physician or hospital)?**

1. **Duty:** Once a physician establishes a professional relationship with a patient, the physician owes that patient certain obligations, such as adhering to the “standard of care.”
2. **Breach of Duty:** If these obligations are not fulfilled, the physician has breached his duties to the patient.
3. **Injury:** An injury must result. The injury may result in general damages (eg, pain and suffering) or special damages (eg, loss of income).
4. **Causation:** The plaintiff must demonstrate that the breach of duty was the *proximate cause* of the injury. But for the breach of duty, the injury should not have occurred.
**How is the standard of care defined and established?**

Individual physicians are expected to perform as any prudent and reasonable physician would in similar circumstances. This does *not* mandate “best” care or optimal care, only care that would meet the minimum standard of a prudent and reasonable physician. As a specialist, the anesthesiologist is held to a higher standard of knowledge and skill with respect to the subject matter of anesthesia than would a general practitioner or a physician in another specialty. Expert witnesses usually provide testimony to define the standard of care in legal proceedings. Medical malpractice cases are governed by the laws of the state or jurisdiction in which the event took place, and these may differ from state to state. For example, some states require that an expert witness have practiced medicine recently in the state or an immediately adjacent state; others have no “residence” requirement for expert witnesses. The specific circumstances pertaining to each individual case are taken into account. The law recognizes that there are differences of opinion and varying schools of thought within the medical profession.

**How is causation determined?**

It is usually the plaintiff who bears the burden of proving that the injury would not have occurred “but for” the negligence of the physician, or that the physician’s action was a “substantial factor” in causing the injury. An exception is the doctrine of *res ipsa loquitur* (“the thing speaks for itself”), which permits a finding of negligence based solely on the evidence. For example, if a set of car keys were visualized inside a patient on a chest radiograph after a thoracotomy, the doctrine of *res ipsa loquitur* would apply. *Res ipsa loquitur* could not be used in the case under discussion because the plaintiff would have to establish that cardiac arrest could not occur in the absence of negligence and that cardiac arrest could not have been due to something outside the control of the anesthesiologist. An important concept is that causation in civil cases in the United States need only be established by a preponderance of the evidence (“more likely than not”)—as opposed to criminal cases, in which all elements of a charged offense must be proved “beyond a reasonable doubt.”

**What factors influence the likelihood of a malpractice suit?**

1. *The Physician–Patient Relationship:* This is particularly important for the anesthesiologist, who usually does not meet the patient until
immediately before the anesthetic is administered. Another problem is that the patient is unconscious while under the anesthesiologist’s care. Thus, the preoperative and postoperative visits with the patient are often the only opportunities to establish a good relationship with the patient. Family members should also be included during these meetings with patients (provided the patient does not object), particularly during the postoperative visit if there has been an intraoperative complication.

2. **Adequacy of Informed Consent:** Rendering care to a competent patient who does not consent constitutes assault and battery. Consent is not enough, however. The patient should be informed of the contemplated procedure, including its reasonably anticipated risks, its possible benefits, and the therapeutic alternatives. The physician may be liable for a complication—even if it is not due to the negligent performance of a procedure—if a jury is convinced that a reasonable person would have refused treatment if properly informed of the possibility of the complication. This does not mean, of course, that a documented consent relieves from liability physicians who violate the standard of care.

3. **Quality of Documentation:** Careful documentation of the perioperative visits, informed consent, consultations with other specialists, intraoperative events, and postoperative care is essential. The viewpoint of many courts and juries, reinforced by plaintiff’s attorneys, is that “if it isn’t written, it wasn’t done.” It goes without saying that medical records should never be intentionally destroyed or altered.

Practice guidelines for preoperative fasting and the use of pharmacological agents to reduce the risk of pulmonary aspiration: Application to healthy patients undergoing elective procedures: An updated report by the American Society of Anesthesiologists Committee on Standards and Practice Parameters. *Anesthesiology.* 2011;114:495.

**SUGGESTED READINGS**

Improper face mask technique can result in continued deflation of the anesthesia reservoir bag despite the adjustable pressure-limiting valve being closed, usually indicating a substantial leak around the mask. In contrast, the generation of high breathing circuit pressures with minimal chest movement and breath sounds implies an obstructed airway or obstructed tubing.

The laryngeal mask airway partially protects the larynx from pharyngeal secretions, but not gastric regurgitation.

After insertion of an endotracheal tube (ETT), the cuff is inflated with the least amount of air necessary to create a seal during positive-pressure ventilation to minimize the pressure transmitted to the tracheal mucosa.

Although the persistent detection of CO$_2$ by a capnograph is the best confirmation of tracheal placement of an ETT, it cannot exclude bronchial intubation. The earliest evidence of bronchial intubation often is an increase in peak inspiratory pressure.

After intubation, the cuff of an ETT should not be felt above the level of the cricoid cartilage, because a prolonged intralaryngeal location may result in postoperative hoarseness and increases the risk of accidental extubation.

Unrecognized esophageal intubation can produce catastrophic results. Prevention of this complication depends on direct visualization of the tip of the ETT passing through the vocal cords, careful auscultation for the presence of bilateral breath sounds and the absence of gastric gurgling while ventilating through the ETT, analysis of exhaled gas for the presence of CO$_2$ (the most reliable automated method), chest
radiography, airway ultrasonography, or use of fiberoptic bronchoscopy.

Clues to the diagnosis of bronchial intubation include unilateral breath sounds, unexpected hypoxia with pulse oximetry (unreliable with high inspired oxygen concentrations), inability to palpate the ETT cuff in the sternal notch during cuff inflation, and decreased breathing bag compliance (high peak inspiratory pressures).

The large negative intrathoracic pressures generated by a struggling patient in laryngospasm can result in the development of negative-pressure pulmonary edema, particularly in healthy patients.

Expert airway management is an essential skill in anesthetic practice. This chapter reviews the anatomy of the upper respiratory tract, describes necessary airway equipment, presents various management techniques, and discusses complications of laryngoscopy, intubation, and extubation. Patient safety depends on a thorough understanding of each of these topics.

ANATOMY

The upper airway consists of the pharynx, nose, mouth, larynx, trachea, and mainstem bronchi. The mouth and pharynx are also a part of the upper gastrointestinal tract. The laryngeal structures in part serve to prevent aspiration into the trachea.

There are two openings to the human airway: the nose, which leads to the nasopharynx, and the mouth, which leads to the oropharynx. These passages are separated anteriorly by the palate, but they join posteriorly in the pharynx (Figure 19–1). The pharynx is a U-shaped fibromuscular structure that extends from the base of the skull to the cricoid cartilage at the entrance to the esophagus. It opens anteriorly into the nasal cavity, the mouth, the larynx, and the nasopharynx, oropharynx, and laryngopharynx, respectively. The nasopharynx is separated from the oropharynx by an imaginary plane that extends posteriorly. At the base of the tongue, the epiglottis functionally separates the oropharynx from the laryngopharynx (or hypopharynx). The epiglottis prevents aspiration by covering the glottis—the opening of the larynx—during swallowing. The larynx is a cartilaginous skeleton held together by ligaments and muscle. The larynx is composed of nine cartilages (Figure 19–2): thyroid, cricoid, epiglottic, and (in pairs) arytenoid, corniculate, and cuneiform. The thyroid cartilage shields the conus elasticus, which forms the vocal cords.
FIGURE 19–1 Anatomy of the airway.
The sensory supply to the upper airway is derived from the cranial nerves (Figure 19–3). The mucous membranes of the nose are innervated by the ophthalmic division (V1) of the trigeminal nerve anteriorly (anterior ethmoidal nerve) and by the maxillary division (V2) posteriorly (sphenopalatine nerves). The palatine nerves provide sensory fibers from the trigeminal nerve (V2) to the superior and inferior surfaces of the hard and soft palate. The olfactory nerve (cranial nerve I) innervates the nasal mucosa to provide the sense of smell. The lingual nerve (a branch of the mandibular division [V3] of the trigeminal nerve) and the glossopharyngeal nerve (cranial nerve IX) provide general sensation to the anterior two-thirds and posterior one-third of the tongue, respectively. Branches of the facial nerve (VII) and glossopharyngeal nerve provide the sensation of taste to those areas, respectively. The glossopharyngeal nerve also innervates the roof of the pharynx, the tonsils, and the undersurface of the soft palate. The vagus nerve (cranial nerve X) provides sensation to the airway below the epiglottis. The superior laryngeal branch of the vagus divides into an external (motor) nerve and an internal (sensory) laryngeal nerve that provide sensory supply to the larynx between the epiglottis and the vocal cords. Another branch of the vagus, the recurrent laryngeal nerve, innervates the larynx below
the vocal cords and the trachea.

FIGURE 19–3 Sensory nerve supply of the airway.

The muscles of the larynx are innervated by the recurrent laryngeal nerve, with the exception of the cricothyroid muscle, which is innervated by the external (motor) laryngeal nerve, a branch of the superior laryngeal nerve. The posterior cricoarytenoid muscles abduct the vocal cords, whereas the lateral cricoarytenoid muscles are the principal adductors.

Phonation involves complex simultaneous actions by several laryngeal muscles. Damage to the motor nerves innervating the larynx leads to a spectrum of speech disorders (Table 19–1). Unilateral denervation of a cricothyroid muscle causes very subtle clinical findings. Bilateral palsy of the superior laryngeal nerve may result in hoarseness or easy tiring of the voice, but airway control is not jeopardized.

TABLE 19–1 The effects of laryngeal nerve injury on the voice.

Unilateral injury to a recurrent laryngeal nerve results in paralysis of the ipsilateral vocal cord, causing deterioration in voice quality. Assuming intact superior laryngeal nerves, *acute* bilateral recurrent laryngeal nerve palsy can result in stridor and respiratory distress because of the remaining unopposed tension of the cricothyroid muscles. Airway problems are less frequent in *chronic* bilateral recurrent laryngeal nerve loss because of the development of various compensatory mechanisms (eg, atrophy of the laryngeal musculature).

Bilateral injury to the vagus nerve affects both the superior and the recurrent laryngeal nerves. Thus, bilateral vagal denervation produces flaccid, midpositioned vocal cords similar to those seen after administration of succinylcholine. Although phonation is severely impaired in these patients, airway control is rarely a problem.

The blood supply of the larynx is derived from branches of the thyroid arteries. The cricothyroid artery arises from the superior thyroid artery itself, the first branch given off from the external carotid artery, and crosses the upper cricothyroid membrane (CTM), which extends from the cricoid cartilage to the thyroid cartilage. The superior thyroid artery is found along the lateral edge of the CTM.

The trachea begins beneath the cricoid cartilage and extends to the carina, the point at which the right and left mainstem bronchi divide (*Figure 19–4*). Anteriorly, the trachea consists of cartilaginous rings; posteriorly, the trachea is membranous.
ROUTINE AIRWAY MANAGEMENT

Routine airway management associated with general anesthesia consists of:

- Preanesthetic airway assessment
- Preparation and equipment check
- Patient positioning
- Preoxygenation (denitrogenation)
- Bag and mask ventilation
- Intubation or placement of a laryngeal mask airway (if indicated)
- Confirmation of proper tube or airway placement
- Extubation

AIRWAY ASSESSMENT

A preanesthetic airway assessment is mandatory before every anesthetic procedure. Several anatomical and functional maneuvers can be performed to estimate the difficulty of endotracheal intubation; successful ventilation (with or without intubation) must be achieved by the anesthetist if mortality and morbidity are to be avoided. Assessments include:

- Mouth opening: an incisor distance of 3 cm or greater is desirable in an adult.
- Mallampati classification: a frequently performed test that examines the size of the tongue in relation to the oral cavity. The more the tongue obstructs the view of the pharyngeal structures, the more difficult intubation may be (Figure 19–5).
- Class I: The entire palatal arch, including the bilateral faucial pillars, is visible down to the bases of the pillars.
- Class II: The upper part of the faucial pillars and most of the uvula are visible.
- Class III: Only the soft and hard palates are visible.
- Class IV: Only the hard palate is visible.
- Thyromental distance: This is the distance between the mentum (chin) and the superior thyroid notch. A distance greater than 3 fingerbreadths is desirable.
- Neck circumference: A neck circumference of greater than 17 inches is associated with difficulties in visualization of the glottic opening.

Although the presence of these examination findings may not be particularly
sensitive for detecting a difficult intubation, the absence of these findings is predictive for relative ease of intubation.

Increasingly, patients present with morbid obesity and body mass indices of 30 kg/m$^2$ or greater. Although some morbidly obese patients have relatively normal head and neck anatomy, others have much redundant pharyngeal tissue and increased neck circumference. Not only may these patients prove to be difficult to intubate, but routine ventilation with bag and mask also may be problematic.

Ultrasound examination of the airway has also been suggested to be of assistance in airway assessment and management (Figures 19–6 through 19–8). Ultrasound can be used as an adjunct to confirm ETT placement as well as to assist in identification of the cricothyroid membrane during emergent cricothyroidotomy.

![Ultrasound image](image)

**FIGURE 19–6** A transverse view of the trachea with landmarks. The anechoic area posterior to the trachea represents shadowing resulting from an attenuation of the ultrasound beam through the dense cartilage of the rings. FIGURE 19–7 The trachea during intubation as the tube passes underneath the probe. The arrow points to a subtle area of increased echogenicity just distal to the tracheal cartilage. This area is where movement is most often visualized in real time during an intubation. (Reproduced with permission from Carmody KA, Moore CL, Feller-Kopman D. Handbook of Critical Care and Emergency Ultrasound. New York, NY: McGraw-Hill Education; 2011.)
A transverse view of the trachea and esophagus during an esophageal intubation. In this image the esophagus is visualized posterior and lateral to the trachea. Two parallel echogenic lines are seen in the proximal esophagus, representing the inner and outer walls of the endotracheal (ET) tube as it passes through the lumen of the esophagus. (Reproduced with permission from Carmody KA, Moore CL, Feller-Kopman D. Handbook of Critical Care and Emergency Ultrasound. New York, NY: McGraw-Hill Education; 2011.)

EQUIPMENT

The following equipment should be routinely available for airway management:

- An oxygen source
- Capability to ventilate with bag and mask
- Laryngoscopes (direct and video)
- Several ETTs of different sizes with available stylets and bougies
- Other (not ETT) airway devices (eg, oral, nasal, supraglottic airways)
- Suction
- Pulse oximetry and CO₂ detection
- Stethoscope
- Tape
- Blood pressure and electrocardiography (ECG) monitors
- Intravenous access

A flexible fiberoptic bronchoscope should be immediately available when difficult intubation is anticipated but need not be present during all routine intubations.

Oral & Nasal Airways

Loss of upper airway muscle tone (eg, weakness of the genioglossus muscle) in anesthetized patients allows the tongue and epiglottis to fall back against the posterior wall of the pharynx. Repositioning the head or a jaw thrust is the preferred technique for opening the airway. To maintain the opening, an artificial airway can be inserted through the mouth or nose to maintain an air passage between the tongue and the posterior pharyngeal wall (Figure 19–9). Awake or lightly anesthetized patients with intact laryngeal reflexes may cough or even develop laryngospasm during airway insertion. Placement of an oral airway is
sometimes facilitated by suppressing airway reflexes, and, in addition, sometimes by depressing the tongue with a tongue blade. Adult oral airways typically come in small (80 mm [Guedel No. 3]), medium (90 mm [Guedel No. 4]), and large (100 mm [Guedel No. 5]) sizes.

**FIGURE 19–9** A: The oropharyngeal airway in place. The airway follows the curvature of the tongue, pulling it and the epiglottis away from the posterior pharyngeal wall and providing a channel for air passage. B: The nasopharyngeal airway in place. The airway passes through the nose and extends to just above the epiglottis. (Modified with permission from Dorsch JA, Dorsch SE. Face masks and airways. In: *Understanding Anesthesia Equipment*. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

The length of a nasal airway can be estimated as the distance from the nares to the meatus of the ear and should be approximately 2 to 4 cm longer than oral airways. Because of the risk of epistaxis, nasal airways are less desirable in anticoagulated or thrombocytopenic patients. Also, nasal airways (and nasogastric tubes) should be used with caution in patients with basilar skull fractures, as there has been a case report of a nasogastric tube entering the cranial vault. All tubes inserted through the nose (eg, nasal airways, nasogastric catheters, nasotracheal tubes) should be lubricated before being advanced along the floor of the nasal passage.

**Face Mask Design & Technique**

The use of a face mask can facilitate the delivery of oxygen or an anesthetic gas from a breathing system to a patient by creating an airtight seal with the patient’s face (Figure 19–10). The rim of the mask is contoured and conforms to a variety of facial features. The mask’s 22-mm orifice attaches to the breathing circuit of the anesthesia machine through a right-angle connector. Several mask designs are available. Transparent masks allow observation of exhaled humidified gas and immediate recognition of vomitus. Retaining hooks surrounding the orifice can be attached to a head strap so that the mask does not have to be continually
held in place. Some pediatric masks are specially designed to minimize apparatus dead space (Figure 19–11).

**FIGURE 19–10** Clear adult face mask.

**FIGURE 19–11** The Rendell–Baker–Soucek pediatric face mask has a shallow body and minimal dead space.

**POSITIONING**

When manipulating the airway, correct patient positioning is very helpful. Relative alignment of the oral and pharyngeal axes is achieved by having the patient in the “sniffing” position. When cervical spine pathology is suspected, the head must be kept in a neutral position during all airway manipulations. In-line stabilization of the neck must be maintained during airway management in these patients, unless appropriate cervical radiographs have been reviewed and
cleared by an appropriate specialist. Patients with morbid obesity should be positioned on a 30° upward ramp (see Figure 41–2), as the functional residual capacity (FRC) of obese patients deteriorates in the supine position, leading to more rapid deoxygenation should ventilation be impaired.

PREOXYGENATION
When possible, preoxygenation with face mask oxygen should precede all airway management interventions. Oxygen is delivered by mask for several minutes prior to anesthetic induction. In this way, the functional residual capacity, the patient’s oxygen reserve, is purged of nitrogen. Up to 90% of the normal FRC of 2 L following preoxygenation is filled with oxygen. Considering the normal oxygen demand of 200 to 250 mL/min, the preoxygenated patient may have a 5 to 8 min oxygen reserve. Increasing the duration of apnea without desaturation improves safety, if ventilation following anesthetic induction is delayed. Conditions that increase oxygen demand (eg, sepsis, pregnancy) and decrease FRC (eg, morbid obesity, pregnancy, ascites) reduce the apneic period before desaturation ensues. Assuming a patent air passage is present, oxygen insufflated into the pharynx may increase the duration of apnea tolerated by the patient. Because oxygen enters the blood from the FRC at a rate faster than CO₂ leaves the blood, a negative pressure is generated in the alveolus, drawing oxygen into the lung (apneic oxygenation). With flow of 100% oxygen and a patent airway, arterial saturation can be maintained for a longer period despite no ventilation, permitting multiple airway interventions should a difficult airway be encountered.

BAG AND MASK VENTILATION
Bag and mask ventilation (BMV) is the first step in airway management in most situations, with the exception of patients undergoing rapid sequence intubation or elective awake intubation. Rapid sequence inductions avoid BMV to minimize stomach inflation and to reduce the potential for the aspiration of gastric contents in nonfasted patients and those with delayed gastric emptying. In emergency situations, BMV precedes attempts at intubation in an effort to oxygenate the patient, with the understanding that there is an implicit risk of aspiration.

Effective mask ventilation requires both a gas-tight mask fit and a patent airway. Improper face mask technique can result in continued deflation of the anesthesia reservoir bag despite the adjustable pressure-limiting valve being
closed, usually indicating a substantial leak around the mask. In contrast, the generation of high breathing circuit pressures with minimal chest movement and breath sounds implies an obstructed airway or obstructed tubing.

If the mask is held with the left hand, the right hand can be used to generate positive-pressure ventilation by squeezing the breathing bag. The mask is held against the face by downward pressure on the mask exerted by the left thumb and index finger (Figure 19–12). The middle and ring finger grasp the mandible to facilitate extension of the atlantooccipital joint. This is a maneuver that is easier to teach with a mannequin or patient than to describe. Finger pressure should be placed on the bony mandible and not on the soft tissues. The little finger is placed under the angle of the jaw and used to thrust the jaw anteriorly, the most important maneuver to open the airway.

**FIGURE 19–12** One-handed face mask technique.

In difficult situations, two hands may be needed to provide adequate jaw thrust and to create a mask seal. Therefore, an assistant may be needed to squeeze the bag, or the machine’s ventilator can be used. In such cases, the thumbs hold the mask down, and the fingertips or knuckles displace the jaw forward (Figure 19–13). Obstruction during expiration may be due to excessive downward pressure from the mask or from a ball-valve effect of the jaw thrust. The former can be relieved by decreasing the pressure on the mask, and the latter
by releasing the jaw thrust during this phase of the respiratory cycle. Positive-pressure ventilation using a mask should normally be limited to 20 cm of H\textsubscript{2}O to avoid stomach inflation.

**FIGURE 19–13** A difficult airway can often be managed with a two-handed technique.

Most patients’ airways can be maintained with a face mask and an oral or nasal airway. Mask ventilation for long periods may result in pressure injury to branches of the trigeminal or facial nerves. Because of the absence of positive airway pressures during spontaneous ventilation, only minimal downward force on the face mask is required to create an adequate seal. If the face mask and mask straps are used for extended periods, the position should be regularly changed to prevent injury. Care should be used to avoid mask or finger contact with the eye, and the eyes should be taped shut as soon as possible to minimize the risk of corneal abrasions.

If the airway is patent, squeezing the bag will result in the rise of the chest.
ventilation is ineffective (no sign of chest rising, no end-tidal CO₂ detected, no condensation in the clear mask), oral or nasal airways can be placed to relieve airway obstruction secondary to lax upper airway muscle tone or redundant pharyngeal tissues. Difficult mask ventilation is often found in patients with morbid obesity, beards, and craniofacial deformities. It is sometimes difficult to form an adequate mask fit with the cheeks of edentulous patients.

In years past, anesthetics were routinely delivered solely by mask or ETT administration. In recent decades, a variety of supraglottic devices has permitted both airway rescue (when adequate BMV is not possible) and routine anesthetic airway management (when intubation is not necessary).

SUPRAGLOTTIC AIRWAY DEVICES

Supraglottic airway devices (SADs) are used with both spontaneously breathing and ventilated patients during anesthesia. They have also been employed as conduits to aid endotracheal intubation when both BMV and endotracheal intubation have failed. All SADs consist of a tube that is connected to a respiratory circuit or breathing bag, which is attached to a hypopharyngeal device that seals and directs airflow to the glottis, trachea, and lungs. Additionally, these airway devices occlude the esophagus with varying degrees of effectiveness, reducing gas distention of the stomach. Different sealing devices to prevent airflow from exiting through the mouth are also available. Some are equipped with a port to suction gastric contents. None offer the protection from aspiration pneumonitis offered by a properly sited, cuffed endotracheal tube.

Laryngeal Mask Airway

A laryngeal mask airway (LMA) consists of a wide-bore tube whose proximal end connects to a breathing circuit with a standard 15-mm connector, and whose distal end is attached to an elliptical cuff that can be inflated through a pilot tube. The deflated cuff is lubricated and inserted blindly into the hypopharynx so that, once inflated, the cuff forms a low-pressure seal around the entrance to the larynx. This requires anesthetic depth and muscle relaxation slightly greater than that required for the insertion of an oral airway. Although insertion is relatively simple (Figure 19–14), attention to detail will improve the success rate (Table 19–2). An ideally positioned cuff is bordered by the base of the tongue superiorly, the pyriform sinuses laterally, and the upper esophageal sphincter inferiorly. If the esophagus lies within the rim of the cuff, gastric distention and
regurgitation become possible. Anatomic variations prevent adequate functioning in some patients. However, if an LMA is not functioning properly after attempts to improve the “fit” of the LMA have failed, most practitioners will try another LMA one size larger or smaller. The shaft can be secured with tape to the skin of the face. The LMA partially protects the larynx from pharyngeal secretions (but not gastric regurgitation), and it should remain in place until the patient has regained airway reflexes. This is usually signaled by coughing and mouth opening on command. The LMA is available in many sizes (Table 19–3).

**FIGURE 19–14**  
A: The laryngeal mask ready for insertion. The cuff should be deflated tightly with the rim facing away from the mask aperture. There should be no folds near the tip.  
B: Initial insertion of the laryngeal mask. Under direct vision, the mask tip is pressed upward against the hard palate. The middle finger...
may be used to push the lower jaw downward. The mask is pressed forward as it is advanced into the pharynx to ensure that the tip remains flattened and avoids the tongue. The jaw should not be held open once the mask is inside the mouth. The nonintubating hand can be used to stabilize the occiput. C: By withdrawing the other fingers and with a slight pronation of the forearm, it is usually possible to push the mask fully into position in one fluid movement. Note that the neck is kept flexed and the head extended. D: The laryngeal mask is grasped with the other hand and the index finger withdrawn. The hand holding the tube presses gently downward until resistance is encountered. (Reproduced with permission from LMA North America.)

**TABLE 19–2** Successful insertion of a laryngeal mask airway depends upon attention to several details.

| 1. Choose the appropriate size (Table 19–3) and check for leaks before insertion. |
| 2. The leading edge of the deflated cuff should be wrinkle free and facing away from the aperture (Figure 19–14A). |
| 3. Lubricate only the back side of the cuff. |
| 4. Ensure adequate anesthesia before attempting insertion. |
| 5. Place patient’s head in sniffing position (Figure 19–14B and Figure 19–26). |
| 6. Use your index finger to guide the cuff along the hard palate and down into the hypopharynx until an increased resistance is felt (Figure 19–14C). The longitudinal black line should always be pointing directly cephalad (i.e., facing the patient’s upper lip). |
| 7. Inflate with the correct amount of air (Table 19–3). |
| 8. Ensure adequate anesthetic depth during patient positioning. |
| 9. Obstruction after insertion is usually due to a downfolded epiglottis or transient laryngospasm. |
| 10. Avoid pharyngeal suction, cuff deflation, or laryngeal mask removal until the patient is awake (e.g., opening mouth on command). |

**TABLE 19–3** A variety of laryngeal masks with different cuff volumes are available for different sized patients.
The LMA provides an alternative to ventilation through a face mask or an ETT (Table 19–4). Relative contraindications for the LMA include patients with pharyngeal pathology (eg, abscess), pharyngeal obstruction, aspiration risk (eg, pregnancy, hiatal hernia), or low pulmonary compliance (eg, restrictive airways disease) requiring peak inspiratory pressures greater than 30 cm H₂O. The LMA may be associated with less frequent bronchospasm than an ETT. Although it is clearly not a substitute for endotracheal intubation, the LMA has proven particularly helpful as a lifesaving, temporizing measure in patients with difficult airways (those who cannot be mask ventilated or intubated) because of its ease of insertion and relatively high success rate (95–99%). It has been used as a conduit for an intubating stylet (eg, gum-elastic bougie), ventilating jet stylet, flexible fiberoptic bronchoscope, or small-diameter (6.0 mm) ETT. Several LMAs are available that have been modified to facilitate placement of a larger ETT, with or without the use of a bronchoscope. Insertion can be performed under topical anesthesia and bilateral superior laryngeal nerve blocks, if the airway must be secured while the patient is awake. Some newer supraglottic devices incorporate a channel to facilitate gastric decompression.

**TABLE 19–4** Advantages and disadvantages of the laryngeal mask airway compared with face mask ventilation or tracheal intubation.¹
Variations in LMA design include:

- The ProSeal LMA, which permits passage of a gastric tube to decompress the stomach
- The I-Gel, which uses a gel occluder rather than inflatable cuff
- The Fastrach intubation LMA, which is designed to facilitate endotracheal intubation through the LMA device
- The LMA CTrach, which incorporates a camera to facilitate passage of an endotracheal tube

Sore throat is a common side effect following SAD use. Injuries to the lingual, hypoglossal, and recurrent laryngeal nerves have been reported. Correct device sizing, avoidance of cuff hyperinflation, adequate lubrication, and gentle movement of the jaw during placement may reduce the likelihood of such injuries.

### Esophageal–Tracheal Combitube

The esophageal–tracheal Combitube consists of two fused tubes, each with a 15-mm connector on its proximal end. The longer blue tube has an occluded distal tip that forces gas to exit through a series of side perforations. The shorter clear tube has an open tip and no side perforations. The Combitube is usually inserted blindly through the mouth and advanced until the two black rings on the shaft lie between the upper and lower teeth. The Combitube has two inflatable cuffs, a 100-mL proximal cuff and a 15-mL distal cuff, both of which should be fully inflated after placement. The distal lumen of the Combitube usually comes to lie in the esophagus approximately 95% of the time so that
ventilation through the longer blue tube will force gas out of the side perforations and into the larynx. The shorter, clear tube can be used for gastric decompression. Alternatively, if the Combitube enters the trachea, ventilation through the clear tube will direct gas into the trachea.

**FIGURE 19–15** Combitube.

**King Laryngeal Tube**

The King laryngeal tube consists of a tube with a small esophageal balloon and a larger balloon for placement in the hypopharynx (Figure 19–16). Both balloons inflate through one inflation line. The lungs are inflated with gas that exits between the two balloons. A suction port distal to the esophageal balloon is present, permitting decompression of the stomach. If ventilation proves difficult after the King tube is inserted and the cuffs are inflated, the tube is likely inserted too deeply. Slowly withdraw the device until compliance improves.
**FIGURE 19–16** King laryngeal tube.

**ENDOTRACHEAL INTUBATION**

Endotracheal intubation is employed both for the conduct of general anesthesia and to facilitate the ventilator management of the critically ill.

**Endotracheal Tubes (ETTs)**

Standards govern ETT manufacturing (in the United States, American National Standard for Anesthetic Equipment; ANSI Z–79). ETTs are most commonly made from polyvinyl chloride. The shape and rigidity of ETTs can be altered by inserting a stylet. The patient end of the tube is beveled to aid visualization and insertion through the vocal cords. Murphy tubes have a hole (the Murphy eye) to decrease the risk of occlusion, should the distal tube opening abut the carina or trachea (Figure 19–17).
Resistance to airflow depends primarily on tube diameter, but is also affected by tube length and curvature. ETT size is usually designated in millimeters of internal diameter, or, less commonly, in the French scale (external diameter in millimeters multiplied by 3). The choice of tube diameter is always a compromise between maximizing flow with a larger size and minimizing airway trauma with a smaller size (Table 19–5).

Most adult ETTs have a cuff inflation system consisting of a valve, pilot balloon, inflating tube, and cuff (Figure 19–17). The valve prevents air loss after cuff inflation. The pilot balloon provides a gross indication of cuff inflation. The inflating tube connects the valve to the cuff and is incorporated into the tube’s wall. By creating a tracheal seal, ETT cuffs permit positive-pressure ventilation and reduce the likelihood of aspiration. Uncuffed tubes are often used in infants and young children; however, in recent years, cuffed pediatric tubes have been increasingly favored.
There are two major types of cuffs: high pressure (low volume) and low pressure (high volume). High-pressure cuffs are associated with more ischemic damage to the tracheal mucosa and are less suitable for intubations of long duration. Low-pressure cuffs may increase the likelihood of sore throat (larger mucosal contact area), aspiration, spontaneous extubation, and difficult insertion (because of the floppy cuff). Nonetheless, because of their lower incidence of mucosal damage, low-pressure cuffs are most frequently employed.

Cuff pressure depends on several factors: inflation volume, the diameter of the cuff in relation to the trachea, tracheal and cuff compliance, and intrathoracic pressure (cuff pressures increase with coughing). Cuff pressure may increase during general anesthesia from diffusion of nitrous oxide from the tracheal mucosa into the ETT cuff.

ETTs have been modified for a variety of specialized applications. Flexible, spiral-wound, wire-reinforced ETTs (armored tubes) resist kinking and may prove valuable in some head and neck surgical procedures or in the prone patient. If an armored tube becomes kinked from extreme pressure (eg, an awake patient biting it), however, the lumen will often remain permanently occluded, and the tube will need replacement. Other specialized tubes include microlaryngeal tubes, double-lumen endotracheal tubes (to facilitate lung isolation and one-lung ventilation), ETTs equipped with bronchial blockers (to facilitate lung isolation and one-lung ventilation), metal tubes designed for laser airway surgery to reduce fire hazards, and preformed curved tubes for nasal and oral intubation in head and neck surgery.

**LARYNGOSCOPES**

A laryngoscope is an instrument used to examine the larynx and to facilitate intubation of the trachea. The handle usually contains batteries to light a bulb on the blade tip (Figure 19–18), or, alternately, to power a fiberoptic bundle that terminates at the tip of the blade. Laryngoscopes with fiberoptic light bundles in their blades can be made magnetic resonance imaging compatible. The Macintosh and Miller blades are the most popular curved and straight designs, respectively, in the United States. The choice of blade depends on personal preference and patient anatomy. Because no blade is perfect for all situations, the clinician should become familiar and proficient with a variety of blade designs (Figure 19–19).
FIGURE 19–18 A rigid laryngoscope.

FIGURE 19–19 An assortment of laryngoscope blades.
VIDEO LARYNGOSCOPES

In recent years, myriad laryngoscopy devices that utilize video technology have revolutionized management of the airway. Direct laryngoscopy with a Macintosh or Miller blade mandates appropriate alignment of the oral, pharyngeal, and laryngeal structures to facilitate a direct view of the glottis. Various maneuvers, such as the “sniffing” position and external movement of the larynx with cricoid pressure during direct laryngoscopy, are used to improve the view. Video- or optically based laryngoscopes have either a video chip (DCI system, GlideScope, McGrath, Airway) or a lens/mirror (Airtraq) at the tip of the intubation blade to transmit a view of the glottis to the operator. These devices differ in the angulation of the blade, the presence of a channel to guide the tube to the glottis, and the single use or multiuse nature of the device.

Video or indirect laryngoscopy most likely offers minimal advantage to patients with uncomplicated airways. However, use in these patients is valuable as a training guide for learners, especially when the trainee is performing a direct laryngoscopy with the device while the instructor views the glottis on the video screen. Additionally, use in uncomplicated airway management patients improves familiarity with the device for times when direct laryngoscopy is not possible.

Indirect laryngoscopes generally improve visualization of laryngeal structures in difficult airways; however, visualization does not always lead to successful intubation. An ETT stylet is recommended when video laryngoscopy is to be performed. Some devices come with stylets designed to facilitate intubation with that particular device. Bending the stylet and ETT in a manner similar to the bend in the curve of the blade often facilitates passage of the ETT into the trachea. Even when the glottic opening is seen clearly, directing the ETT into the trachea can be difficult.

Indirect laryngoscopy may result in less displacement of the cervical spine than direct laryngoscopy; nevertheless, all precautions associated with airway manipulation in a patient with a possible cervical spine fracture should be maintained.

Varieties of indirect laryngoscopes include:

- Various Macintosh and Miller blades in pediatric and adult sizes have video capability in the Storz DCI system. The system can also incorporate an optical intubating stylet (Figure 19–20). The blades are similar to conventional intubation blades, permitting direct laryngoscopy and indirect video laryngoscopy. Assistants and instructors are able to see the view
obtained by the operator and adjust their maneuvers accordingly to facilitate intubation or to provide instruction, respectively.

**FIGURE 19–20** Optical intubating stylet.

- The McGrath laryngoscope is a portable video laryngoscope with a blade length that can be adjusted to accommodate the airway of a child of age 5 years up to an adult (**Figure 19–21**). The blade can be disconnected from the handle to facilitate its insertion in morbidly obese patients in whom the space between the upper chest and head is reduced. The blade is inserted midline, with the laryngeal structures viewed at a distance to enhance intubation success.
The GlideScope comes with disposable adult- and pediatric-sized blades (Figure 19–22). The blade is inserted midline and advanced until glottic structures are identified. The GlideScope has a 60° angle, preventing direct laryngoscopy and necessitating the use of stylet that is similar in shape to the blade.
Airtraq is a single-use optical laryngoscope available in pediatric and adult sizes (Figure 19–23). The device has a channel to guide the endotracheal tube to the glottis. This device is inserted midline. Success is more likely when the device is not positioned too close to the glottis.
Figure 19–23 Airtraq optical laryngoscope.

- Video intubating stylets have a video capability and light source. The stylet is introduced, and the glottis identified. Intubation with a video stylet may result in less cervical spine movement than with other techniques.

Flexible Fiberoptic Bronchoscopes

In some situations—for example, patients with unstable cervical spines, poor range of motion of the temporomandibular joint, or certain congenital or acquired upper airway anomalies—laryngoscopy with direct or indirect laryngoscopes may be undesirable or impossible. A flexible fiberoptic bronchoscope (FOB) allows indirect visualization of the larynx in such cases or in any situation in which awake intubation is planned (Figure 19–24). Bronchoscopes are constructed of coated glass fibers that transmit light and images by internal reflection (ie, a light beam becomes trapped within a fiber and exits unchanged at the opposite end). The insertion tube contains two bundles of fibers, each consisting of 10,000 to 15,000 fibers. One bundle transmits light from the light source (light source or incoherent bundle), which is either external to the device or contained within the handle (Figure 19–24B), whereas the other provides a high-resolution image (image or coherent bundle). Directional manipulation of the insertion tube is accomplished with angulation wires. Aspiration channels allow suctioning of secretions, insufflation of oxygen, or instillation of local anesthetic. Aspiration channels can be difficult to clean,
and, if not properly cleaned and sterilized after each use, may promote infection.

**TECHNIQUES OF DIRECT & INDIRECT LARYNGOSCOPY & INTUBATION**

**Indications for Intubation**

Inserting a tube into the trachea has become a routine part of delivering a general anesthetic. Intubation is not a risk-free procedure, and it is not a requirement for all patients receiving general anesthesia. An ETT is generally placed to protect the airway and for airway access. Intubation is indicated in patients who are at risk of aspiration and in those undergoing surgical procedures involving body cavities, the head and neck, and those who will be positioned so that the airway will be less accessible (eg, those undergoing surgery in the prone position, or whose head is rotated away from the anesthesia workstation). Mask ventilation or ventilation with an LMA is usually satisfactory for short minor procedures such as cystoscopy, examination under anesthesia, inguinal hernia repairs, extremity surgery, and so forth. Nevertheless, the indications for use of supraglottic airway devices during anesthesia continues to expand.
Preparation for Direct Laryngoscopy

Preparation for intubation includes checking equipment and properly positioning the patient. The ETT should be examined. The tube’s cuff can be tested by inflating the cuff using a syringe. Maintenance of cuff pressure after detaching the syringe ensures proper cuff and valve function. Some anesthesiologists cut the ETT to a preset length to decrease the dead space, the risk of bronchial intubation, and the risk of occlusion from tube kinking (Table 19–5). The connector should be pushed firmly into the tube to decrease the likelihood of disconnection. If a stylet is used, it should be inserted into the ETT, which is then bent to resemble a hockey stick (Figure 19–25). This shape facilitates intubation of an anteriorly positioned larynx. The desired blade is locked onto the laryngoscope handle, and bulb function is tested. The light intensity should remain constant even if the bulb is jiggled. A blinking light signals a poor electrical contact, whereas fading indicates depleted batteries. An extra handle, blade, ETT (one size smaller than the anticipated optimal size), stylet, and intubating bougie should be immediately available. A functioning suction unit is needed to clear the airway in case of unexpected secretions, blood, or emesis.

FIGURE 19–25 An endotracheal tube with a stylet bent to resemble a hockey stick.

Adequate glottis exposure during laryngoscopy often depends on correct patient positioning. The patient’s head should be level with the anesthesiologist’s waist or higher to prevent unnecessary back strain during laryngoscopy.

Direct laryngoscopy displaces pharyngeal soft tissues to create a direct line of vision from the mouth to the glottic opening. Moderate head elevation (5–10 cm above the surgical table) and extension of the atlantooccipital joint place the
patient in the desired sniffing position (Figure 19–26). The lower portion of the cervical spine is flexed by resting the head on a pillow or other soft support.

As previously discussed, preparation for induction and intubation also involves routine preoxygenation. Preoxygenation can be omitted in patients who object to the face mask; however, failing to preoxygenate increases the risk of rapid desaturation following apnea.

Because general anesthesia abolishes the protective corneal reflex, care must be taken during this period not to injure the patient’s eyes by unintentionally abrading the cornea. Thus, the eyes are routinely taped shut as soon as possible, often after applying an ophthalmic ointment before manipulation of the airway.
**Orotracheal Intubation**

The laryngoscope is held in the left hand. With the patient’s mouth opened the blade is introduced into the right side of the oropharynx—with care to avoid the teeth. The tongue is swept to the left and up into the floor of the pharynx by the blade’s flange. Successful sweeping of the tongue leftward clears the view for ETT placement. The tip of a curved blade is usually inserted into the vallecula, and the straight blade tip covers the epiglottis. With either blade, the handle is raised up and away from the patient in a plane perpendicular to the patient’s mandible to expose the vocal cords (**Figure 19–27**). Trapping a lip between the teeth and the blade and leverage on the teeth are avoided. The ETT is taken with the right hand, and its tip is passed through the abducted vocal cords. The “backward, upward, rightward, pressure” (BURP) maneuver applied externally moves an anteriorly positioned glottis posterior to facilitate visualization of the glottis. The ETT cuff should lie in the upper trachea, but beyond the larynx. The laryngoscope is withdrawn, again with care to avoid tooth damage. The cuff is inflated with the least amount of air necessary to create a seal during positive-pressure ventilation to minimize the pressure transmitted to the tracheal mucosa. Overinflation may inhibit capillary blood flow, injuring the trachea. Compressing the pilot balloon with the fingers is not a reliable method of determining whether cuff pressure is either sufficient or excessive.
After intubation, the chest and epigastrium are immediately auscultated, and a capnographic tracing (the definitive test) is monitored to ensure intratracheal location (Figure 19–28). If there is doubt as to whether the tube is in the esophagus or trachea, repeat the laryngoscopy to confirm placement. End-tidal CO$_2$ will not be produced if there is no cardiac output. FOB through the tube and visualization of the tracheal rings and carina will likewise confirm correct placement. Otherwise, the tube is taped or tied to secure its position. Although the persistent detection of CO$_2$ by a capnograph is the best confirmation of tracheal placement of an ETT, it cannot exclude bronchial intubation. The earliest evidence of bronchial intubation often is an increase in peak inspiratory pressure. Proper tube location can be reconfirmed by palpating the cuff in the sternal notch while compressing the pilot balloon with the other hand. The cuff should not be felt above the level of the cricoid cartilage, because a prolonged intralaryngeal location may result in postoperative hoarseness and increases the risk of accidental extubation. Tube position can also be documented by chest radiography.
**FIGURE 19–28** Sites for auscultation of breath sounds at the apices and over the stomach.

The description presented here assumes an unconscious patient. Oral intubation is usually poorly tolerated by awake, fit patients. Intravenous sedation, application of a local anesthetic spray in the oropharynx, regional nerve block, and constant reassurance will improve patient acceptance.
A failed intubation should not be followed by identical repeated attempts. Changes must be made to increase the likelihood of success, such as repositioning the patient, decreasing the tube size, adding a stylet, selecting a different blade, using an indirect laryngoscope, attempting a nasal route, or requesting the assistance of another anesthesia provider. If the patient is also difficult to ventilate with a mask, alternative forms of airway management (eg, second-generation supraglottic airway devices, jet ventilation via percutaneous tracheal catheter, cricothyrotomy, tracheostomy) must be immediately pursued. The guidelines developed by the American Society of Anesthesiologists for the management of a difficult airway include a treatment plan algorithm (Figure 19–29).
FIGURE 19–29 Difficult airway algorithm. Notes: (a) Other options include (but are not limited to): surgery utilizing face mask or supraglottic airway (SGA) anesthesia (eg, laryngeal mask airway [LMA], intubating LMA [ILMA], laryngeal tube), local anesthesia infiltration, or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the emergency pathway. (b) Invasive airway access includes surgical or percutaneous airway, jet ventilation, and retrograde intubation. (c)
Alternative difficult intubation approaches include (but are not limited to) video-assisted laryngoscopy, alternative laryngoscope blades, SGA (eg, LMA or ILMA) as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, and blind oral or nasal intubation. (d) Consider re-preparation of the patient for awake intubation or canceling surgery. (e) Emergency noninvasive airway ventilation consists of an SGA. (Reproduced with permission from American Society of Anesthesiologists Task Force on the Management of the Difficult Airway. Practice guidelines for management of the difficult airway: An updated report by the American Society of Anesthesiologists Task Force on the Management of the Difficult Airway. *Anesthesiology*. 2003 May;98(5):1269-1277.)

The Difficult Airway Society (DAS) also provides a useful approach for the management of the unanticipated difficult airway (*Figure 19–30*).

The combined use of a video laryngoscope and an intubation bougie often can
facilitate intubation, when the endotracheal tube cannot be directed into the glottis despite good visualization of the laryngeal opening (Figure 19–31). Progression through the DAS plans A to D prevents the anesthetist from unnecessarily repeating the same failed approaches to airway management and maximizes the possibility of preserving patient oxygenation as the airway is secured.

**FIGURE 19–31** Bougie.

**Nasotracheal Intubation**

Nasal intubation is similar to oral intubation except that the ETT is advanced through the nose and nasopharynx into the oropharynx before laryngoscopy. The nostril through which the patient breathes most easily is selected in advance and prepared. Phenylephrine (0.5% or 0.25%) or tolazoline nose drops constrict blood vessels and shrink mucous membranes. If the patient is awake, local anesthetic ointment (for the nostril, delivered via an ointment-coated nasopharyngeal airway), spray (for the oropharynx), and nerve blocks can also be utilized.

An ETT lubricated with water-soluble jelly is introduced along the floor of the nose, below the inferior turbinate, at an angle perpendicular to the face. The tube’s bevel should be directed laterally away from the turbinates. To ensure that the tube passes along the floor of the nasal cavity, the proximal end of the ETT should be pulled cephalad. The tube is gradually advanced, until its tip can be visualized in the oropharynx. Laryngoscopy, as discussed, reveals the abducted vocal cords. Often the distal end of the ETT can be pushed into the trachea without difficulty. If difficulty is encountered, the tip of the tube may be directed through the vocal cords with Magill forceps, being careful not to damage the cuff. Nasal passage of ETTs, airways, or nasogastric catheters carries greater risk in patients with severe midfacial trauma because of the risk of intracranial placement (Figure 19–32).
FIGURE 19–32 Radiograph demonstrating a 7.0-mm endotracheal tube placed through the cribriform plate into the cranial vault in a patient with a basilar skull fracture.

Although less used today, blind nasal intubation of spontaneously breathing patients can be employed. In this technique, after applying topical anesthetic to the nostril and pharynx, a breathing tube is passed through the nasopharynx. Using breath sounds as a guide, it is directed toward the glottis. When breath sounds are maximal, the anesthetist advances the tube during inspiration in an effort to blindly pass the tube into the trachea.

Flexible Fiberoptic Intubation

Fiberoptic intubation (FOI) is routinely performed in awake or sedated patients with problematic airways. FOI is ideal for:

- A small mouth opening
• Minimizing cervical spine movement in trauma or rheumatoid arthritis
• Upper airway obstruction, such as angioedema or tumor mass
• Facial deformities, facial trauma

FOI can be performed awake or asleep via oral or nasal routes in the following scenarios:

- **Awake FOI**—Predicted inability to ventilate by mask, upper airway obstruction
- **Asleep FOI**—Failed intubation, desire for minimal cervical spine movement in patients who refuse awake intubation, anticipated difficult intubation when ventilation by mask appears easy
- **Oral FOI**—Facial, skull injuries
- **Nasal FOI**—A poor mouth opening

When FOI is considered, careful planning is necessary, as it will otherwise add to the anesthesia time prior to surgery. Patients should be informed of the need for awake intubation as a part of the informed consent process.

The airway is anesthetized with a local anesthetic spray, and patient sedation is provided, as tolerated. Dexmedetomidine has the advantage of preserving respiration while providing sedation. Airway anesthesia is discussed in the Case Discussion at the end of this chapter.

If nasal FOI is planned, both nostrils are prepared with vasoconstrictive spray. The nostril through which the patient breathes more easily is identified. Oxygen can be insufflated through the suction port and down the aspiration channel of the FOB to improve oxygenation and blow secretions away from the tip.

Alternatively, a large nasal airway (eg, 36FR) can be inserted in the contralateral nostril. The breathing circuit can be directly connected to the end of this nasal airway to administer 100% oxygen during laryngoscopy. If the patient is unconscious and not breathing spontaneously, the mouth can be closed and ventilation attempted through the single nasal airway. When this technique is used, adequacy of ventilation and oxygenation should be confirmed by capnography and pulse oximetry. The lubricated shaft of the FOB is introduced into the ETT lumen. It is important to keep the shaft of the bronchoscope relatively straight (Figure 19–33) so that if the head of the bronchoscope is rotated in one direction, the distal end will move to a similar degree and in the same direction. As the tip of the FOB passes through the distal end of the ETT, the epiglottis or glottis should be visible. The tip of the bronchoscope is
manipulated, as needed, to pass the abducted cords.

**FIGURE 19–33** Correct technique for manipulating a fiberoptic bronchoscope through an endotracheal tube is shown in the top panel; avoid curvature in the bronchoscope, which makes manipulation difficult.

Having an assistant thrust the jaw forward or apply cricoid pressure may improve visualization in difficult cases. Grasping the tongue with gauze and pulling it forward may also facilitate intubation.

Once in the trachea, the FOB is advanced to within sight of the carina. The presence of tracheal rings and the carina is proof of proper positioning. The ETT is pushed off the FOB. The acute angle around the arytenoid cartilage and epiglottis may prevent easy advancement of the tube. Use of an armored tube usually decreases this problem due to its greater lateral flexibility and more
obtusely angled distal end. Proper ETT position is confirmed by viewing the tip of the tube an appropriate distance (3 cm in adults) above the carina before the FOB is withdrawn.

Oral FOI proceeds similarly, with the aid of various oral airway devices to direct the FOB toward the glottis and to reduce obstruction of the view by the tongue.

**SURGICAL AIRWAY TECHNIQUES**

“Invasive” airways are required when the “can’t intubate, can’t ventilate” scenario presents and may be performed in anticipation of such circumstances in selected patients. The options include surgical cricothyrotomy, catheter or needle cricothyrotomy, transtracheal catheter with jet ventilation, and retrograde intubation.

Surgical cricothyrotomy refers to surgical incision of the cricothyroid membrane (CTM) and placement of a breathing tube. More recently, several needle/dilator cricothyrotomy kits have become available. Unlike surgical cricothyrotomy, where a horizontal incision is made across the CTM, these kits utilize the Seldinger catheter/wire/dilator technique. A catheter attached to a syringe is inserted across the CTM (Figure 19–34). When air is aspirated, a guidewire is passed through the catheter into the trachea (Figure 19–35). A dilator is then passed over the guidewire, and a breathing tube placed (Figure 19–36).
FIGURE 19–34 Cricothyrotomy. Slide catheter into trachea. (Used with permission from Lawrence B. Stack, MD.)

FIGURE 19–35 Cricothyrotomy. Incision at wire entry site. Remove catheter and make incision at the wire entry site. (Used with permission from Lawrence B. Stack, MD.)

FIGURE 19–36 Cricothyrotomy. Insert tracheostomy tube/introducer. Insert both devices over the wire and into the trachea. (Used with permission from Lawrence B. Stack, MD.)

Catheter-based salvage procedures can also be performed. A 16- or 14-gauge
intravenous cannula is attached to a syringe and passed through the CTM toward the carina. Air is aspirated. If a jet ventilation system is available, it can be attached. The catheter must be secured, otherwise the jet pressure will push the catheter out of the airway, leading to potentially disastrous subcutaneous emphysema. Short (1-s) bursts of oxygen ventilate the patient. Sufficient outflow of expired air must be assured to avoid barotrauma. Patients ventilated in this manner may develop subcutaneous or mediastinal emphysema and may become hypercapneic despite adequate oxygenation. Transtracheal jet ventilation will usually require conversion to a surgical airway or tracheal intubation.

Should a jet ventilation system not be available, a 3-mL syringe can be attached to the catheter and the syringe plunger removed. A 7.0-mm internal diameter ETT connector can be inserted into the syringe and attached to a breathing circuit or an AMBU bag. As with the jet ventilation system, adequate exhalation must occur to avoid barotraumas.

Retrograde intubation is another approach to secure an airway. A wire is passed via a catheter placed in the CTM. The wire is angulated cephalad and emerges either through the mouth or nose. The distal end of the wire is secured with a clamp to prevent it from passing through the CTM. The wire can then be threaded into an FOB with a loaded endotracheal tube to facilitate and confirm placement. Conversely, a small endotracheal tube can be guided by the wire into the trachea. Once placed, the wire is removed.

PROBLEMS FOLLOWING INTUBATION

Following apparently successful intubation, several scenarios may develop that require immediate attention. Anesthesia staff must confirm that the tube is correctly placed with auscultation of bilateral breath sounds immediately following placement. Detection of end-tidal CO$_2$ remains the gold standard in this regard, with the caveat that cardiac output must be present for end-tidal CO$_2$ production.

Decreases in oxygen saturation can occur following tube placement. This is often secondary to endobronchial intubation, especially in small children and infants. Decreased oxygen saturation perioperatively may be due to inadequate oxygen delivery (oxygen not turned on, patient not ventilated) or to ventilation/perfusion mismatch (almost any form of lung disease). When saturation declines, the patient’s chest is auscultated to confirm bilateral tube placement and to listen for wheezes, rhonchi, and rales consistent with lung pathology. The breathing circuit is checked. An intraoperative chest radiograph
may be needed to identify the cause of desaturation. Intraoperative fiberoptic bronchoscopy can also be performed and used to confirm proper tube placement and to clear mucous plugs. Bronchodilators and deeper planes of inhalation anesthetics are administered to treat bronchospasm. Obese patients may desaturate secondary to a reduced FRC and atelectasis. Application of positive end-expiratory pressure may improve oxygenation.

Should the end-tidal CO₂ decline suddenly, pulmonary (thrombus) or venous air embolism should be considered. Likewise, other causes of a sudden decline in cardiac output or a leak in the circuit should be considered.

A rising end-tidal CO₂ may be secondary to hypoventilation or increased CO₂ production, as occurs with malignant hyperthermia, sepsis, a depleted CO₂ absorber, or breathing circuit malfunction.

Increases in airway pressure may indicate an obstructed or kinked endotracheal tube or reduced pulmonary compliance. The endotracheal tube should be suctioned to confirm that it is patent and the lungs auscultated to detect signs of bronchospasm, pulmonary edema, endobronchial intubation, or pneumothorax.

Decreases in airway pressure can occur secondary to leaks in the breathing circuit or inadvertent extubation.

**TECHNIQUES OF EXTUBATION**

Most often, extubation should be performed when a patient is either deeply anesthetized or awake. In either case, adequate recovery from neuromuscular blocking agents should be established prior to extubation.

Extubation during a light plane of anesthesia (ie, a state between deep and awake) is avoided because of an increased risk of laryngospasm. The distinction between deep and light anesthesia is usually apparent during pharyngeal suctioning: any reaction to suctioning (eg, breath holding, coughing) signals a light plane of anesthesia, whereas no reaction is characteristic of a deep plane. Similarly, eye opening or purposeful movements imply that the patient is sufficiently awake for extubation.

Extubating an awake patient is usually associated with coughing (bucking) on the ETT. This reaction increases the heart rate, central venous pressure, arterial blood pressure, intracranial pressure, intraabdominal pressure, and intraocular pressure. It may also cause wound dehiscence and increased bleeding. The presence of a ETT in an awake asthmatic patient may trigger bronchospasm. Some practitioners attempt to decrease the likelihood of these effects by
administering 1.5 mg/kg of intravenous lidocaine 1–2 min before suctioning and extubation; however, extubation during deep anesthesia may be preferable in patients who cannot tolerate these effects (provided such patients are not at risk of aspiration and/or do not have airways that may be difficult to maintain after removal of the ETT).

Regardless of whether the tube is removed when the patient is deeply anesthetized or awake, the patient’s pharynx should be thoroughly suctioned before extubation to decrease the potential for aspiration of blood and secretions. In addition, patients should be ventilated with 100% oxygen in case it becomes difficult to establish an airway after the ETT is removed. Just prior to extubation, the ETT is untaped or untied and its cuff is deflated. The tube is withdrawn in a single smooth motion, and a face mask is applied to deliver oxygen. Oxygen delivery by face mask is maintained during the period of transportation to the postanesthesia care area.

**COMPLICATIONS OF LARYNGOSCOPY & INTUBATION**

The complications of laryngoscopy and intubation include hypoxia, hypercarbia, dental and airway trauma, tube malpositioning, physiological responses to airway instrumentation, and tube malfunction. These complications can occur during laryngoscopy and intubation, while the tube is in place, or following extubation (*Table 19–6*).

**Airway Trauma**

Instrumentation with a metal laryngoscope blade and insertion of a stiff ETT often traumatizes delicate airway tissues. Tooth damage is a common cause of
(relatively small) malpractice claims against anesthesiologists. Laryngoscopy and intubation can lead to a range of complications from sore throat to tracheal stenosis. Most of these are due to prolonged external pressure on sensitive airway structures. When these pressures exceed the capillary–arteriolar blood pressure (approximately 30 mm Hg), tissue ischemia can lead to a sequence of inflammation, ulceration, granulation, and stenosis. Inflation of an ETT cuff to the minimum pressure that creates a seal during routine positive-pressure ventilation (usually at least 20 mm Hg) reduces tracheal blood flow by 75% at the cuff site. Further cuff inflation or induced hypotension can totally eliminate mucosal blood flow.

Postintubation croup caused by glottic, laryngeal, or tracheal edema is particularly serious in children. The efficacy of corticosteroids (eg, dexamethasone—0.2 mg/kg, up to a maximum of 12 mg) in preventing postextubation airway edema remains controversial, but this approach is often used. Vocal cord paralysis from cuff compression or other trauma to the recurrent laryngeal nerve results in hoarseness and increases the risk of aspiration. The incidence of postoperative hoarseness seems to increase with obesity, difficult intubations, and anesthetics of long duration. Curiously, applying a water-soluble lubricant or a local anesthetic-containing gel to the tip or cuff of the ETT does not decrease the incidence of postoperative sore throat or hoarseness, and, in some studies, actually increased the incidence of these complications. Smaller tubes (size 6.5 in women and size 7.0 in men) are associated with fewer complaints of postoperative sore throat. Repeated attempts at laryngoscopy during a difficult intubation may lead to periglottic edema and the inability to ventilate with a face mask, thus turning a bad situation into a life-threatening one.

Errors of Endotracheal Tube Positioning

Unrecognized esophageal intubation can produce catastrophic results. Prevention of this complication depends on direct visualization of the tip of the ETT passing through the vocal cords, careful auscultation for the presence of bilateral breath sounds and the absence of gastric gurgling while ventilating through the ETT, detection of CO₂ in exhaled gas (the most reliable automated method), chest radiography, airway ultrasonography, or the use of an FOB.

Even though it is confirmed that the tube is in the trachea, it may not be correctly positioned. Overly “deep” insertion usually results in intubation of the right mainstem bronchus because the right bronchus forms a less acute angle
with the trachea than the left bronchus. Clues to the diagnosis of bronchial intubation include unilateral breath sounds, unexpected hypoxia with pulse oximetry (unreliable with high inspired oxygen concentrations), inability to palpate the ETT cuff in the sternal notch during cuff inflation, and decreased breathing-bag compliance (high peak inspiratory pressures).

In contrast, inadequate insertion depth will position the cuff in the larynx, predisposing the patient to laryngeal trauma. Inadequate depth of insertion can be detected by palpating the cuff over the thyroid cartilage. Because no one technique protects against all possibilities for misplacing an ETT, minimal testing should include chest auscultation, routine capnography, and occasionally cuff palpation.

If the patient is repositioned, tube placement must be reconfirmed. Neck extension or lateral rotation most often moves an ETT away from the carina, whereas neck flexion most often moves the tube toward the carina.

At no time should excessive force be employed during intubation. Esophageal intubations can result in esophageal rupture and mediastinitis. Mediastinitis presents as severe sore throat, fever, sepsis, and subcutaneous air often manifesting as crepitus. Early intervention is necessary to avoid mortality. If esophageal perforation is suspected, consultation with an otolaryngologist or thoracic surgeon is recommended. Vocal cord injury can likewise result from repeated, forceful attempts at endotracheal intubation.

**Physiological Responses to Airway Instrumentation**

Laryngoscopy and tracheal intubation violate the patient’s protective airway reflexes and predictably lead to hypertension and tachycardia when performed under “light” planes of general anesthesia. The insertion of an LMA is typically associated with less hemodynamic change. Hemodynamic changes can be attenuated by intravenous administration of lidocaine, opioids, or β-blockers, or deeper planes of inhalation anesthesia in the minutes before laryngoscopy. Hypotensive agents, including sodium nitroprusside, nitroglycerin, esmolol, nicardipine, and clevidipine, can attenuate the transient hypertensive response associated with laryngoscopy and intubation. Cardiac arrhythmias—particularly ventricular premature beats—sometimes occur during intubation and may indicate light anesthesia.

**Laryngospasm** is a forceful involuntary spasm of the laryngeal musculature caused by sensory stimulation of the superior laryngeal nerve. Triggering stimuli include pharyngeal secretions or passing an ETT through the larynx during
extubation. Laryngospasm is usually prevented by extubating patients either deeply asleep or fully awake, but it can occur—albeit rarely—in an awake patient. Treatment of laryngospasm includes providing gentle positive-pressure ventilation with an anesthesia bag and mask using 100% oxygen or administering intravenous lidocaine (1–1.5 mg/kg). If laryngospasm persists and hypoxia develops, small doses of succinylcholine (0.25–0.5 mg/kg) may be required (perhaps in combination with small doses of propofol or another anesthetic) to relax the laryngeal muscles and to allow controlled ventilation. The large negative intrathoracic pressures generated by a struggling patient during laryngospasm can result in the development of negative-pressure pulmonary edema, particularly in healthy patients.

Whereas laryngospasm may result from an abnormally sensitive reflex, aspiration can result from depression of laryngeal reflexes following prolonged intubation and general anesthesia.

Bronchospasm is another reflex response to intubation and is most common in asthmatic patients. Bronchospasm can sometimes be a clue to bronchial intubation. Other pathophysiological effects of intubation include increased intracranial and intraocular pressures.

**Endotracheal Tube Malfunction**

ETTs do not always function as intended. Polyvinyl chloride tubes may be ignited by cautery or laser in an oxygen/nitrous oxide–enriched environment. Valve or cuff damage is not unusual and should be excluded by careful inspection of the ETT prior to insertion. Obstruction of the ETT can result from kinking, from foreign body aspiration, or from thick or inspissated secretions in the lumen.

---

**CASE DISCUSSION**

**Evaluation & Management of a Difficult Airway**

A 47-year-old man with a long history of tobacco and alcohol abuse presents for emergency drainage of a right-sided submandibular abscess.

What are some important anesthetic considerations during the
**preoperative evaluation of a patient with an abnormal airway?**

Induction of general anesthesia followed by direct laryngoscopy and oral intubation is dangerous, if not impossible, in several situations. (Table 19–7). To determine the optimal intubation technique, the anesthesiologist must elicit an airway history and carefully examine the patient’s head and neck. Any available prior anesthesia records should be reviewed for previous problems in airway management. If a facial deformity is severe enough to preclude a good mask seal, positive-pressure ventilation may be impossible. Furthermore, patients with hypopharyngeal disease are more dependent on awake muscle tone to maintain airway patency. These two groups of patients should generally not be allowed to become apneic—including induction of anesthesia, sedation, or muscle paralysis—until their airway is secured.

**TABLE 19–7**  Conditions associated with difficult intubations.
If there is an abnormal limitation of the temporomandibular joint that may not improve with muscle paralysis, a nasal approach with an FOB should be considered. Infection confined to the floor of the mouth usually does not preclude nasal intubation. If the hypopharynx is involved to the level of the hyoid bone, however, any translaryngeal attempt will be difficult. Other clues to a potentially difficult laryngoscopy include limited neck extension (<35°), a distance between the tip of the patient’s mandible
and hyoid bone of less than 7 cm, a sternomentals distance of less than 12.5 cm with the head fully extended and the mouth closed, and a poorly visualized uvula during voluntary tongue protrusion. It must be stressed that because no examination technique is foolproof and the signs of a difficult airway may be subtle, the anesthesiologist must always be prepared for unanticipated difficulties.

The anesthesiologist should also evaluate the patient for signs of airway obstruction (eg, chest retraction, stridor) and hypoxia (agitation, restlessness, anxiety, lethargy). Aspiration pneumonia is more likely if the patient has recently eaten or if pus is draining from an abscess into the mouth. In either case, techniques that ablate laryngeal reflexes (eg, topical anesthesia) should be avoided.

Cervical trauma or disease is a factor that should be evaluated prior to direct laryngoscopy. Cervical arthritis or previous cervical fusion may make it difficult for the head to be put in the sniffing position; these patients are candidates for bronchoscopy to secure the airway, as discussed previously. Trauma patients with unstable necks or whose neck has not yet been “cleared” are also candidates for bronchoscopy for tracheal intubation. Alternatively, laryngoscopy with in-line stabilization can be performed (Figure 19–37).

![Technique for airway management of a patient with suspected spinal cord injury. One individual holds the head firmly with the patient on a backboard, the cervical collar left alone if in place, ensuring...](image)
that neither the head nor neck moves with direct laryngoscopy. A second person applies cricoid pressure and the third performs laryngoscopy and intubation.

In the case under discussion, physical examination reveals swelling below the mandible and trismus that limits the patient’s ability to open his mouth. Mask fit does not seem to be impaired. CT of the head and neck suggests that the infection has spread along tissue planes and is displacing the airway to the left.

**Which intubation technique is indicated?**

Oral and nasal intubations can be performed in awake patients. Whether the patient is awake or asleep or whether intubation is to be oral or nasal, it can be performed with direct laryngoscopy, fiberoptic visualization, or video laryngoscopy techniques.

Intubation may be difficult in this patient, however, because of limited mouth opening and distortion/displacement of the glottis. Induction of anesthesia should, therefore, be delayed until after the airway has been secured. Useful alternatives include awake fiberoptic intubation, awake video laryngoscopy, or awake use of optical stylets. The final decision depends on the availability of equipment and the experiences and preferences of the anesthesia caregivers.

Regardless of which alternative is chosen, an emergency surgical airway may be necessary. An experienced team, including a surgeon, should be in the operating room and all necessary equipment should be available and unwrapped. The neck can be prepped and draped.

**What premedication would be appropriate for this patient?**

Any loss of consciousness or interference with airway reflexes could result in airway obstruction or aspiration. Glycopyrrolate would be a good choice of premedication because it minimizes upper airway secretions without crossing the blood–brain barrier. Parenteral sedatives should be very carefully titrated. Dexmedetomidine and ketamine preserve respiratory effort and could be used as sedatives. Psychological preparation of the patient, including explaining each step planned in securing the airway, may improve patient cooperation.

**What nerve blocks could be helpful during an awake...**
intubation?

The lingual and some pharyngeal branches of the glossopharyngeal nerve that provide sensation to the posterior third of the tongue and oropharynx are easily blocked by bilateral injection of 2 mL of local anesthetic into the base of the palatoglossal arch (also known as the anterior tonsillar pillar) with a 25-gauge spinal needle (Figure 19–38).

**FIGURE 19–38** Nerve block. While the tongue is laterally retracted with a tongue blade, the base of the palatoglossal arch is infiltrated with local anesthetic to block the lingual and pharyngeal branches of the glossopharyngeal nerve. Note that the lingual branches of the glossopharyngeal nerve are not the same as the lingual nerve, which is a branch of the trigeminal nerve.

Bilateral **superior laryngeal nerve blocks** and a transtracheal block would anesthetize the airway below the epiglottis (Figure 19–39). The hyoid bone is located, and 3 mL of 2% lidocaine is infiltrated 1 cm below each greater cornu, where the internal branch of the superior laryngeal nerves penetrates the thyrohyoid membrane.
A transtracheal block is performed by identifying and penetrating the CTM while the neck is extended. After confirmation of an intratracheal position by aspiration of air, 4 mL of 4% lidocaine is injected into the trachea at end expiration. A deep inhalation and cough immediately following injection distribute the anesthetic throughout the trachea. Although these blocks may allow the awake patient to tolerate intubation better, they also obtund protective cough reflexes, depress the swallowing reflex, and may lead to aspiration. Topical anesthesia of the pharynx may induce a transient obstruction from the loss of reflex regulation of airway caliber at the level of the glottis.

A relatively simple alternative to all of these is to allow the patient to breath atomized lidocaine for several minutes prior to instrumentation as is typically done for outpatient bronchoscopy.

Because of this patient’s increased risk for aspiration, local anesthesia might best be limited to the nasal passages. Four percent cocaine has no advantages compared with a mixture of 4% lidocaine and 0.25% phenylephrine and can cause cardiovascular side effects. The maximum safe dose of local anesthetic should be calculated—and not exceeded. Local
anesthetic is applied to the nasal mucosa with cotton-tipped applicators until a nasal airway that has been lubricated with lidocaine jelly can be placed into the naris with minimal discomfort. Benzocaine spray is frequently used to topicalize the airway, but can produce methemoglobinemia, and for this reason we prefer lidocaine.

**Why is it necessary to be prepared for a surgical airway?**

Laryngospasm is always a possible complication of intubation in the nonparalyzed patient, even if the patient remains awake. Laryngospasm may make positive-pressure ventilation with a mask impossible. If succinylcholine is administered to break the spasm, the consequent relaxation of pharyngeal muscles may lead to upper airway obstruction and continued inability to ventilate. In this situation, an emergency cricothyrotomy may be lifesaving.

**What are some alternative techniques that might be successful?**

Other possible strategies include the retrograde passage of a long guidewire or epidural catheter through a needle inserted across the CTM. The catheter is guided cephalad into the pharynx and out through the nose or mouth. An ETT is passed over the catheter, which is withdrawn after the tube has entered the larynx. Variations of this technique include passing the retrograde wire through the suction port of a flexible FOB or the lumen of a reintubation stylet that has been preloaded with an ETT. These thicker shafts help the ETT negotiate the bend into the larynx more easily. Obviously, a vast array of specialized airway equipment exists and must be readily available for management of difficult airways (Table 19–8). Either of these techniques would have been difficult in the patient described in this case because of the swelling and anatomic distortion of the neck that can accompany a submandibular abscess.

**TABLE 19–8** Suggested contents of the portable storage unit for difficult airway management.\(^1^,\(^2^\)
What are some approaches when the airway is unexpectedly difficult?

The unexpected difficult airway can present both in elective surgical patients and also in emergency intubations in intensive care units, the emergency department, or general hospital wards. Should video laryngoscopy fail even after attempts with an intubating bougie, an intubating LMA should be attempted (Figure 19–40). If ventilation is adequate, an FOB can be loaded with an ETT and passed through the LMA into the trachea. Correct tube position is confirmed by visualization of the carina.

FIGURE 19–40 Intubating laryngeal mask airway.

GUIDELINES

- Rigid laryngoscope blades of alternate design and size from those routinely used.
- Endotracheal tubes (ETTs) of assorted size.
- ETT guides. Examples include (but are not limited to) semirigid stylets with or without a hollow core for jet ventilation, light wands, and forceps designed to manipulate the distal portion of the ETT.
- Laryngeal mask airways of assorted sizes.
- Fiberoptic intubation equipment and assorted video and indirect laryngoscopes.
- Retrograde intubation equipment.
- At least one device suitable for emergency nonsurgical airway ventilation. Examples include (but are not limited to) transtracheal jet ventilator, hollow jet ventilation stylet, and Combitube.
- Equipment suitable for emergency surgical airway access (eg, cricothyrotomy).
- An exhaled CO₂ detector.

*The items listed in this table are suggestions. The contents of the portable storage unit should be customized to meet the specific needs, preferences, and skills of the practitioner and healthcare facility.

Patel A, Nouraei SAR. Transnasal humidified rapid insufflation ventilatory exchange (THRIVE): A physiological method of increasing apnoea time in

In contrast to action potentials in axons, the spike in cardiac action potentials is followed by a plateau phase that lasts 0.2 to 0.3 s. Whereas the action potential for skeletal muscle and nerves is due to the abrupt opening of voltage-gated sodium channels in the cell membrane, in cardiac muscle it is initiated by voltage-gated sodium channels (the spike) and maintained by voltage-gated calcium channels (the plateau).

Potent inhalational agents depress sinoatrial (SA) node automaticity. These agents seem to have only modest direct effects on the atrioventricular (AV) node, prolonging conduction time and increasing refractoriness. This combination of effects likely explains the frequent occurrence of junctional tachycardia when an anticholinergic agent is administered for sinus bradycardia during inhalation anesthesia; junctional pacemakers are accelerated more than those in the SA node.

Studies suggest that volatile anesthetics depress cardiac contractility by decreasing the entry of Ca\(^{2+}\) into cells during depolarization (affecting T- and L-type calcium channels), altering the kinetics of Ca\(^{2+}\) release and uptake into the sarcoplasmic reticulum, and decreasing the sensitivity of contractile proteins to calcium.

Because the normal cardiac index (CI) has a wide range, it is a relatively insensitive measurement of ventricular performance. Abnormalities in CI therefore usually reflect gross ventricular impairment.

In the absence of hypoxia or severe anemia, measurement of mixed venous oxygen tension (or saturation) provides an estimate of the adequacy of cardiac output.
Patients with reduced ventricular compliance are most affected by loss of a normally timed atrial systole.

Cardiac output in patients with marked right or left ventricular impairment is very sensitive to acute increases in afterload.

The ventricular ejection fraction, the fraction of the end-diastolic ventricular volume ejected, is the most commonly used clinical measurement of systolic function.

Left ventricular diastolic function can be assessed clinically by Doppler echocardiography in a transthoracic or transesophageal examination.

Because the endocardium is subjected to the greatest intramural pressures during systole, it tends to be most vulnerable to ischemia during decreases in coronary perfusion pressure.

The failing heart becomes increasingly dependent on circulating catecholamines. Abrupt withdrawal in sympathetic outflow or decreases in circulating catecholamine levels, such as can occur following induction of anesthesia, may lead to acute cardiac decompensation.

Anesthesiologists must have a thorough understanding of cardiovascular physiology. Anesthetic successes and failures are often directly related to the skill of the practitioner in manipulating cardiovascular physiology. This chapter reviews the physiology of the heart and the systemic circulation and the pathophysiology of heart failure.

The circulatory system consists of the heart, blood vessels, and blood. Its function is to provide oxygen and nutrients to the tissues and to carry away the products of metabolism. The heart propels blood through two vascular systems arranged in series. In the normally low-pressure pulmonary circulation, venous blood flows past the alveolar–capillary membrane, takes up oxygen, and releases CO₂. In the high-pressure systemic circulation, oxygenated arterial blood is pumped to tissues, and the byproducts of metabolism are taken up for elimination by the lungs, kidneys, or liver.

The Heart

The heart can be functionally divided into right and left pumps, each consisting of an atrium and a ventricle. The atria serve as both conduits and priming pumps,
whereas the ventricles act as the major pumping chambers. The right ventricle receives systemic venous (deoxygenated) blood and pumps it into the pulmonary circulation, whereas the left ventricle receives pulmonary venous (oxygenated) blood and pumps it into the systemic circulation. Four valves normally ensure unidirectional flow through each chamber. The normal pumping action of the heart is the result of a complex series of electrically driven and mechanical events. Electrical events precede mechanical ones.

The heart consists of specialized striated muscle in a connective tissue skeleton. Cardiac muscle can be divided into atrial, ventricular, and specialized pacemaker and conducting cells. The self-excitatory nature of cardiac muscle cells and their unique organization allow the heart to function as a highly efficient pump. Serial low-resistance connections (intercalated disks) between individual myocardial cells allow the rapid and orderly spread of depolarization in each pumping chamber. Electrical activity readily spreads from one atrium to another and from one ventricle to another via specialized conduction pathways. The normal absence of direct connections between the atria and ventricles except through the atrioventricular (AV) node delays ventricular depolarization, enabling the atria to prime the ventricles.

**CARDIAC ACTION POTENTIALS**

At rest, the myocardial cell membrane is nominally permeable to K⁺, but is relatively impermeable to Na⁺. A membrane-bound Na⁺–K⁺-adenosine triphosphatase (ATPase) concentrates K⁺ intracellularly and extrudes Na⁺ out of the cell. Relative to extracellular concentrations intracellular Na⁺ concentration is kept low and intracellular K⁺ concentration is kept high. The relative impermeability of the membrane to calcium also maintains a high extracellular to cytoplasmic calcium gradient. Movement of K⁺ out of the cell and down its concentration gradient results in a net loss of positive charges from inside the cell. An electrical potential is established across the cell membrane, with the inside of the cell negative with respect to the extracellular environment, because anions do not accompany K⁺. Thus, the resting membrane potential represents the balance between two opposing forces: the movement of K⁺ down its concentration gradient and the electrical attraction of the negatively charged intracellular space for the positively charged K⁺.

The normal ventricular cell resting membrane potential is –80 to –90 mV. As with other excitable tissues (nerve, skeletal muscle, and some endocrine cells), when the cell membrane potential becomes less negative and reaches a threshold
value, a characteristic action potential (depolarization) develops (Figure 20–1 and Table 20–1). The action potential transiently increases the membrane potential of the myocardial cell to +20 mV. In contrast to action potentials in axons, the spike in cardiac action potentials is followed by a plateau phase that lasts 0.2 to 0.3 s. Whereas the action potential for skeletal muscle and nerves is due exclusively to the opening of voltage-gated sodium channels, in cardiac muscle the action potential is initiated by voltage-gated sodium channels (the spike) and maintained by voltage-gated calcium channels (the plateau). In pacemaker cells depolarization is initiated by voltage-gated calcium channels rather than by sodium channels. The plateau phase is maintained by calcium flow into the cell and potassium flow out of the cell. Voltage-gated sodium channels inactivate and cease to conduct within milliseconds of opening. Subsequent termination of calcium channel permeability and activation of several forms of voltage-gated potassium channels restores the membrane potential to its resting value.
FIGURE 20–1 Cardiac action potentials. A: Note the characteristic contours of action potentials recorded from different parts of the heart. LAF, left anterior fascicle. B: Pacemaker cells in the sinoatrial (SA) node lack the same distinct phases as atrial and ventricular muscle cells and display prominent spontaneous diastolic depolarization. See Table 20–1 for an explanation of the different phases of the action potential. (Modified with permission from Barrett KE. Ganong’s Review of Medical Physiology. 24th ed. New York, NY: McGraw-Hill; 2012.)

TABLE 20–1 Cardiac action potential.
Following depolarization, the cells are typically refractory to subsequent normal depolarizing stimuli until “phase 4.” The absolute refractory period is the minimum interval between two maximal stimuli that will result in an action potential. The relative refractory period is the additional time beyond the absolute refractory period in which a maximal stimulus, but not a stimulus of normal intensity, will produce a depolarization.

Table 20–2 lists some of the multiple types of ion channels in cardiac muscle membrane. Some are activated by a change in cell membrane voltage, whereas others open only when bound by ligands. T-type (transient) voltage-gated calcium channels play a role in phase 0 of depolarization. (A more modern nomenclature for voltage-gated calcium channels—Cav1, Cav2, Cav3—is creeping into the scientific literature but remains uncommon in clinical usage.) During the plateau phase (phase 2), Ca^{2+} inflow occurs through slow L-type (long-lasting), voltage-gated calcium channels. Multiple potassium channel forms contribute repolarization, and a full discussion of this topic is beyond the focus of this textbook.

**Table 20–2** Cardiac ion channels.¹²
The cardiac impulse normally originates in the sinoatrial (SA) node, a group of specialized pacemaker cells in the sulcus terminalis, located posteriorly at the junction of the right atrium and the superior vena cava. The slow influx of Na\(^+\) through so-called hyperpolarization-activated cyclic nucleotide–gated (HCN) channels results in a less negative resting membrane potential (–50 to –60 mV). This has three important consequences: near constant inactivation of voltage-gated sodium channels, an action potential that is primarily due to ion movement across the slow calcium channels and with a threshold of –40 mV, and regular spontaneous depolarizations. During each cycle, Na\(^+\) ions passing through HCN channels causes the cell membrane to become progressively less negative; when the threshold potential is reached, calcium channels open and an action potential develops. Inactivation of L-type calcium channels and activation of potassium channels returns the cells in the SA node to their normal resting membrane potential.

The impulse generated at the SA node is normally rapidly conducted across the atria and to the AV node. Specialized atrial fibers may speed up conduction to both the left atrium and the AV node. The AV node is located in the septal
wall of the right atrium, just anterior to the opening of the coronary sinus and above the insertion of the septal leaflet of the tricuspid valve. The normally slower rate of spontaneous depolarization in AV junctional areas (40–60 times/min) allows the faster SA node to control heart rate. Any factor that decreases the rate of SA node depolarization or increases the automaticity of AV junctional areas allows the junctional areas to function as the pacemaker for the heart.

Impulses from the SA node normally reach the AV node after about 0.04 s, but leave after another 0.11 s. This delay is the result of the slowly conducting small myocardial fibers within the AV node, which depend on L-type calcium channels for propagation of the action potential. In contrast, conduction of the impulse between adjoining cells in the atria and in the ventricles is due primarily to activation of sodium channels. The lower fibers of the AV node combine to form the common bundle of His. This specialized group of fibers passes into the interventricular septum before dividing into left and right branches to form the complex network of Purkinje fibers that depolarizes both ventricles. In sharp contrast to AV nodal tissue, His–Purkinje fibers have the fastest conduction velocities in the heart, resulting in nearly simultaneous depolarization of the entire endocardium of both ventricles (normally within 0.03 s). Synchronized depolarization of the lateral and septal walls of the left ventricle promotes effective ventricular contraction. When synchronized contraction of the septal and lateral walls is impaired (eg, in heart failure patients), ventricular function may be improved by biventricular pacing and cardiac resynchronization therapy. The spread of the impulse from the endocardium to the epicardium through ventricular muscle requires an additional 0.03 s. Thus, an impulse arising from the SA node normally requires less than 0.2 s to depolarize the entire heart.

Potent inhaled anesthetics depress SA node automaticity. These agents seem to have only modest direct effects on the AV node, prolonging conduction time and increasing refractoriness. This combination of effects likely explains the occurrence of junctional tachycardia when an anticholinergic is administered for sinus bradycardia during inhalation anesthesia; junctional pacemakers are accelerated more than those in the SA node. The electrophysiological effects of volatile agents on Purkinje fibers and ventricular muscle are complex due to autonomic interactions. Both antiarrhythmic and arrhythmogenic properties are described. The former may be due to direct depression of Ca\(^{2+}\) influxes, whereas the latter generally involves potentiation of catecholamines, especially with the now seldom-used halothane. Intravenous induction agents have limited electrophysiological effects in usual clinical doses. Opioids, particularly fentanyl
and sufentanil, can depress cardiac conduction, increasing the time of AV node conduction and the refractory period and prolonging the duration of the Purkinje fiber action potential.

Local anesthetics have important electrophysiological effects on the heart at blood concentrations that are generally associated with systemic toxicity. In the case of lidocaine, electrophysiological effects at low blood concentrations can be therapeutic. At high blood concentrations, local anesthetics depress conduction; at extremely high concentrations, they also depress the SA node. The most potent local anesthetics—bupivacaine, etidocaine, and to a lesser degree, ropivacaine—seem to have the most potent effects on the heart, particularly on Purkinje fibers and ventricular muscle. Bupivacaine, like all local anesthetics, preferentially binds open or inactivated sodium channels. Bupivacaine dissociates from them more slowly than less toxic agents. It can cause profound sinus bradycardia and sinus node arrest and malignant ventricular arrhythmias; furthermore, it can depress left ventricular contractility. Twenty percent lipid emulsions have been used to treat local anesthetic cardiac toxicity. The mechanisms of action of this therapy are unclear, although most likely the lipid serves as reservoir for circulating bupivacaine, decreasing the amount of bupivacaine in the myocardium.

The clinically used calcium channel blockers are organic compounds that block Ca\(^{2+}\) influx through L-type but not T-type channels. In a manner reminiscent of local anesthetics and sodium channels, agents such as verapamil, and to a lesser extent, diltiazem, preferentially bind the calcium channel in its depolarized inactivated state (use-dependent blockade). Calcium channel blockers are employed perioperatively as antihypertensives and as antiarrhythmics.

**MECHANISM OF CONTRACTION**

Myocardial cells contract as a result of the interaction of two overlapping, rigid contractile proteins, actin and myosin. Dystrophin, a large intracellular protein, connects actin to the cell membrane (sarcolemma). Cell shortening occurs when the actin and myosin are allowed to fully interact and slide over one another. This interaction is normally prevented by two regulatory proteins, troponin and tropomyosin; troponin is composed of three subunits (troponin I, troponin C, and troponin T). Troponin is attached to actin at regular intervals, whereas tropomyosin lies within the center of the actin structure. An increase in intracellular Ca\(^{2+}\) concentration (from about 10\(^{-7}\) to 10\(^{-5}\) mol/L) promotes
contraction as Ca\textsuperscript{2+} ions bind troponin C. The resulting conformational change in these regulatory proteins exposes the active sites on actin that allow interaction with myosin bridges (points of overlapping). The active site on myosin functions as a magnesium-dependent ATPase whose activity is enhanced by the increase in intracellular Ca\textsuperscript{2+} concentration. A series of attachments and disengagements occur as each myosin bridge advances over successive active sites on actin. Adenosine triphosphate (ATP) is consumed during each attachment. Relaxation occurs as Ca\textsuperscript{2+} is actively pumped back into the sarcoplasmic reticulum by a Ca\textsuperscript{2+}–Mg\textsuperscript{2+}-ATPase; the resulting drop in intracellular Ca\textsuperscript{2+} concentration allows the troponin–tropomyosin complex to again prevent the interaction between actin and myosin.

**Excitation–Contraction Coupling**

The quantity of Ca\textsuperscript{2+} ions required to initiate contraction exceeds that entering the cell through L-type calcium channels during phase 2. The small amount that does enter through slow calcium channels triggers the release of much larger amounts of Ca\textsuperscript{2+} stored intracellularly (calcium-dependent calcium release) within cisterns in the sarcoplasmic reticulum.

The action potential of muscle cells depolarizes their T systems, tubular extensions of the cell membrane that transverse the cell in close approximation to the muscle fibrils, via L-type voltage-gated calcium channels. This initial increase in intracellular Ca\textsuperscript{2+} triggers an even greater Ca\textsuperscript{2+} inflow across ryanodine receptors, a nonvoltage-dependent calcium channel found in the sarcoplasmic reticulum. The force of contraction is directly dependent on the magnitude of the initial Ca\textsuperscript{2+} influx.

During relaxation, when the L-type channels close, a membrane-bound Ca\textsuperscript{2+}–Mg\textsuperscript{2+}-ATPase actively transports Ca\textsuperscript{2+} back into the sarcoplasmic reticulum. Thus, relaxation of the heart also requires ATP. Ca\textsuperscript{2+} is also extruded extracellularly by an exchange of intracellular Ca\textsuperscript{2+} for extracellular sodium in a 1:3 ratio by the Na\textsuperscript{+}–Ca\textsuperscript{2+} exchanger in the cell membrane (Figure 20–2).
The quantity of intracellular Ca\(^{2+}\) available, its rate of delivery, and its rate of removal determine, respectively, the maximum tension developed, the rate of contraction, and the rate of relaxation. Sympathetic stimulation increases the force of contraction by raising intracellular Ca\(^{2+}\) concentration via a β\(_1\) adrenergic receptor-mediated increase in intracellular cyclic adenosine monophosphate (cAMP) through the action of a stimulatory G protein. The increase in cAMP recruits additional open calcium channels. Phosphodiesterase inhibitors, such as milrinone, produce similar effects by preventing the breakdown of intracellular cAMP. Milrinone has lusitropic effects, improving relaxation and diastolic function. Digitalis glycosides increase intracellular Ca\(^{2+}\) concentration through inhibition of the membrane-bound Na\(^+\)–K\(^+\)-ATPase; the resulting small increase in intracellular Na\(^+\) relatively disfavors the normal pumping of Ca\(^{2+}\) from the cytoplasm via the Na\(^+\)–Ca\(^{2+}\) exchange mechanism, increasing the intracellular Ca\(^{2+}\) concentration. Glucagon enhances contractility by increasing intracellular cAMP levels via activation of a specific receptor. The newer agent levosimendan is a calcium sensitizer that enhances contractility by
binding to troponin C. The investigational drug omecamtiv mecarbil is a myosin activator that increases the duration of cardiac muscle contractility. Istaroxime has both inotropic and lusitropic effects, improving both systolic and diastolic function (Table 20–3).

In contrast, release of acetylcholine following vagal stimulation depresses contractility through increased cyclic guanosine monophosphate (cGMP) levels and inhibition of adenylyl cyclase; these effects are mediated by an inhibitory G
protein. Acidosis inhibits L-type calcium channels and therefore also depresses cardiac contractility by unfavorably altering intracellular Ca\textsuperscript{2+} kinetics (Figure 20–3).

**FIGURE 20–3** Diagram of intracellular signaling cascades within cardiomyocytes altered by inotropes Dopamine, Dobutamine, and Norepinephrine that activate the β\textsubscript{1}-adrenergic receptor, which activates the G protein Gas, which in turn, activates adenylyl cyclase. Adenylyl cyclase converts ATP to cAMP when activated. cAMP can activate PKA, which then phosphorylates the L-type calcium channel, among other targets. cAMP is converted to AMP by PDE. Milrinone inhibits PDE-3, thereby increasing the effective concentration of cAMP. Calcium influx through the L-type calcium channel induces activation of ryanodine receptors, leading to calcium-induced Ca\textsuperscript{2+} release. Free intracellular Ca\textsuperscript{2+} interacts with troponin C, which changes the binding properties of tropomyosin and allows the interaction between actin and myosin. Levosimendan potentiates the interaction between troponin and calcium. It may also have PDE-3 inhibitor activity. Omecamtiv mecarbil increases the rate of ATP turnover and slows the rate of ADP release, thereby increasing the number of myosin molecules bound to actin at any given time. SERCA is responsible for uptake of calcium into the sarcoplasmic reticulum while the Na\textsuperscript{+}–K\textsuperscript{+}-ATPase participates in resetting the membrane potential of the cell. Istaroxime inhibits Na\textsuperscript{+}–K\textsuperscript{+}-ATPase while also potentiating SERCA.
Digoxin inhibits the Na\(^+\)-K\(^+\)-ATPase. *Red arrows* denote agonists, whereas *black arrows* signify antagonists. AC, adenylyl cyclase; ADP, adenosine diphosphate; ATP, adenosine triphosphate; β\(_1\)AR, β\(_1\)-adrenergic receptor; cAMP, cyclic adenosine monophosphate; LTCC, L-type calcium channel; PDE, phosphodiesterase; PKA, protein kinase A; RyR, ryanodine receptor; SERCA, sarco/endoplasmic reticulum Ca\(^{2+}\)-ATPase. *Reproduced with permission from Francis GS, Bartos JA, Adatya S, et al. Inotropes. J Am Coll Cardiol. 2014 May 27;63:2069-2078.*

Studies suggest that volatile anesthetics depress cardiac contractility by decreasing the entry of Ca\(^{2+}\) into cells during depolarization (affecting T- and L-type calcium channels), altering the kinetics of Ca\(^{2+}\) release and uptake into the sarcoplasmic reticulum, and decreasing the sensitivity of contractile proteins to Ca\(^{2+}\). Inhalational anesthetics appear to have minimal effect upon early diastolic relaxation in subjects without known diastolic dysfunction. However, they do decrease atrial function perhaps resulting in reduced late diastolic filling. Anesthetic-induced cardiac depression is potentiated by hypocalcemia, β-adrenergic blockade, and calcium channel blockers. Nitrous oxide also produces concentration-dependent decreases in contractility by reducing the availability of intracellular Ca\(^{2+}\) during contraction. The mechanisms of direct cardiac depression from intravenous anesthetics are not well established, but presumably involve similar actions. Of all the typical intravenous induction agents, ketamine seems to have the least depressant effect on contractility due to its central nervous system excitatory effects.

**INNERVATION OF THE HEART**

Parasympathetic fibers innervate the atria and conducting tissues. Acetylcholine acts on specific cardiac muscarinic receptors (M\(_2\)) to produce negative chronotropic, dromotropic, and inotropic effects. In contrast, sympathetic fibers are more widely distributed throughout the heart. Cardiac sympathetic fibers originate in the thoracic spinal cord (T1–T4) and travel to the heart initially through the cervical (stellate) ganglia and from the ganglia as the cardiac nerves. Norepinephrine release at the heart causes positive chronotropic, dromotropic, and inotropic effects primarily through activation of β\(_1\)-adrenergic receptors. β\(_2\)-Adrenergic receptors are normally fewer in number and are found primarily in the atria; activation increases heart rate and, to a lesser extent, contractility. The relative fraction of β\(_2\)- to β\(_1\)-adrenergic receptors increases in heart failure.

Cardiac autonomic innervation has an apparent sidedness, because the right
sympathetic and right vagus nerves primarily affect the SA node, whereas the left sympathetic and vagus nerves principally affect the AV node. Vagal effects frequently have a very rapid onset and resolution, whereas sympathetic influences generally have a more gradual onset and dissipation. Sinus arrhythmia is a cyclic variation in heart rate that corresponds to respiration (increasing with inspiration and decreasing during expiration); it is due to cyclic changes in vagal tone.

THE CARDIAC CYCLE

The cardiac cycle can be defined by both electrical and mechanical events (Figure 20–4). Systole refers to contraction and diastole refers to relaxation. Most diastolic ventricular filling occurs passively before atrial contraction. Contraction of the atria normally contributes 20% to 30% of ventricular filling. Three waves can generally be identified on atrial or central venous pressure tracings (Figure 20–4). The a wave is due to atrial systole. The c wave coincides with ventricular contraction and is said to be caused by bulging of the AV valve into the atrium. The v wave is the result of pressure buildup from venous return before the AV valve opens again. The x descent is the decline in pressure between the c and v waves and is thought to be due to a pulling down of the atrium by ventricular contraction. Incompetence of the AV valve on either side of the heart abolishes the x descent on that side, resulting in a prominent cv wave. The y descent follows the v wave and represents the decline in atrial pressure as the AV valve opens. The notch in the aortic pressure tracing is referred to as the incisura and is said to represent the brief pressure change from transient backflow of blood into the left ventricle just before aortic valve closure.
Phases of cardiac cycle:
1. Atrial systole
2. Isometric contraction
3. Ejection
4. Isometric relaxation
5. Filling

**DETERMINANTS OF VENTRICULAR PERFORMANCE**

Discussions of ventricular function usually refer to the left ventricle, but the same concepts apply to the right ventricle. Although the ventricles are often thought of as functioning separately, their interdependence has clearly been demonstrated. Moreover, factors affecting systolic and diastolic functions can be differentiated: Systolic function involves ventricular ejection, whereas diastolic function is related to ventricular filling.

Ventricular systolic function is often (erroneously) equated with cardiac output, which can be defined as the volume of blood pumped by the heart per minute. Because the two ventricles function in series, their outputs are normally equal. Cardiac output (CO) is expressed by the following equation:

\[ \text{CO} = \text{SV} \times \text{HR} \]

where SV is the stroke volume (the volume pumped per contraction) and HR is heart rate. To compensate for variations in body size, CO is often expressed in terms of total body surface area:

\[ \text{CI} = \frac{\text{CO}}{\text{BSA}} \]

where CI is the cardiac index and BSA is body surface area. BSA is usually obtained from nomograms based on height and weight. Normal CI is 2.5 to 4.2 L/min/m². Because the normal CI has a wide range, it is a relatively insensitive measurement of ventricular performance. Abnormalities in CI therefore usually reflect gross ventricular impairment. A more accurate assessment can be obtained if the response of the cardiac output to exercise is evaluated. Under these conditions, failure of the cardiac output to increase and keep up with oxygen consumption is reflected by a decreasing mixed venous oxygen saturation. A decrease in mixed venous oxygen saturation in response to increased demand usually reflects inadequate tissue perfusion. Thus, in the absence of hypoxia or severe anemia, measurement of mixed venous oxygen tension (or saturation) provides an estimate of the adequacy of cardiac output.
1. **Heart Rate**

When stroke volume remains constant, cardiac output is directly proportional to heart rate. Heart rate is an intrinsic function of the SA node (spontaneous depolarization), but is modified by autonomic, humoral, and local factors. The normal intrinsic rate of the SA node in young adults is about 90 to 100 beats/min, but it decreases with age based on the following formula:

\[
\text{Normal intrinsic heart rate} = 118 \text{ beats/min} - (0.57 \times \text{Age})
\]

Enhanced vagal activity slows the heart rate via stimulation of M₂ cholinergic receptors, whereas enhanced sympathetic activity increases the heart rate mainly through activation of β₁-adrenergic receptors and, to lesser extent, β₂-adrenergic receptors (see above).

2. **Stroke Volume**

Stroke volume is normally determined by three major factors: preload, afterload, and contractility. This analysis is analogous to laboratory observations on skeletal muscle preparations. Preload is muscle length prior to contraction, whereas afterload is the tension against which the muscle must contract. Contractility is an intrinsic property of the muscle that is related to the force of contraction but is independent of both preload and afterload. Because the heart is a three-dimensional multichambered pump, both ventricular geometric form and valvular dysfunction can also affect stroke volume (Table 20–4).

**TABLE 20–4  Major factors affecting cardiac stroke volume.**

<table>
<thead>
<tr>
<th>Preload</th>
<th>Afterload</th>
<th>Contractility</th>
<th>Wall motion abnormalities</th>
<th>Valvular dysfunction</th>
</tr>
</thead>
</table>

**Preload**

Ventricular preload is end-diastolic volume, which is generally dependent on ventricular filling. The relationship between cardiac output and left ventricular end-diastolic volume was first described by Starling (Figure 20–5). Note that
when the heart rate and contractility remain constant, cardiac output increases with increasing preload until excessive end-diastolic volumes are reached. At that point, cardiac output does not appreciably change—or may even decrease. Excessive distention of either ventricle can lead to dilation and incompetence of the AV valves.

**A. Determinants of Ventricular Filling**

Ventricular filling can be influenced by a variety of factors (**Table 20–5**), of which the most important is venous return. The heart cannot pump what the heart does not receive; therefore, venous return normally equals cardiac output. Because most of the other factors affecting venous return are usually fixed, vascular capacity is normally its major determinant. Increases in metabolic activity reduce vascular capacity, so that venous return to the heart and cardiac output increase as the volume of venous capacitance vessels decreases. Changes in blood volume and vascular capacity are important causes of intraoperative and postoperative changes in ventricular filling and cardiac output. Any factor that alters the normally small venous pressure gradient favoring blood return to the
heart also affects cardiac filling. Such factors include changes in intrathoracic pressure (positive-pressure ventilation or thoracotomy), posture (positioning during surgery), and pericardial pressure (pericardial disease).

**TABLE 20–5 Factors affecting ventricular preload.**

</tbody>
</table>

The most important determinant of right ventricular preload is venous return. **In the absence of significant pulmonary or right ventricular dysfunction, venous return is also the major determinant of left ventricular preload.**

Both heart rate and rhythm can affect ventricular preload. Increases in heart rate are associated with proportionately greater reductions in diastole than systole. Ventricular filling therefore progressively becomes impaired at increased heart rates (>120 beats/min in adults). Absent (atrial fibrillation), ineffective (atrial flutter), or altered timing of atrial contraction (low atrial or junctional rhythms) can also reduce ventricular filling by 20% to 30%. Patients with reduced ventricular compliance are more affected by the loss of a normally timed atrial systole than are those with normal ventricular compliance.

**B. Diastolic Function and Ventricular Compliance**

Left ventricular end-diastolic pressure (LVEDP) can be used as a measure of preload only if the relationship between ventricular volume and pressure (ventricular compliance) is constant. However, ventricular compliance is normally nonlinear (Figure 20–6). Impaired diastolic function reduces ventricular compliance. Therefore, the same LVEDP that corresponds to a normal preload in a normal patient may correspond to a decreased preload in a patient with impaired diastolic function. Many factors are known to influence ventricular diastolic function and compliance. Nonetheless, measurement of LVEDP or other pressures approximating LVEDP (such as pulmonary artery
occlusion pressure) are potential means of estimating left ventricular preload. Changes in central venous pressure can be used as a rough index for changes in right and left ventricular preload in most normal individuals.

**FIGURE 20–6** Normal and abnormal ventricular compliance.

Factors affecting ventricular compliance can be separated into those related to the rate of relaxation (early diastolic compliance) and passive stiffness of the ventricles (late diastolic compliance). Hypertrophy (from hypertension or aortic valve stenosis), ischemia, and asynchrony reduce early compliance; hypertrophy and fibrosis reduce late compliance. Extrinsic factors (such as pericardial disease, excessive distention of the contralateral ventricle, increased airway or pleural pressure, tumors, and surgical compression) can also reduce ventricular compliance. Because of its normally thinner wall, the right ventricle is more compliant than the left.

**Afterload**

Afterload for the intact heart is commonly equated with either ventricular wall tension during systole or arterial impedance to ejection. Wall tension may be thought of as the pressure the ventricle must overcome to reduce its cavity volume. If the ventricle is assumed to be spherical, ventricular wall tension can be expressed by Laplace’s law:
where \( P \) is intraventricular pressure, \( R \) is the ventricular radius, and \( H \) is wall thickness. Although the normal ventricle is usually ellipsoidal, this relationship is still useful. The larger the ventricular radius, the greater the wall tension required to develop the same ventricular pressure. Conversely, an increase in wall thickness reduces ventricular wall tension.

Systolic intraventricular pressure is dependent on the force of ventricular contraction; the viscoelastic properties of the aorta, its proximal branches, and blood (viscosity and density); and **systemic vascular resistance (SVR)**. Arteriolar tone is the primary determinant of SVR. Because viscoelastic properties are generally fixed in any given patient, left ventricular afterload is usually equated clinically with SVR, which is calculated by the following equation:

\[
SVR = 80 \times \frac{MAP - CVP}{CO}
\]

where MAP is mean arterial pressure in millimeters of mercury, CVP is central venous pressure in millimeters of mercury, and CO is cardiac output in liters per minute. Normal SVR is 900–1500 dyn \( \cdot \) s \( \cdot \) cm\(^{-5}\). Systolic blood pressure may also be used as an approximation of left ventricular afterload in the absence of chronic changes in the size, shape, or thickness of the ventricular wall or acute changes in systemic vascular resistance. Some clinicians prefer to use CI instead of CO in calculating a systemic vascular resistance index (SVRI), so that SVRI = SVR \( \times \) BSA (body surface area).

Right ventricular afterload is mainly dependent on pulmonary vascular resistance (PVR) and is expressed by the following equation:

\[
PVR = 80 \times \frac{PAP - LAP}{CO}
\]

where PAP is mean pulmonary artery pressure and LAP is left atrial pressure. In practice, pulmonary capillary wedge pressure (PCWP) can be substituted as an approximation for LAP. Normal PVR is 50 to 150 dyn \( \cdot \) s \( \cdot \) cm\(^{-5}\).

Cardiac output is inversely related to large changes in afterload on the left ventricle; however, small increases or decreases in afterload may have no effect on cardiac output. Because of its thinner wall, the right ventricle is more...
sensitive to changes in afterload than is the left ventricle. Cardiac output in patients with marked right or left ventricular impairment is very sensitive to acute increases in afterload. The latter is particularly true in the presence of drug- or ischemia-induced myocardial depression or chronic heart failure.

**Contractility**

Cardiac contractility (inotropy) is the intrinsic ability of the myocardium to pump in the absence of changes in preload or afterload. Contractility is related to the rate of myocardial muscle shortening, which is, in turn, dependent on the intracellular Ca$^{2+}$ concentration during systole. Increases in heart rate can also enhance contractility under some conditions, perhaps because of the increased availability of intracellular Ca$^{2+}$.

Contractility can be altered by neural, humoral, or pharmacological influences. Sympathetic nervous system activity normally has the most important effect on contractility. Sympathetic fibers innervate atrial and ventricular muscle, as well as nodal tissues. In addition to its positive chronotropic effect, norepinephrine release also enhances contractility primarily via $\beta_1$-receptor activation. $\alpha$-Adrenergic receptors are also present in the myocardium, but seem to have only minor positive inotropic and chronotropic effects that are overwhelmed by the vascular actions of $\alpha$-adrenergic agonists when these drugs are administered systemically. Sympathomimetic drugs and secretion of epinephrine from the adrenal glands similarly increase contractility via $\beta_1$-receptor activation.

Myocardial contractility is depressed by hypoxia, acidosis, depletion of catecholamine stores within the heart, and loss of functioning muscle mass as a result of ischemia or infarction. At large enough doses, most anesthetics and antiarrhythmic agents are negative inotropes (ie, they decrease contractility).

**Wall Motion Abnormalities**

Regional wall motion abnormalities cause a breakdown of the analogy between the intact heart and skeletal muscle preparations. Such abnormalities may be due to ischemia, scarring, hypertrophy, or altered conduction. When the ventricular cavity does not collapse symmetrically or fully, emptying becomes impaired. Hypokinesis (decreased contraction), akinesis (failure to contract), and dyskinesis (paradoxic bulging) during systole reflect increasing degrees of contraction abnormalities. Although contractility may be normal or even
enhanced in some areas, abnormalities in other areas of the ventricle can impair emptying and reduce stroke volume. The severity of the impairment depends on the size and number of abnormally contracting areas.

**Valvular Dysfunction**

Valvular dysfunction can involve any one of the four valves in the heart and can include stenosis, regurgitation (incompetence), or both. Stenosis of an AV valve (tricuspid or mitral) reduces stroke volume primarily by decreasing ventricular preload, whereas stenosis of a semilunar valve (pulmonary or aortic) reduces stroke volume primarily by increasing ventricular afterload. In contrast, valvular regurgitation can reduce stroke volume without changes in preload, afterload, or contractility and without wall motion abnormalities. The effective stroke volume is reduced by the regurgitant volume with every contraction. When an AV valve is incompetent, a significant part of the ventricular end-diastolic volume can flow backward into the atrium during systole; the stroke volume is reduced by the regurgitant volume. Similarly, when a semilunar valve is incompetent, a fraction of end-diastolic volume arises from backward flow into the ventricle during diastole.

**ASSESSMENT OF VENTRICULAR FUNCTION**

1. **Ventricular Function Curves**

Plotting cardiac output or stroke volume against preload can be useful in evaluating pathological states and understanding drug therapy. Normal right and left ventricular function curves are shown in Figure 20–7.
Ventricular pressure–volume diagrams dissociate contractility from both preload and afterload. Two points are identified on such diagrams: the end-systolic point (ESP) and the end-diastolic point (EDP) (Figure 20–8). ESP is reflective of systolic function, whereas EDP is more reflective of diastolic function. For any given contractile state, all ESPs are on the same line (ie, the relationship between end-systolic volume and end-systolic pressure is fixed). Figure 20–9 describes the events occurring in the left ventricle during each cardiac cycle.
FIGURE 20–8 Ventricular pressure–volume diagrams. A: A single ventricular contraction. Note that stroke volume represents change in volume on the x-axis (difference between end-systolic volume and end-diastolic volume). Note also that the circumscribed area represents external work performed by the ventricle. B: Increasing preload with constant contractility and afterload. C: Increasing afterload with constant preload and contractility. D: Increasing contractility with constant preload and afterload. ESP, end-systolic point; EDP, end-diastolic point.
FIGURE 20–9 The pressure–volume loop depicts graphically the hemodynamic changes in the left ventricle during a heartbeat and the ejection of one stroke volume (SV). Segment A–B occurs at the beginning of systole after the mitral valve closes. Point A: The left ventricular end-diastolic pressure is noted on the graph at the end of diastolic filling. Pressure in the ventricle gradually builds until point B is reached, when the aortic valve opens and blood is ejected from the ventricle. The aortic valve closes when ejection is complete at end systole. The line at point D identifies end systole. Moving the slope of this line to the reader’s right represents a shift to a less contractile state. Moving the slope to the left reflects a more highly contractile ventricle. Segment D–E represents isovolumetric relaxation. Once pressure in the ventricle is reduced the mitral valve again opens (point E) and diastolic filling resumes in preparation for the heart’s next systole. Point C reflects peak systolic pressure. ESPV, end-systolic pressure–volume; LVEDP, left ventricular end-diastolic pressure; LVEDV, left ventricular end-diastolic volume. (Reproduced with permission from Hoffman WJ, Wasnick JD. Postoperative Critical Care of the Massachusetts General Hospital. 2nd ed. Boston, MA: Little, Brown and Company; 1992.)

2. Assessment of Systolic Function
The change in ventricular pressure over time during systole (dP/dt) is defined by the first derivative of the ventricular pressure curve and can be used as a measure
of contractility. Contractility is directly proportional to $dP/dt$, but accurate measurement of this value requires a high-fidelity ("Millar") ventricular catheter. Ventricular systolic function is routinely estimated using echocardiography.

**Ejection Fraction**

The ventricular ejection fraction (EF), the fraction of the end-diastolic ventricular volume ejected, is the most commonly used clinical measurement of systolic function. EF can be calculated by the following equation:

$$EF = \frac{EDV - ESV}{EDV}$$

where EDV is left ventricular diastolic volume and ESV is end-systolic volume. Normal EF is approximately 0.67 ± 0.08. Measurements can be made preoperatively from cardiac catheterization, radionucleotide studies, or transthoracic (TTE) or transesophageal echocardiography (TEE). Pulmonary artery catheters with fast-response thermistors allow measurement of the right ventricular EF. Unfortunately, when pulmonary vascular resistance increases, decreases in right ventricular EF may reflect afterload rather than contractility. Left ventricular EF is not an accurate measure of ventricular contractility in the presence of mitral insufficiency.

Myocardial deformation analysis provides another measure to quantify ventricular function by assessing the movement of speckles from echocardiographic images. Deformation of the heart occurs along three dimensions: circumferential, radial, and longitudinal (Figure 20–10). Strain is a measure of the change of length between two points. Using strain analysis, echocardiography can determine the percent change in length at different points of the myocardium (Figure 20–11). Longitudinal strain is measured at various segments during systole and diastole; the global strain is −21%, reflecting the average deformation for all segments. Normal estimates for strain under anesthesia are not established; however, −19% to −22% longitudinal strain is a normal range established for healthy patients undergoing transthoracic echocardiography. Longitudinal strain is a negative change because during systole the ventricle shortens, resulting in L being less than $L_0$. The degree to which estimates of myocardial deformation will be incorporated into perioperative management remains to be determined.
Strain describes fractional change of a myocardial segment length compared with its initial length (at end-diastole). $\varepsilon$, myocardial strain; $L$, length at end-systole; $L_0$, initial length. FIGURE 20–11 Longitudinal strain analysis assessed with Cardiac Motion Quantification (CMQ) (Philips Medical Systems, Andover, MA). A: Midesophageal two-chamber echocardiographic view depicting the left ventricle, where the myocardial walls are divided into six segments distinguished by color-coded labels and dots. Segmental strain measurements are shown adjacent to each segment. The myocardium is colored in shades of red corresponding to percent longitudinal shortening (strain) measured by the red-to-blue scale on the upper right-hand side. B: Longitudinal strain curves, which are color-coded to correspond to myocardial segments in A, with time on the x-axis relative to the cardiac cycle and percent shortening (strain) on the y-axis, demonstrate shortening during systole and returning to baseline at end-diastole. The pink curve, for example, represents the apical anterior wall that experiences peak shortening of −26% during systole (yellow dot identifies peak systolic strain). In contrast, end-systolic strain, measured at time of aortic valve closure, measures −23%, demonstrating that peak strain may differ from end-systolic strain. The
dotted white curve represents global longitudinal strain. BA, basal anterior; MA, mid anterior; ApA, apical anterior, BI, basal inferior; MI, mid inferior; Apl, apical inferior myocardial walls; G.L. Strain, global longitudinal strain; AVC, aortic valve closure. (Reproduced with permission from Cleveland Clinic Center for Medical Art & Photography © 2013. All Rights Reserved.)

3. Assessment of Diastolic Function

Left ventricular diastolic function can be assessed clinically by Doppler echocardiography on a transthoracic or transesophageal examination. Flow velocities are measured across the mitral valve during diastole, or by interrogation of the motion of the mitral valve annulus (“tissue Doppler”). Three patterns of diastolic dysfunction are generally recognized based on isovolumetric relaxation time, the ratio of peak early diastolic flow (E) to peak atrial systolic flow (A), and the deceleration time (DT) of E (DT_E) (Figure 20–12). Tissue Doppler is frequently used to distinguish “pseudonormal” from normal diastolic function. Tissue Doppler discerns the velocity of movement of the myocardial tissue during the cardiac cycle. During systole the mitral annulus moves toward the apex of the heart, away from the echocardiography probe in the esophagus. A negative deflection s’ wave is generated, reflecting systolic movement away from the probe. During diastolic filling the mitral annulus moves toward the transesophageal echocardiography probe, producing a positive e’ wave. An e’ wave peak velocity of less than 8 cm/s is associated with impaired diastolic function. An E/e’ wave ratio that is greater than 15 is consistent with elevated left ventricular end-diastolic pressure (Figures 20–13 and 20-14).

Systemic Circulation

The systemic vasculature can be divided functionally into arteries, arterioles, capillaries, and veins. Arteries are the high-pressure conduits that supply the various organs. Arterioles are the small vessels that directly feed and control blood flow through each capillary bed. Capillaries are thin-walled vessels that allow the exchange of nutrients between blood and tissues. Veins return blood from capillary beds to the heart.

The distribution of blood between the various components of the circulatory system is shown in Table 20–6. Note that most of the blood volume is in the systemic circulation—specifically, within systemic veins. Changes in systemic venous tone allow these vessels to function as a reservoir for blood. Following significant blood or fluid losses, a sympathetically mediated increase in vascular
tone reduces the capacity of these vessels and shifts blood into other parts of the vascular system. Conversely, increased capacity (“venodilation”) allows these vessels to accommodate increases in blood volume. Sympathetic control of vascular tone is an important determinant of venous return to the heart. Reduced venous tone following induction of anesthesia frequently results in pooling of blood, reduced cardiac output, and hypotension.

Many factors influence blood flow in the vascular tree, including metabolic products, endothelium-derived factors, the autonomic nervous system, and circulating hormones.

**AUTOREGULATION**

Most tissue beds regulate their own blood flow (autoregulation). Arterioles generally dilate in response to reduced perfusion pressure or increased tissue demand. Conversely, arterioles constrict in response to increased pressure or reduced tissue demand. These phenomena are likely due to both an intrinsic response of vascular smooth muscle to stretch and the accumulation of vasodilatory metabolic byproducts. The latter may include $K^+$, $H^+$, $CO_2$, adenosine, and lactate.

**ENDOTHELIUM-DERIVED FACTORS**

The vascular endothelium is metabolically active in elaborating or modifying substances that directly or indirectly play a major role in controlling blood pressure and flow. These include vasodilators (eg, nitric oxide, prostacyclin [PGI$_2$]), vasoconstrictors (eg, endothelins, thromboxane A$_2$), anticoagulants (eg, thrombomodulin, protein C), fibrinolytics (eg, tissue plasminogen activator), and
factors that inhibit platelet aggregation (eg, nitric oxide and PGI₂). Nitric oxide is synthesized from arginine by nitric oxide synthetase. This substance has a number of functions. It binds guanylate cyclase, increasing cGMP levels and potently produces vasodilation. Endothelially derived vasoconstrictors (endothelins) are released in response to thrombin and epinephrine.

**AUTONOMIC CONTROL OF THE SYSTEMIC VASCULATURE**

Although the parasympathetic system can exert important influences on the circulation, autonomic control of the vasculature is primarily sympathetic. Sympathetic outflow to the circulation passes out of the spinal cord at all thoracic segments and the first two lumbar segments. These fibers reach blood vessels via specific autonomic nerves or by traveling along spinal nerves. Sympathetic fibers innervate all parts of the vasculature except for capillaries. Their principal function is to regulate vascular tone. Variations of arterial vascular tone serve to regulate blood pressure and the distribution of blood flow to the various organs, whereas variations in venous tone alter vascular capacity, venous pooling, and venous return to the heart.

The vasculature has sympathetic vasoconstrictor and vasodilator fibers, but the former are more important physiologically in most tissue beds. Sympathetic-induced vasoconstriction (via α₁-adrenergic receptors) can be potent in skeletal muscle, kidneys, gut, and skin; it is least active in the brain and heart. The most important vasodilatory fibers are those feeding skeletal muscle, mediating increased blood flow (via β₂-adrenergic receptors) in response to exercise. Vasodepressor (vasovagal) syncope, which can occur following intense emotional strain associated with high sympathetic tone, results from reflex activation of both vagal and sympathetic vasodilator fibers.

Vascular tone and autonomic influences on the heart are controlled by vasomotor centers in the reticular formation of the medulla and lower pons. Distinct vasoconstrictor and vasodilator areas have been identified. Vasoconstriction is mediated by the anterolateral areas of the lower pons and upper medulla. They are also responsible for adrenal secretion of catecholamines, as well as the enhancement of cardiac automaticity and contractility. Vasodilatory areas, which are located in the lower medulla, are also adrenergic. They function by projecting inhibitory fibers upward to the vasoconstrictor areas. Vasomotor output is modified by inputs from throughout the central nervous system, including the hypothalamus, cerebral cortex, and the
other areas in the brainstem. Areas in the posterolateral medulla receive input from both the vagal and the glossopharyngeal nerves and play an important role in mediating a variety of circulatory reflexes. The sympathetic system normally maintains some tonic vasoconstriction on the vascular tree. Loss of this tone following induction of anesthesia or sympathectomy frequently contributes to perioperative hypotension.

**ARTERIAL BLOOD PRESSURE**

Systemic blood flow is pulsatile in large arteries because of the heart’s cyclic activity; when the blood reaches the systemic capillaries, flow is continuous (laminar). The mean pressure falls to less than 20 mm Hg in the large systemic veins that return blood to the heart. The largest pressure drop, nearly 50%, is across the arterioles, and the arterioles account for the majority of SVR.

MAP is proportionate to the product of SVR × CO. This relationship is based on an analogy to Ohm’s law, as applied to the circulation:

\[
\text{MAP} - \text{CVP} \approx \text{SVR} \times \text{CO}
\]

Because CVP is normally very small compared with MAP, the former can usually be ignored. From this relationship, it is readily apparent that hypotension is the result of a decrease in SVR, CO, or both: To maintain arterial blood pressure, a decrease in either SVR or CO must be compensated by an increase in the other. MAP may be estimated by the following formula:

\[
\text{MAP} = \text{Diastolic pressure} + \frac{\text{Pulse pressure}}{3}
\]

where pulse pressure is the difference between systolic and diastolic blood pressure. Arterial pulse pressure is directly related to stroke volume, but is inversely related to the compliance of the arterial tree. Thus, decreases in pulse pressure may be due to a decrease in stroke volume, an increase in SVR, or both. Increased pulse pressure increases shear stress on vessel walls, potentially leading to atherosclerotic plaque rupture and thrombosis or rupture of aneurysms. Increased pulse pressure in patients undergoing cardiac surgery has been associated with adverse renal and neurological outcomes.

Transmission of the arterial pressure wave from large arteries to smaller vessels in the periphery is faster than the actual movement of blood; the pressure wave velocity is 15 times the velocity of blood in the aorta. Moreover,
reflections of the propagating waves off arterial walls widen pulse pressure before the pulse wave is completely dampened in very small arteries. Thus, the pulse pressure is generally greater when measured in the femoral or dorsalis pedis arteries than in the aorta.

**Control of Arterial Blood Pressure**

Arterial blood pressure is regulated by a series of immediate, intermediate, and long-term adjustments that involve complex neural, humoral, and renal mechanisms.

**A. Immediate Control**

Minute-to-minute control of blood pressure is primarily the function of autonomic nervous system reflexes. Changes in blood pressure are sensed both centrally (in hypothalamic and brainstem areas) and peripherally by specialized sensors (baroreceptors). Decreases in arterial blood pressure result in increased sympathetic tone, increased adrenal secretion of epinephrine, and reduced vagal activity. The resulting systemic vasoconstriction, increased heart rate, and enhanced cardiac contractility serve to increase blood pressure.

Peripheral baroreceptors are located at the bifurcation of the common carotid arteries and the aortic arch. Elevations in blood pressure increase baroreceptor discharge, inhibiting systemic vasoconstriction and enhancing vagal tone (baroreceptor reflex). Reductions in blood pressure decrease baroreceptor discharge, allowing vasoconstriction and reduction of vagal tone. Carotid baroreceptors send afferent signals to circulatory brainstem centers via Hering’s nerve (a branch of the glossopharyngeal nerve), whereas aortic baroreceptor afferent signals travel along the vagus nerve. Of the two peripheral sensors, the carotid baroreceptor is physiologically more important and serves to minimize changes in blood pressure caused by acute events, such as a change in posture. Carotid baroreceptors sense MAP most effectively between pressures of 80 and 160 mm Hg. Adaptation to acute changes in blood pressure occurs over the course of 1 to 2 days, rendering this reflex ineffective for longer term blood pressure control. All volatile anesthetics depress the normal baroreceptor response, but isoflurane and desflurane seem to have less effect. Cardiopulmonary stretch receptors located in the atria, left ventricle, and pulmonary circulation can cause a similar effect.

**B. Intermediate Control**
In the course of a few minutes, sustained decreases in arterial pressure, together with enhanced sympathetic outflow, activate the renin–angiotensin–aldosterone system, increase secretion of arginine vasopressin (AVP), and alter normal capillary fluid exchange. Both angiotensin II and AVP are potent arteriolar vasoconstrictors. Their immediate action is to increase SVR. In contrast to formation of angiotensin II, which responds to relatively smaller changes, sufficient AVP secretion to produce vasoconstriction will only occur in response to more marked degrees of hypotension. Angiotensin constricts arterioles via AT₁ receptors. AVP mediates vasoconstriction via V₁ receptors and exerts its antidiuretic effect via V₂ receptors.

Sustained changes in arterial blood pressure can also alter fluid exchange in tissues by their secondary effects on capillary pressures. Hypertension increases interstitial movement of intravascular fluid, whereas hypotension increases reabsorption of interstitial fluid. Such compensatory changes in intravascular volume can reduce fluctuations in blood pressure, particularly in the absence of adequate renal function (see below).

C. Long-Term Control
The effects of slower renal mechanisms become apparent within hours of sustained changes in arterial pressure. As a result, the kidneys alter total body sodium and water balance to restore blood pressure to normal. Hypotension results in sodium (and water) retention, whereas hypertension generally increases sodium excretion in normal individuals.

ANATOMY & PHYSIOLOGY OF THE CORONARY CIRCULATION

1. Anatomy
Myocardial blood supply is derived entirely from the right and left coronary arteries (Figure 20–15). Blood flows from epicardial to endocardial vessels. After perfusing the myocardium, blood returns to the right atrium via the coronary sinus and the anterior cardiac veins. A small amount of blood returns directly into the chambers of the heart by way of the thebesian veins.

The right coronary artery (RCA) normally supplies the right atrium, most of the right ventricle, and a variable portion of the left ventricle (inferior wall). In 85% of persons, the RCA gives rise to the posterior descending artery (PDA), which supplies the superior–posterior interventricular septum and inferior wall—
a right dominant circulation; in the remaining 15% of persons, the PDA is a branch of the left coronary artery—a left dominant circulation.

The left coronary artery normally supplies the left atrium and most of the interventricular septum and left ventricle (septal, anterior, and lateral walls). After a short course, the left main coronary artery bifurcates into the left anterior descending artery (LAD) and the circumflex artery (CX); the LAD supplies the septum and anterior wall and the CX supplies the lateral wall. In a left dominant circulation, the CX wraps around the AV groove and continues down as the PDA to also supply most of the posterior septum and inferior wall.

The arterial supply to the SA node may be derived from either the RCA (60% of individuals) or the LAD (the remaining 40%). The AV node is usually supplied by the RCA (85–90%) or, less frequently, by the CX (10–15%); the bundle of His has a dual blood supply derived from the PDA and LAD. The anterior papillary muscle of the mitral valve also has a dual blood supply that is fed by diagonal branches of the LAD and marginal branches of the CX. In contrast, the posterior papillary of the mitral valve is usually supplied only by the PDA and is therefore much more vulnerable to ischemic dysfunction.

### 2. Determinants of Coronary Perfusion

Coronary perfusion is unique in that it is intermittent rather than continuous, as it is in other organs. During contraction, intramyocardial pressures in the left ventricle approach systemic arterial pressure. The force of left ventricular contraction almost completely occludes the intramyocardial part of the coronary arteries. **Coronary perfusion pressure is usually determined by the difference between aortic pressure and ventricular pressure.** The left ventricle is perfused almost entirely during diastole. In contrast, the right ventricle is perfused during both systole and diastole (Figure 20–16). Moreover, as a determinant of left heart myocardial blood flow, arterial diastolic pressure is more important than MAP. Therefore, left coronary artery perfusion pressure is determined by the difference between arterial diastolic pressure and left ventricular end-diastolic pressure (LVEDP).
Decreases in aortic pressure or increases in ventricular end-diastolic pressure can reduce coronary perfusion pressure. Increases in heart rate also decrease coronary perfusion because of the disproportionately greater reduction in
diastolic time as heart rate increases (Figure 20–17). Because the endocardium is subjected to the greatest intramural pressures during systole, it tends to be most vulnerable to ischemia during decreases in coronary perfusion pressure.

**FIGURE 20–17** The relationship between diastolic time and heart rate.

**Control of Coronary Blood Flow**

Coronary blood flow normally parallels myocardial metabolic demand. In the average adult man, coronary blood flow is approximately 250 mL/min at rest. The myocardium regulates its own blood flow closely between perfusion pressures of 50 and 120 mm Hg. Beyond this range, blood flow becomes increasingly pressure dependent.

Under normal conditions, changes in blood flow are entirely due to variations in coronary arterial tone (resistance) in response to metabolic demand. Hypoxia—either directly, or indirectly through the release of adenosine—causes coronary vasodilation. Autonomic influences are generally weak. Both α₁- and β₂-adrenergic receptors are present in the coronary arteries. The α₁-receptors are primarily located on larger epicardial vessels, whereas the β₂-receptors are mainly found on the smaller intramuscular and subendocardial vessels.
Sympathetic stimulation generally increases myocardial blood flow because of an increase in metabolic demand and a predominance of β₂-receptor activation. Parasympathetic effects on the coronary vasculature are generally minor and weakly vasodilatory.

3. Myocardial Oxygen Balance

Myocardial oxygen demand is usually the most important determinant of myocardial blood flow. Relative contributions to oxygen requirements include basal requirements (20%), electrical activity (1%), volume work (15%), and pressure work (64%). The myocardium usually extracts 65% of the oxygen in arterial blood, compared with 25% in most other tissues. Coronary sinus oxygen saturation is usually 30%. Therefore, the myocardium (unlike other tissues) cannot compensate for reductions in blood flow by extracting more oxygen from hemoglobin. Any increases in myocardial metabolic demand must be met by an increase in coronary blood flow. Table 20–7 lists the most important factors in myocardial oxygen demand and supply. Note that the heart rate and, to a lesser extent, ventricular end-diastolic pressure are important determinants of both supply and demand.

EFFECTS OF ANESTHETIC AGENTS

Most volatile anesthetic agents are coronary vasodilators. Their effect on coronary blood flow is variable because of their direct vasodilating properties, reduction of myocardial metabolic requirements, and effects on arterial blood pressure.

Volatile agents exert beneficial effects in experimental myocardial ischemia and infarction. They reduce myocardial oxygen requirements and protect against reperfusion injury; these effects are mediated by activation of ATP-sensitive K⁺ (K<sub>ATP</sub>) channels. Some evidence also suggests that volatile anesthetics enhance recovery of the “stunned” myocardium (hypocontractile, but recoverable, myocardium after ischemia). Moreover, although volatile anesthetics decrease myocardial contractility, they can be potentially beneficial in patients with heart failure because most of them decrease preload and afterload.

The Pathophysiology of Heart Failure

Systolic heart failure occurs when the heart is unable to pump a sufficient amount of blood to meet the body’s metabolic requirements. Clinical manifestations usually reflect the effects of the low cardiac output on tissues (eg, fatigue, dyspnea, oxygen debt, acidosis), the damming-up of blood behind the failing ventricle (dependent edema or pulmonary venous congestion), or both. The left ventricle is most commonly the primary cause, often with secondary involvement of the right ventricle. Isolated right ventricular failure can occur in the setting of advanced disease of the lung parenchyma or pulmonary vasculature. Left ventricular failure is most commonly the result of myocardial dysfunction, usually from coronary artery disease, but may also be the result of viral disease, toxins, untreated hypertension, valvular dysfunction, arrhythmias, or pericardial disease.

Diastolic dysfunction can be present in the absence of signs or symptoms of heart failure, as for example in patients with hypertension or aortic valve stenosis. Symptoms arising from diastolic dysfunction are the result of atrial hypertension and pulmonary congestion (Figure 20–18). Failure of the heart to relax during diastole leads to elevated left ventricular end-diastolic pressure, which is transmitted to the left atrium and pulmonary vasculature. Common causes of diastolic dysfunction include hypertension, coronary artery disease, hypertrophic cardiomyopathy, valvular heart disease, and pericardial disease.
Diastolic dysfunction is not the same as diastolic heart failure. In the patient with systolic heart failure the heart compensates by dilating, which leads to an increase in end-diastolic ventricular volume in an attempt to preserve the stroke volume. In patients with diastolic failure, poor ventricular relaxation leads to a higher LVEDP than would be noted in a patient without diastolic dysfunction for the same end-diastolic volume.

**FIGURE 20–18** Ventricular pressure–volume relationships in isolated systolic and diastolic dysfunction.

Diastolic dysfunction is diagnosed echocardiographically. Placing the pulse wave Doppler sample gate at the tips of the mitral valve during left ventricular filling will produce the characteristic diastolic flow pattern (Figure 20–13). In patients with normal diastolic function, the ratio between the peak velocities of the early (E) and the atrial (A) waves is from 0.8 to 2. In the early stages of diastolic dysfunction, the primary abnormality is impaired relaxation. When left ventricular relaxation is delayed, the initial pressure gradient between the left atrium and the left ventricle is reduced, resulting in a decline in early filling, and, consequently, a reduced peak E wave velocity. The A wave velocity is increased relative to the E wave, and the E/A ratio is reduced. As diastolic dysfunction advances, the left atrial pressure increases, restoring the gradient between the left atrium and left ventricle with an apparent restoration of the normal E/A ratio. This pattern is characterized as “pseudonormalized.” Using the E/A ratio alone cannot distinguish between a normal and pseudonormalized pattern of diastolic inflow. As diastolic dysfunction worsens further, a restrictive pattern is obtained. In this scenario, the left ventricle is so stiff that pressure builds in the left atrium, resulting in a dramatic peak of early filling and a prominent, tall, narrow E wave. Because the ventricle is so poorly compliant, the atrial contraction contributes little to filling, resulting in a diminished A wave and an E/A ratio greater than
Doppler patterns of pulmonary venous flow have been used to distinguish between a pseudonormalized and normal E/A ratio. Currently, most echocardiographers use tissue Doppler to examine the movement of the lateral annulus of the mitral valve during ventricular filling (Figure 20–13). Tissue Doppler allows the echocardiographer to determine both the velocity and the direction of the movement of the heart. During systole, the heart contracts toward the apex, away from a TEE transducer in the esophagus. This motion produces the s' wave of systole. During early and late diastolic filling, the heart moves toward the transducer producing the e' and a' waves. Like the inflow patterns achieved with pulse wave Doppler, characteristic patterns of diastolic dysfunction are reflected in the tissue Doppler trace. An e' wave less than 8 cm/s is consistent with diastolic dysfunction. Of note, the tissue Doppler trace does not produce a pseudonormalized pattern, permitting the echocardiographer to readily distinguish between normal and abnormal diastolic function.

Cardiac output may be reduced at rest with heart failure, but the key point is that the heart is incapable of appropriately increasing cardiac output and oxygen delivery in response to demand. Inadequate oxygen delivery to tissues is reflected by a low mixed venous oxygen tension and an increase in the arteriovenous oxygen content difference. In compensated heart failure, the arteriovenous difference may be normal at rest, but it rapidly widens during stress or exercise.

**COMPENSATORY MECHANISMS**

Compensatory mechanisms generally present in patients with heart failure include activation of the sympathetic nervous system and the renin–angiotensin–aldosterone system and increased release of AVP. One result is increased preload (fluid retention). Although these mechanisms can initially compensate for mild to moderate cardiac dysfunction, with increasing severity of dysfunction, they may actually worsen the cardiac impairment. Many of the drug treatments of chronic heart failure serve to counteract these mechanisms.

**Increased Preload**

An increase in ventricular size not only reflects an inability to keep up with an increased circulating blood volume, but also serves to increase stroke volume by moving the heart up the Starling curve (see Figure 20–5). Even when EF is reduced, an increase in ventricular end-diastolic volume can maintain a normal
stroke volume. Worsening venous congestion caused by the pooling of blood behind the failing ventricle and excessive ventricular dilation can rapidly lead to clinical deterioration. Left ventricular failure results in pulmonary vascular congestion and progressive transudation of fluid, first into the pulmonary interstitium and then into alveoli (pulmonary edema). Right ventricular failure leads to systemic venous hypertension, which results in peripheral edema, hepatic congestion and dysfunction, and ascites. Dilation of the annulus of either the mitral or tricuspid valves from ventricular dilation leads to valvular regurgitation, further impairing ventricular output.

**Increased Sympathetic Tone**

Sympathetic activation increases release of norepinephrine from nerve endings in the heart and secretion of epinephrine from the adrenal glands into the circulation. Although enhanced sympathetic outflow can initially maintain cardiac output by increasing heart rate and contractility, worsening ventricular function elicits increasing degrees of vasoconstriction in an effort to maintain arterial blood pressure. The associated increase in afterload, however, reduces cardiac output and exacerbates the ventricular failure.

Chronic sympathetic activation in patients with heart failure eventually decreases the response of adrenergic receptors to catecholamines (receptor uncoupling), the number of receptors (downregulation), and cardiac catecholamine stores. Nonetheless, the failing heart becomes increasingly dependent on circulating catecholamines. Abrupt withdrawal in sympathetic outflow or decreases in circulating catecholamine levels, such as can occur following induction of anesthesia, may lead to acute cardiac decompensation. A reduced density of M2 receptors also decreases parasympathetic influences on the heart.

Sympathetic activation tends to redistribute systemic blood flow output away from the skin, gut, kidneys, and skeletal muscle to the heart and brain. Decreased renal perfusion, together with β1-adrenergic activity at the juxtaglomerular apparatus, activates the renin–angiotensin–aldosterone axis, which leads to sodium retention and interstitial edema. Moreover, vasoconstriction secondary to elevated angiotensin II levels increases left ventricular afterload and causes further deterioration of systolic function. The latter partially accounts for the efficacy of angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers in heart failure. Symptoms may also improve in some patients with careful, low-dose β-adrenergic blockade. Outcomes in heart failure are
improved by administration of ACE inhibitors (and/or angiotensin receptor blockers), certain long-acting β-blockers (carvedilol or extended-release metoprolol), and aldosterone inhibitors (spironolactone or eplerenone).

Circulating AVP levels, often markedly increased in patients with severe heart failure, will increase ventricular afterload and are responsible for a defect in free water clearance that is commonly associated with hyponatremia.

Brain natriuretic peptide (BNP) is produced in the heart in response to myocyte distention. Elevated BNP concentration (>500 pg/mL) usually indicates heart failure, and measurement of BNP concentration can be used to distinguish between heart failure and lung disease as a cause of dyspnea. Recombinant BNP was developed as a vasodilator and inhibitor of the renin–angiotensin–aldosterone system for use in patients with severe decompensated heart failure, but outcomes were not improved with its use.

**Ventricular Hypertrophy**

Ventricular hypertrophy can occur with or without dilation, depending on the type of stress imposed on the ventricle. When the heart is subjected to either pressure or volume overload, the initial response is to increase sarcomere length and optimally overlap actin and myosin. With time, ventricular muscle mass begins to increase in response to the abnormal stress.

In the volume-overloaded ventricle, the problem is an increase in diastolic wall stress. The increase in ventricular muscle mass is sufficient only to compensate for the increase in diameter: The ratio of the ventricular radius to wall thickness is unchanged. Sarcomeres replicate mainly in series, resulting in eccentric hypertrophy. Although ventricular EF remains depressed, the increase in end-diastolic volume can maintain normal at-rest stroke volume (and cardiac output).

The problem in a pressure-overloaded ventricle is an increase in systolic wall stress. In this case, sarcomeres mainly replicate in parallel, resulting in concentric hypertrophy: The hypertrophy is such that the ratio of myocardial wall thickness to ventricular radius increases. As can be seen from Laplace’s law, systolic wall stress can then be normalized. Ventricular hypertrophy, particularly that caused by pressure overload, usually results in progressive diastolic dysfunction. The most common reasons for isolated left ventricular hypertrophy are hypertension and aortic stenosis.
A Patient With a Short P–R Interval

A 38-year-old man is scheduled for endoscopic sinus surgery following a recent onset of headaches. He gives a history of having passed out at least once during one of these headaches. A preoperative electrocardiogram (ECG) is normal, except for a P–R interval of 0.116 s with normal P-wave morphology.

What is the significance of the short P–R interval?

The P–R interval, which is measured from the beginning of atrial depolarization (P wave) to the beginning of ventricular depolarization (QRS complex), usually represents the time required for depolarization of both atria, the AV node, and the His–Purkinje system. Although the P–R interval can vary with heart rate, it is normally 0.12 to 0.2 s in duration.

What is preexcitation?

Preexcitation usually refers to early depolarization of the ventricles by an abnormal conduction pathway from the atria. Rarely, more than one such pathway is present. The most common form of preexcitation is due to the presence of an accessory pathway (bundle of Kent) that connects one of the atria with one of the ventricles. This abnormal connection between the atria and ventricles allows electrical impulses to bypass the AV node (hence the term bypass tract). The ability to conduct impulses along the bypass tract can be quite variable and may be only intermittent or rate dependent. Bypass tracts can conduct in both directions, retrograde only (ventricle to atrium), or, rarely, anterograde only (atrium to ventricle). The name Wolff–Parkinson–White (WPW) syndrome is often applied to ventricular preexcitation associated with tachyarrhythmias.

How does preexcitation shorten the P–R interval?

In patients with preexcitation, the normal cardiac impulse originating from the SA node is conducted simultaneously through the normal (AV nodal) and anomalous (bypass tract) pathways. Because conduction is more rapid in the anomalous pathway than in the AV nodal pathway, the cardiac impulse rapidly reaches and depolarizes the area of the ventricles where the
bypass tract ends. This early depolarization of the ventricle is reflected by a short P–R interval and a slurred initial deflection (δ wave) in the QRS complex. The spread of the anomalous impulse to the rest of the ventricle is delayed because it must be conducted by ordinary ventricular muscle, not by the much faster Purkinje system. The remainder of the ventricle is then depolarized by the normal impulse from the AV node as it catches up with the preexcitation front. Although the P–R interval is shortened, the resulting QRS is slightly prolonged and represents a fusion complex of normal and abnormal ventricular depolarizations.

The P–R interval in patients with preexcitation depends on relative conduction times between the AV nodal pathway and the bypass pathway. If conduction through the former is fast, preexcitation (and the δ wave) is less prominent, and QRS will be relatively normal. If conduction is delayed in the AV nodal pathway, preexcitation is more prominent, and more of the ventricle will be depolarized by the abnormally conducted impulse. When the AV nodal pathway is completely blocked, the entire ventricle is depolarized by the bypass pathway, resulting in a very short P–R interval, a very prominent δ wave, and a wide, bizarre QRS complex. Other factors that can affect the degree of preexcitation include interatrial conduction time, the distance of the atrial end of the bypass tract from the SA node, and autonomic tone. The P–R interval is often normal or only slightly shortened with a left lateral bypass tract (the most common location). Preexcitation may be more apparent at fast heart rates because conduction slows through the AV node with increasing heart rates. Secondary ST-segment and T-wave changes are also common because of abnormal ventricular repolarization.

**What is the clinical significance of preexcitation?**

Preexcitation occurs in approximately 0.3% of the general population. Up to 50% of affected persons develop paroxysmal tachyarrhythmias, typically paroxysmal supraventricular tachycardia (PSVT). Although most patients are otherwise normal, preexcitation can be associated with other cardiac anomalies, including Ebstein anomaly, mitral valve prolapse, and cardiomyopathies. Depending on its conductive properties, the bypass tract in some patients may predispose them to tachyarrhythmias and even sudden death. Tachyarrhythmias include PSVT, atrial fibrillation, and, less commonly, atrial flutter. Ventricular fibrillation can be precipitated by a critically timed premature atrial beat that travels down the bypass tract and catches the ventricle at a vulnerable period. Alternatively, very rapid
conduction of impulses into the ventricles by the bypass tract during atrial fibrillation can rapidly lead to myocardial ischemia, hypoperfusion, and hypoxia and culminate in ventricular fibrillation.

Recognition of the preexcitation phenomenon is also important because its QRS morphology on the surface ECG can mimic bundle branch block, right ventricular hypertrophy, ischemia, myocardial infarction, and ventricular tachycardia (during atrial fibrillation).

**What is the significance of the history of syncope in this patient?**

This patient should be evaluated preoperatively with electrophysiological studies, and may possibly require curative radiofrequency ablation of the bypass tract with antiarrhythmic drug therapy. Such studies can identify the location of the bypass tracts, reasonably predict the potential for malignant arrhythmias by programmed pacing, and assess the efficacy of antiarrhythmic therapy if curative ablation is not possible. Ablation is reported to be curative in over 90% of patients. A history of syncope may be ominous because it may indicate the ability to conduct impulses very rapidly through the bypass tract, leading to systemic hypoperfusion and perhaps predisposing the patient to sudden death.

**How do tachyarrhythmias generally develop?**

Tachyarrhythmias develop as a result of either abnormal impulse formation or abnormal impulse propagation (reentry). Abnormal impulses result from enhanced automaticity, abnormal automaticity, or triggered activity. Usually, only cells of the SA node, specialized atrial conduction pathways, AV nodal junctional areas, and the His–Purkinje system depolarize spontaneously. Because diastolic repolarization (phase 4) is fastest in the SA node, other areas of automaticity are suppressed. Enhanced or abnormal automaticity in other areas, however, can usurp pacemaker function from the SA node and lead to tachyarrhythmias. Triggered activity is the result of either early after-depolarizations (phase 2 or 3) or delayed after-depolarizations (after phase 3). It consists of small-amplitude depolarizations that can follow action potentials under some conditions in atrial, ventricular, and His–Purkinje tissue. If these after-depolarizations reach threshold potential, they can result in an extrasystole or repetitive sustained tachyarrhythmias. Factors that can promote the formation of abnormal impulses include increased catecholamine levels, electrolyte
disorders (hyperkalemia, hypokalemia, and hypercalcemia), ischemia, hypoxia, mechanical stretch, and drug toxicity (particularly digoxin).

The most common mechanism for tachyarrhythmias is reentry. Four conditions are necessary to initiate and sustain reentry (Figure 20–19): (1) two areas in the myocardium that differ in conductivity or refractoriness and that can form a closed electrical loop; (2) unidirectional block in one pathway (Figure 20–19A and B); (3) slow conduction or sufficient length in the circuit to allow recovery of the conduction block in the first pathway (Figure 20–19C); and (4) excitation of the initially blocked pathway to complete the loop (Figure 20–19D). Reentry is usually precipitated by a premature cardiac impulse.

**FIGURE 20–19 A–D:** The mechanism of reentry. See text for description.

*What is the mechanism of PSVT in patients with WPW syndrome?*

If the bypass tract is refractory during anterograde conduction of a
cardiac impulse, as during a critically timed atrial premature contraction (APC), and the impulse is conducted by the AV node, the same impulse can be conducted retrograde from the ventricle back into the atria via the bypass tract. The retrograde impulse can then depolarize the atrium and travel down the AV nodal pathway again, establishing a continuous repetitive circuit (circus movement). The impulse reciprocates between the atria and ventricles and conduction alternates between the AV nodal pathway and the bypass tract. The term concealed conduction is often applied because the absence of preexcitation during this arrhythmia results in a normal QRS that lacks a δ wave.

The circus movement less commonly involves anterograde conduction through the bypass tract and retrograde conduction through the AV nodal pathway. In such instances, the QRS has a δ wave and is completely abnormal; the arrhythmia can be mistaken for ventricular tachycardia.

**What other mechanisms may be responsible for PSVT?**

In addition to the WPW syndrome, PSVT can be caused by AV reentrant tachycardia, AV nodal reentrant tachycardia, and SA node and atrial reentrant tachycardias. Patients with AV reentrant tachycardia have an extranodal bypass tract similar to patients with WPW syndrome, but the bypass tract conducts only retrograde; preexcitation and a δ wave are absent.

Functional differences in conduction and refractoriness may occur within the AV node, SA node, or atria; a large bypass tract is not necessary. Thus, the circus movement may occur on a smaller scale within the AV node, SA node, or atria, respectively.

**How does atrial fibrillation in patients with WPW syndrome differ from the arrhythmia in other patients?**

Atrial fibrillation can occur when a cardiac impulse is conducted rapidly retrograde up into the atria and arrives to find different parts of the atria out of phase in recovery from the impulse. Once atrial fibrillation is established, conduction into the ventricles most commonly occurs through the bypass tract only; because of the accessory pathway’s ability to conduct very rapidly (unlike the AV nodal pathway), the ventricular rate is typically very rapid (180–300 beats/min). The majority of QRS complexes are abnormal, but periodic conduction of an impulse through the AV nodal pathway results in occasional normal-looking QRS complexes. Less commonly, impulses during atrial fibrillation are conducted mainly through
the AV nodal pathway (resulting in mostly normal QRS complexes) or through both the bypass tract and the AV nodal pathway (resulting in a mixture of normal, fusion, and abnormal QRS complexes). As stated previously, atrial fibrillation in patients with WPW syndrome is a very dangerous arrhythmia.

**What anesthetic agents can safely be used in patients with preexcitation?**

Few data are available comparing the use of different anesthetic agents or techniques in patients with preexcitation. Almost all the volatile and intravenous agents have been used. Volatile anesthetics increase antegrade refractoriness in both normal and accessory pathways. Propofol, opioids, and benzodiazepines seem to have little direct electrophysiological effects, but can alter autonomic tone, generally reducing sympathetic outflow. Factors that tend to cause sympathetic stimulation and increased cardiac automaticity are undesirable. Light anesthesia, hypercapnia, acidosis, and even transient hypoxia will activate the sympathetic system and are to be avoided. When patients with preexcitation are anesthetized for electrophysiological study and surgical ablation, opioids, propofol, and benzodiazepines may be the agents least likely to alter conduction characteristics.

**How are antiarrhythmic agents selected for tachyarrhythmias?**

Most antiarrhythmic agents act by altering myocardial cell conduction (phase 0), repolarization (phase 3), or automaticity (phase 4). Prolongation of repolarization increases the refractoriness of cells. Many antiarrhythmic drugs also exert direct or indirect autonomic effects. Although antiarrhythmic agents are generally classified according to broad mechanisms of action or electrophysiological effects (Table 20–8), the most commonly used classification system is not perfect because some agents have more than one mechanism of action.

**TABLE 20–8 Summary of antiarrhythmic drugs.**

</tbody>
</table>

Quinidine: Similar to procainamide but more toxic (onset, termination, duration). Rarely used in arrhythmias.
Doxapram: Similar to procainamide but significant antimuscarinic effects; may precipitate heart failure; not commonly used.

Mexiteline: Orally active congeners of lidocaine; used in ventricular arrhythmias, chronic pain syndromes.

Propafenone: Orally active, weak $\beta$-blocking activity, supraventricular arrhythmias; hepatic metabolism.
Marlietine: Phenothiazine derivative, orally active; ventricular arrhythmias, proarrhythmic. Withdrawn in USA.

Esmolol: Short-acting, IV only used for intraoperative and other acute arrhythmias.
Selection of an antiarrhythmic agent generally depends on whether the arrhythmia is ventricular or supraventricular and whether acute control or chronic therapy is required. Intravenous agents are usually employed in the acute management of arrhythmias, whereas oral agents are reserved for chronic therapy (Table 20–9).

**TABLE 20–9 Clinical pharmacological properties of antiarrhythmic drugs.**

| CLASS 3 | Amiodarone | Blocks I_{Na}, I_{Ca}, I_{K1} channels, β-adrenoceptors | Prolongs action potential duration and QT interval | Slows AV node conduction | Low incidence of torsades de points | Oral, IV | Variable absorption and tissue accumulation | Hepatic metabolism, elimination complex and slow first-pass hepatic and heart block, in diseased heart, peripheral vasodilation, pulmonary and hepatic toxicity | Hypotension, hypokalemia, tachycardia, bradycardia, heart block, in patients with renal failure, allergic reactions, QT prolongation |Potassium channel blocker, may act as an AHR blocker or β-blocker |

| Defibrill | I_{Ca} block | Prolongs action potential, effective refractory period | Maintenance or restoration of sinus rhythm in atrial fibrillation | Oral, IV | Fetal-excitatory | Torsades de points | Fetal in mortality | Reduces in hypokalemia | QT-prolonging drugs |

**CLASS 4**

| Verapamil | Calcium channel (L-type) blocker | Slows SA node automaticity and AV node conduction velocity | Decreases cardiac contractility and blood pressure | Oral, IV | Hepatic metabolism and AV node conduction | QT-prolonging drugs | Calcium in patients with hepatic dysfunction |

**MISCELLANEOUS**

| Adenosine | Activates inward rectifier K+ blocks I_{Ca} | Very brief, usually complete AV blockade | Paroxysmal supraventricular tachycardia | Oral, IV | Duration 10–15 s | Fainting, flushing, chest tightness, dizziness | Toxicity: | QT-prolonging drugs |

| Magnesium | Poorly understood, interacts with Na+/K+/ATPase, I_{K1} and Ca2+ channels | Normalizes or increases plasma Mg2+ | Torsades de points | Oral, IV | Duration dependent on dose | Fainting, Muscle weakness, pain, tremors | Toxicity: |

| Potassium | Increases K+ permeability, K+ currents | Slows ectopic pacemakers, slows conduction velocity in heart | Digitalis-induced arrhythmias, hypokalemia | Oral, IV | Toxicity: Rebound arrhythmias, fibrillation or arrest in overdose | Hypokalemia |

**Which agents are most useful for tachyarrhythmias in patients with WPW syndrome?**

Cardioversion is the treatment of choice in hemodynamically compromised patients. Small doses of phenylephrine (100 mcg), together with vagal maneuvers (carotid massage if not contraindicated by carotid occlusive disease), help support arterial blood pressure and may terminate the arrhythmia. The most useful pharmacological agents are class Ia drugs (eg, procainamide). Procainamide increases the refractory period and decreases conduction in the accessory pathway. Moreover, class Ia drugs frequently terminate and can suppress the recurrence of PSVT and atrial fibrillation. Amiodarone is not recommended. Adenosine, verapamil, and digoxin are contraindicated during atrial fibrillation or flutter in these patients because they can dangerously accelerate the ventricular response. Both types of agents decrease conduction through the AV node, favoring conduction of impulses down the accessory pathway. The bypass tract is capable of conducting impulses into the ventricles much faster than the AV node.

2 May suppress diastolic sino-aortic.
3 Anti-cholinergic effect and direct depressant action.
4 Especially in Wolff-Parkinson-White syndrome.
5 May be effective in atrial arrhythmias caused by digitalis.
nodal pathway. Digoxin may also increase the ventricular response by shortening the refractory period and increasing conduction in accessory pathways. Although verapamil can terminate PSVT, its use in this setting may be hazardous because patients can subsequently develop atrial fibrillation or flutter. Moreover, atrial fibrillation may not be readily distinguishable from ventricular tachycardia in these patients if wide-QRS tachycardia develops.

**SUGGESTED READINGS**

Anesthesia for Patients with Cardiovascular Disease

KEY CONCEPTS

1. Cardiovascular complications are estimated to account for 25% to 50% of deaths following noncardiac surgery. Perioperative myocardial infarction (MI), pulmonary edema, systolic and diastolic heart failure, arrhythmias, stroke, and thromboembolism are the most common diagnoses in patients with preexisting cardiovascular disease.

2. Regardless of the level of preoperative blood pressure control, many patients with hypertension display an accentuated hypotensive response to induction of anesthesia, followed by an exaggerated hypertensive response to intubation.

3. Patients with extensive coronary artery disease, a history of MI, or ventricular dysfunction are at risk of adverse cardiovascular complications.

4. The sudden withdrawal of antianginal medication perioperatively—particularly β-blockers—can precipitate a sudden, rebound increase in ischemic episodes.

5. The overwhelming priority in managing patients with ischemic heart disease is maintaining a favorable myocardial supply–demand relationship. Autonomic-mediated increases in heart rate and blood pressure should be controlled with deeper planes of general anesthesia or adrenergic blockage, vasodilators, or a combination of these.

6. Intraarterial pressure monitoring is reasonable in most patients with severe coronary artery disease and major or multiple cardiac risk factors who are undergoing any but the most minor procedures. Central venous (or rarely pulmonary artery) pressure can be monitored during prolonged or complicated procedures involving large fluid shifts or
blood loss.

The principal hemodynamic goals in managing mitral stenosis are to maintain a sinus rhythm (if present preoperatively) and to avoid tachycardia, large increases in cardiac output, and both hypovolemia and fluid overload by judicious administration of intravenous fluids.

Anesthetic management of mitral regurgitation should be tailored to the severity of regurgitation as well as the underlying left ventricular function. Factors that exacerbate the regurgitation, such as slow heart rates and acute increases in afterload, should be avoided.

Maintenance of normal sinus rhythm, heart rate, vascular resistance, and intravascular volume is critical in patients with aortic stenosis. Loss of a normally timed atrial systole often leads to rapid deterioration, particularly when associated with tachycardia.

Bradycardia and increases in systemic vascular resistance (SVR) increase the regurgitant volume in patients with aortic regurgitation, whereas tachycardia can contribute to myocardial ischemia. Excessive myocardial depression should also be avoided. The compensatory increase in cardiac preload should be maintained, but excessive fluid replacement can readily result in pulmonary edema.

In patients with congenital heart disease, an increase in SVR relative to pulmonary vascular resistance (PVR) favors left-to-right shunting, whereas an increase in PVR relative to SVR favors right-to-left shunting.

The presence of shunt flow between the right and left hearts, regardless of the direction of blood flow, mandates the meticulous exclusion of air bubbles or particulate material from intravenous fluids to prevent paradoxical embolism into the cerebral or coronary circulations.

The goals of anesthetic management in patients with tetralogy of Fallot should be to maintain intravascular volume and SVR. Increases in PVR, such as might occur from acidosis or excessive airway pressures, should be avoided. The right-to-left shunting tends to slow the uptake of inhalation anesthetics; in contrast, it may accelerate the onset of intravenous agents.

The transplanted heart is totally denervated, so direct autonomic influences are absent. Moreover, the absence of reflex increases in heart rate can make patients particularly sensitive to rapid vasodilation. Indirect vasopressors, such as ephedrine, are less effective than direct-acting agents because of the absence of catecholamine stores in
myocardial neurons.

Cardiovascular diseases—particularly hypertensive, ischemic, congenital, and valvular heart disease—are among the medical illnesses most frequently encountered in anesthetic practice and are a major cause of perioperative morbidity and mortality. The neuroendocrine response to surgical stimulation and the circulatory effects of anesthetic agents, endotracheal intubation, positive-pressure ventilation, blood loss, fluid shifts, and alterations in body temperature impose additional burdens on an often already compromised cardiovascular system. Most anesthetic agents cause cardiac depression, vasodilation, or both. Even anesthetics that have no direct circulatory effects may cause apparent circulatory depression in severely compromised patients who are dependent on the enhanced sympathetic activity characteristic of heart failure or acute blood loss. Decreased sympathetic activity as a consequence of the anesthetized state can lead to acute circulatory collapse.

Anesthetic management of patients with cardiovascular disease requires a thorough knowledge of normal cardiac physiology, the circulatory effects of the various anesthetic agents, and the pathophysiology and treatment of these diseases. The same principles used in treating cardiovascular diseases in patients not undergoing surgery should be used perioperatively. In most instances, the choice of anesthetic agent is not terribly important; on the other hand, knowing how the agent is used, understanding the underlying pathophysiology, and understanding how the two interact are critical.

Patients with severe cardiovascular illnesses commonly undergo both cardiac and noncardiac surgery. The American College of Cardiology (ACC) has collaborated with the American Heart Association (AHA) in issuing numerous guidelines related to the management of patients with heart disease, and many of their recommendations are relevant to patients undergoing sedation or anesthesia. Because guidelines change as new evidence becomes available, readers are advised to review the AHA website for current evidence-based indications for the management of heart disease.

**Perioperative Cardiovascular Evaluation and Preparation for Noncardiac Surgery**

The prevalence of cardiovascular disease increases with advancing age. Moreover, the number of patients older than 65 years of age is expected to
increase by 25% to 35% over the next two decades. Cardiovascular complications are estimated to account for 25% to 50% of deaths following noncardiac surgery. Perioperative myocardial infarction (MI), pulmonary edema, systolic and diastolic heart failure, arrhythmias, stroke, and thromboembolism are the most common diagnoses in patients with preexisting cardiovascular disease. The relatively high prevalence of cardiovascular disorders in surgical patients has given rise to attempts to define cardiac risk or the likelihood of intraoperative or postoperative fatal or life-threatening cardiac complications.

The ACC/AHA Task Force Report provides guidelines for perioperative cardiovascular evaluation. The guidelines state that the patient’s medical history is critical in determining the requirements for preoperative cardiac evaluation and that certain conditions (eg, unstable coronary syndromes and decompensated heart failure) warrant cardiology intervention prior to all but emergency procedures. The preoperative history should also address any past procedures, such as cardioverter defibrillator implants, coronary stents, and other interventions. Additionally, the patient’s ability to perform the tasks of daily living should be assessed as a guide to determine functional capacity. A patient with a history of cardiac disease and advanced age, but good exercise tolerance, will likely have a lower perioperative risk than a similar individual with dyspnea after minimal physical activity (Table 21–1).

²kph, kilometers per hour; MET, metabolic equivalent; mph, miles per hour.

The patient should be queried about other disease processes that frequently accompany heart disease. Cardiac patients often present with obstructive pulmonary disease, reduced kidney function, and diabetes mellitus.

A physical examination should be performed on all patients, and the heart and lungs should be auscultated. The physical examination is especially useful in
patients with certain conditions. For example, if a harsh systolic murmur suggestive of aortic stenosis is detected in a candidate for elective surgery, additional ultrasound evaluation will likely be warranted, as aortic stenosis substantially increases the risks in patients undergoing noncardiac surgery.

The following conditions are associated with increased risk:

- Ischemic heart disease (history of MI, evidence on electrocardiogram [ECG], chest pain)
- Congestive heart failure (dyspnea, pulmonary edema)
- Cerebral vascular disease (stroke)
- High-risk surgery (vascular, thoracic)
- Diabetes mellitus
- Preoperative creatinine greater than 2 mg/dL

The ACC/AHA guidelines identify conditions that are a major cardiac risk and warrant intensive management prior to all but emergent surgery. These conditions include unstable coronary syndromes (recent MI, unstable angina), decompensated heart failure, significant arrhythmias, and severe valvular heart disease. The ACC/AHA guidelines identify an MI within 7 days, or one within 1 month with myocardium at risk for ischemia, as “active” cardiac conditions. On the other hand, evidence of past MI with no myocardium thought at ischemic risk is considered a low risk for perioperative infarction after noncardiac surgery. The ACC/AHA guidelines classify recommendations into four categories, as class I (benefit >>> risk), class IIa (benefit >> risk), class IIb (benefit ≥ risk), and class III (no benefit or harm). Additionally, they grade the strength of the evidence upon which the recommendations is based as A (multiple randomized trials), B (limited trials, nonrandomized studies), and C (consensus of experts, case studies).

Class I recommendations are as follows:

- Patients who have a need for emergency noncardiac surgery should proceed to the operating room with perioperative surveillance and postoperative risk factor management
- Patients with active cardiac conditions should be evaluated by a cardiologist and treated according to ACC/AHA guidelines
- Patients undergoing low-risk procedures should proceed to surgery
- Patients with poor exercise tolerance (<4 metabolic equivalents [METs]) and no known risk factors should proceed to surgery
The ACC/AHA guidelines use an algorithmic approach to discern risks of major adverse cardiac events (MACE; eg, perioperative death or myocardial infarction). Risks accrue secondary both to the nature of surgery and because of patient characteristics. The ACC/AHA suggest various risk calculators that are available online (eg, American College of Surgeons risk calculator, www.surgicalriskcalculator.com) to estimate patient risk of perioperative major adverse cardiac events (Figure 21–1).
FIGURE 21–1  Stepwise approach to perioperative cardiac assessment for coronary artery disease (CAD). Colors correspond to the following classes of recommendations: class I, green; class IIa, yellow; class IIb, orange; class III, red. Step 1: In patients scheduled for surgery with risk factors for or known CAD, determine the urgency of surgery. If an emergency, then determine the clinical risk factors that may influence perioperative management and proceed to surgery with appropriate monitoring and management strategies based on the clinical assessment (see Section 2.1 of the ACC/AHA guidelines for more information on CAD). (For patients with symptomatic heart failure [HF], valvular heart disease [VHD], or arrhythmias, see Sections 2.2, 2.4, and 2.5 of the guidelines for information on evaluation and management.) Step 2: If the surgery is urgent or elective, determine if the patient has an acute coronary syndrome (ACS). If yes, then refer patient for cardiology evaluation and management according to guideline-directed medical therapy (GDMT) according to the UA/NSTEMI and STEMI clinical practice guidelines (CPGs). Step 3: If the patient has risk factors for stable CAD, then estimate the perioperative risk of major adverse cardiac event (MACE) on the basis of the combined clinical/surgical risk. This estimate can use the American College of Surgeons NSQIP risk calculator (http://www.surgicalriskcalculator.com) or incorporate the Revised Cardiac Risk Index (RCRI) with an estimation of surgical risk. For example, a patient undergoing very low-risk surgery (eg, ophthalmologic surgery), even with multiple risk factors, would have a low risk of MACE, whereas a patient undergoing major vascular surgery with few risk factors would have an elevated risk of MACE (see Section 3 of the ACC/AHA guidelines). Step 4: If the patient has a low risk of MACE (<1%), then no further testing is needed, and the patient may proceed to surgery (see Section 3 of the guidelines). Step 5: If the patient is at elevated risk of MACE, then determine functional capacity with an objective measure or scale such as the Duke Activity Status Index (DASI). If the patient has moderate, good, or excellent functional capacity (>4 METs), then proceed to surgery without further evaluation (see Section 4.1 of the ACC/AHA guidelines). Step 6: If the patient has poor (<4 METs) or unknown functional capacity, then the clinician should consult with the patient and perioperative team to determine whether further testing will impact patient decision making (eg, decision to perform original surgery or willingness to undergo coronary artery bypass graft or percutaneous coronary intervention, depending on the results of the test) or perioperative care. If yes, then pharmacological stress testing is appropriate. In those patients with unknown functional capacity, exercise stress testing may be reasonable to perform. If the stress test is abnormal, consider coronary angiography and
revascularization depending on the extent of the abnormal test. The patient can then proceed to surgery with GDMT or consider alternative strategies, such as noninvasive treatment of the indication for surgery (eg, radiation therapy for cancer) or palliation. If the test is normal, proceed to surgery according to GDMT (see Section 5.3 of the guidelines). Step 7: If testing will not impact decision making or care, then proceed to surgery according to GDMT or consider alternative strategies, such as noninvasive treatment of the indication for surgery (eg, radiation therapy for cancer) or palliation. MET, metabolic equivalent; NB, No Benefit; NSQIP, National Surgical Quality Improvement Program; STEMI, ST-elevation myocardial infarction; UA/NSTEMI, unstable angina/non–ST-elevation myocardial infarction. (Reproduced with permission from Fleisher LA, Fleischman KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: A report of the American College of Cardiology/American Heart Association Task Force on practice guidelines. J Am Coll Cardiol. 2014 Dec 9;64(22):e77-e137.)

The ACC/AHA guidelines also provide specific recommendations regarding various preexistent cardiac conditions (eg, heart failure, valvular heart disease, arrhythmias) likely to be encountered perioperatively. Recommendations regarding supplemental preoperative evaluation are presented in Table 21–2.

**TABLE 21–2** Summary of recommendations for supplemental preoperative evaluation.¹
**CORONARY ARTERY DISEASE**

The ACC/AHA guidelines suggest that 60 days or more should elapse after an MI before noncardiac surgery in patients who were not treated with a coronary intervention. Moreover, an MI within 6 months of surgery is associated with increased perioperative mortality. Increased patient age and frailty are likewise associated with greater risk for acute coronary syndromes and stroke. Recently, studies have found a surprising number of asymptomatic patients with elevated levels of troponin after surgery. Such findings are indicative of myocardial injury despite there being no other evidence suggestive of MI. Nevertheless, these patients are at considerably increased risk. The specific management of these patients remains controversial.

HYPERTENSION

Patients with hypertension frequently present for elective surgical procedures. Some will have been effectively managed, but unfortunately, many others will not have been. Hypertension is a leading cause of death and disability in most Western societies and the most prevalent preoperative medical abnormality in surgical patients, with an overall prevalence of 20% to 25%. Long-standing uncontrolled hypertension accelerates atherosclerosis and hypertensive organ damage. Hypertension is a major risk factor for cardiac, cerebral, renal, and vascular disease. **Complications of hypertension include MI, congestive heart failure, stroke, renal failure, peripheral occlusive disease, and aortic dissection.** The presence of concentric left ventricular hypertrophy (LVH) in hypertensive patients may be an important predictor of cardiac mortality. However, systolic blood pressures below 180 mm Hg, and diastolic pressures below 110 mm Hg, have not been associated with increased perioperative risks. When patients present with systolic blood pressures greater than 180 mm Hg and diastolic pressures greater than 110 mm Hg, anesthesiologists face the dilemma of delaying surgery to allow optimization of oral antihypertensive therapy, but adding the risk of a surgical delay versus proceeding with surgery and achieving blood pressure control with rapidly acting intravenous agents. The incidence of adverse cardiac events in patients treated and operated upon may be similar to that in patients delayed to allow for better long-term blood pressure control. Of note, patients with preoperative hypertension are more likely than others to develop intraoperative hypotension.

Blood pressure measurements are affected by many variables, including posture, time of day, emotional state, recent activity, and drug intake, as well as the equipment and technique used. A diagnosis of hypertension cannot be made with one preoperative reading, but requires confirmation by a history of consistently elevated measurements. Although preoperative anxiety or pain may produce some degree of hypertension in normal patients, patients with a history of hypertension generally exhibit greater preoperative elevations in blood pressure.

Epidemiological studies demonstrate a direct and continuous correlation between both diastolic and systolic blood pressures and mortality rates. The definition of systemic hypertension is arbitrary: a consistently elevated diastolic blood pressure greater than 90 mm Hg or a systolic pressure greater than 140 mm Hg. A common classification scheme is listed in **Table 21–3.** Prehypertension is said to exist when the diastolic pressure is 80–89 mm Hg or the systolic pressure is 120–139 mm Hg. Whether patients with borderline
hypertension are at some increased risk for cardiovascular complications remains unclear. Accelerated or severe hypertension is defined as a recent, sustained, and progressive increase in blood pressure, usually with diastolic blood pressures in excess of 110 to 119 mm Hg. Kidney dysfunction is often present in such patients. A hypertensive urgency reflects blood pressure elevation of >180/120 mm Hg without signs of organ injury (eg, hypertensive encephalopathy, heart failure). A hypertensive emergency is characterized by severe hypertension (>180/120 mm Hg) often associated with papilledema, encephalopathy, or other organ injury.

**Pathophysiology**

Hypertension can be either idiopathic (essential) or, less commonly, secondary to other medical conditions such as renal disease, renal artery stenosis, primary hyperaldosteronism, Cushing disease, acromegaly, pheochromocytoma, pregnancy, or estrogen therapy. Essential hypertension accounts for 80% to 95% of cases and may be associated with an abnormal baseline elevation of cardiac output, systemic vascular resistance (SVR), or both. An evolving pattern is commonly seen over the course of the disease, where cardiac output returns to (or remains) normal, but SVR becomes abnormally high. The chronic increase in cardiac afterload results in concentric left ventricular hypertrophy and altered diastolic function. Hypertension also alters cerebral autoregulation, such that normal cerebral blood flow is maintained in the face of high blood pressures; autoregulation limits may be in the range of mean blood pressures of 110 to 180
mm Hg.

The mechanisms responsible for the changes observed in hypertensive patients seem to involve vascular hypertrophy, hyperinsulinemia, abnormal increases in intracellular calcium, and increased intracellular sodium concentrations in vascular smooth muscle and renal tubular cells. Sympathetic nervous system overactivity and enhanced responses to sympathetic agonists are present in some patients. Hypertensive patients sometimes display an exaggerated response to vasopressors and vasodilators. Overactivity of the renin–angiotensin–aldosterone system seems to play an important role in patients with accelerated hypertension.

**Long-Term Treatment**

Effective drug therapy reduces the progression of hypertension and the incidence of stroke, congestive heart failure, coronary artery disease (CAD), and kidney damage. Effective treatment can also delay and sometimes reverse concomitant pathophysiological changes, such as left ventricular hypertrophy and altered cerebral autoregulation.

Some patients with mild hypertension require only single-drug therapy, which may consist of a thiazide diuretic, angiotensin-converting enzyme (ACE) inhibitor, angiotensin-receptor blocker (ARB), β-adrenergic blocker, or calcium channel blocker, although guidelines and outcome studies favor the first three options. Concomitant illnesses should guide drug selection. All patients with a prior MI should receive a β-adrenergic blocker and an ACE inhibitor (or ARB) to improve outcomes, irrespective of the presence of hypertension. In many patients, the “guideline-specified” agents will also be more than sufficient to control hypertension.

Patients with moderate to severe hypertension often require two or three drugs for control. The combination of a diuretic with a β-adrenergic blocker and an ACE inhibitor is often effective when single-drug therapy is not. As previously noted, ACE inhibitors (or ARBs) prolong survival in patients with congestive heart failure, left ventricular dysfunction, or a prior MI. Familiarity with the names, mechanisms of action, and side effects of commonly used antihypertensive agents is important for anesthesiologists (Table 21–4).

*Proprazol: Nonselective prototype β-blocker

Metoprolol and atenolol: Very widely used β-selective blockers
PREOPERATIVE MANAGEMENT

A recurring question in anesthetic practice is the degree of preoperative hypertension that is acceptable for patients scheduled for elective surgery. Except for optimally controlled patients, most hypertensive patients present to the operating room with some degree of hypertension. Although data suggest that even moderate preoperative hypertension (diastolic pressure >90–110 mm Hg) is not clearly statistically associated with postoperative complications, other data indicate that the untreated or poorly controlled hypertensive patient is more apt to experience intraoperative episodes of myocardial ischemia, arrhythmias, or hemodynamic instability. Careful intraoperative adjustments in anesthetic depth and use of vasoactive drugs should reduce the incidence of postoperative complications referable to poor preoperative control of hypertension.

Although patients should ideally undergo elective surgery only when rendered normotensive, accomplishing this over the short term is not always feasible or even desirable because hypertensive patients have altered cerebral...
autoregulation. Excessive reductions in blood pressure can compromise cerebral perfusion. Moreover, the decision to delay or to proceed with surgery should be individualized, based on the severity of the preoperative blood pressure elevation; the likelihood of coexisting myocardial ischemia, ventricular dysfunction, or cerebrovascular or renal complications; and the nature and urgency of the procedure. With rare exceptions, antihypertensive drug therapy should be continued up to the time of surgery. Some clinicians withhold ACE inhibitors and ARBs on the morning of surgery because of their association with an increased incidence of intraoperative hypotension; however, withholding these agents increases the risk of marked perioperative hypertension and the need for parenteral antihypertensive agents. It also requires the surgical team to remember to restart the medication after surgery. The decision to delay elective surgical procedures in patients with sustained preoperative diastolic blood pressures higher than 110 mm Hg should be made when the perceived benefits of delayed surgery exceed the risks. Unfortunately, there are few appropriate studies to guide the decision-making.

**History**

The preoperative history should address the severity and duration of the hypertension, the drug therapy currently prescribed, and the presence or absence of hypertensive complications. Symptoms of myocardial ischemia, ventricular failure, impaired cerebral perfusion, or peripheral vascular disease should be elicited, as well as the patient’s record of compliance with the drug regimen. The patient should be questioned regarding chest pain, exercise tolerance, shortness of breath (particularly at night), dependent edema, postural lightheadedness, syncope, episodic visual disturbances or episodic neurological symptoms, and claudication. Adverse effects of current antihypertensive drug therapy (Table 21–5) should also be identified.

**TABLE 21–5** Adverse effects of long-term antihypertensive therapy.
Physical Examination & Laboratory Evaluation

Ophthalmoscopy is useful in hypertensive patients. Visible changes in the retinal vasculature usually parallel the severity and progression of arteriosclerosis and hypertensive damage in other organs. An S₄ cardiac gallop is common in patients with LVH. Other physical findings, such as pulmonary rales and an S₃ cardiac gallop, are late findings and indicate congestive heart failure. Blood pressure can be measured in both the supine and standing positions. Orthostatic changes may be due to volume depletion, excessive vasodilation, or sympatholytic drug therapy. Preoperative administration of a carbohydrate drink the night before and on the morning of surgery can promote hemodynamic stability after induction of anesthesia. Although asymptomatic carotid bruits are usually hemodynamically insignificant, they may be reflective of atherosclerotic vascular disease that may affect the coronary circulation. When a bruit is detected, further workup should be guided by the urgency of the scheduled surgery and the likelihood that further investigations, if diagnostic, would result in a change in therapy. Doppler studies of the carotid arteries can be used to define the extent of carotid disease.

The ECG is often normal, but in patients with a long history of hypertension, it may show evidence of ischemia, conduction abnormalities, an old infarction, or LVH or strain. A normal ECG does not exclude CAD or LVH. Similarly, a normal heart size on a chest radiograph does not exclude ventricular
hypertrophy. Echocardiography is a sensitive test for LVH and can be used to evaluate ventricular systolic and diastolic functions in patients with symptoms of heart failure. Chest radiographs are rarely useful in an asymptomatic patient, but may show frank cardiomegaly or pulmonary vascular congestion.

Kidney function is typically evaluated by measurement of serum creatinine levels. Serum electrolyte levels (K) should be determined in patients taking diuretics or digoxin or those with kidney impairment. Mild to moderate hypokalemia (3–3.5 mEq/L) is often seen in patients taking diuretics, but does not have adverse outcome effects. Potassium replacement should be undertaken only in patients who are symptomatic or who are also taking digoxin. Hypomagnesemia is often present and may be a cause of perioperative arrhythmias. Hyperkalemia may be encountered in patients who are taking potassium-sparing diuretics or ACE inhibitors, particularly those with impaired renal function.

**Premedication**

Mild to moderate preoperative hypertension often resolves following administration of an agent such as midazolam.

**INTRAOPERATIVE MANAGEMENT**

**Objectives**

The anesthetic for a hypertensive patient should maintain an appropriately stable blood pressure range. Patients with borderline hypertension may be treated as normotensive patients. Those with long-standing or poorly controlled hypertension, however, have altered autoregulation of cerebral blood flow; higher than normal mean blood pressures may be required to maintain adequate cerebral blood flow. Hypertension, particularly in association with tachycardia, can precipitate or exacerbate myocardial ischemia, ventricular dysfunction, or both. Arterial blood pressure should generally be kept within 20% of preoperative levels.

**Monitoring**

Most hypertensive patients do not require special intraoperative monitors. Direct intraarterial pressure monitoring should be reserved for patients with wide swings in blood pressure and those undergoing major surgical procedures.
induced with rapid or marked changes in cardiac preload or afterload. Electrocardiographic monitoring should focus on detecting signs of ischemia. Urinary output should generally be monitored with an indwelling urinary catheter in patients with a preexisting kidney impairment who are undergoing procedures expected to last more than 2 h. Ventricular compliance (see Chapter 20) is typically reduced in patients with ventricular hypertrophy. Excessive intravenous fluid administration in patients with decreased ventricular compliance can also result in elevated pulmonary arterial pressures and pulmonary congestion.

**Induction**

Induction of anesthesia and endotracheal intubation are often associated with hemodynamic instability in hypertensive patients. Regardless of the level of preoperative blood pressure control, many patients with hypertension display an accentuated hypotensive response to induction of anesthesia, followed by an exaggerated hypertensive response to intubation. Many, if not most, antihypertensive agents and general anesthetics are vasodilators, cardiac depressants, or both. In addition, many hypertensive patients present for surgery in a volume-depleted state. Sympatholytic agents attenuate the normal protective circulatory reflexes, reducing sympathetic tone and unmasking vagal activity.

Hypertensive patients may exhibit severe hypertension during airway manipulation. One of several techniques may be used before intubation to attenuate the hypertensive response:

- Deepening anesthesia with a potent volatile agent
- Administering a bolus of an opioid (fentanyl, 2.5–5 mcg/kg; alfentanil, 15–25 mcg/kg; sufentanil, 0.5–1.0 mcg/kg; or remifentanil, 0.5–1 mcg/kg)
- Administering lidocaine, 1.5 mg/kg intravenously, intratracheally, or topically in the airway
- Achieving β-adrenergic blockade with esmolol, 0.3–1.5 mg/kg; metoprolol 1–5 mg; or labetalol, 5–20 mg

**Choice of Anesthetic Agents**

**A. Induction Agents**

The superiority of any one agent or technique over another has not been established. Propofol, barbiturates, benzodiazepines, and etomidate are equally
safe for inducing general anesthesia in most hypertensive patients. Ketamine by itself can precipitate marked hypertension; however, it is almost never used as a single agent. When administered with a small dose of another agent, such as a benzodiazepine or propofol, ketamine’s sympathetic stimulating properties can be blunted or eliminated.

B. Maintenance Agents
Anesthesia may be safely maintained with volatile or intravenous agents. Regardless of the primary maintenance technique, addition of a volatile agent or intravenous vasodilator generally allows convenient intraoperative blood pressure control.

C. Vasopressors
Should hypotension develop, a small dose of a direct-acting agent, such as phenylephrine (25–50 mcg), may be beneficial. Patients taking sympatholytics preoperatively may exhibit a decreased response to ephedrine. Vasopressin as a bolus or infusion can also be employed to restore vascular tone in the hypotensive patient.

Intraoperative Hypertension
Intraoperative hypertension not responding to an increase in anesthetic depth (particularly with a volatile agent) can be treated with a variety of parenteral agents (Table 21–6). Readily reversible causes—such as inadequate anesthetic depth, hypoxemia, or hypercapnia—should always be excluded before initiating antihypertensive therapy. Selection of a hypotensive agent depends on the severity, acuteness, and cause of hypertension; the baseline ventricular function; the heart rate; and the presence of bronchospastic pulmonary disease. β-Adrenergic blockade alone or as a supplement is a good choice for a patient with good ventricular function and an elevated heart rate, but is relatively contraindicated in a patient with reactive airway disease. Metoprolol, esmolol, or labetalol is often used intraoperatively. Nicardipine or clevidipine may be preferable to β-blockers for patients with bronchospastic disease. Nitroprusside remains the most rapid and effective agent for the intraoperative treatment of moderate to severe hypertension. Nitroglycerin may be less effective, but is also useful in treating or preventing myocardial ischemia. Fenoldopam, a dopaminergic agonist, is also a useful hypotensive agent; furthermore, it increases renal blood flow. Hydralazine provides sustained blood pressure
control, but also has a delayed onset and can cause reflex tachycardia. Reflex tachycardia is not seen with labetalol because of its combined α- and β-adrenergic blockade.

**POSTOPERATIVE MANAGEMENT**

Postoperative hypertension is common and should be anticipated in patients who have poorly controlled baseline blood pressure. Close blood pressure monitoring should be continued in both the postanesthesia care unit and the early postoperative period. Postoperatively, marked sustained elevations in blood pressure can contribute to the formation of wound hematomas and the disruption of vascular suture lines.

Hypertension in the recovery period is often multifactorial and enhanced by respiratory abnormalities, anxiety and pain, volume overload, bladder distention, or any combination of these. Contributing causes should be corrected and parenteral antihypertensive agents given if necessary. Intravenous labetalol is particularly useful in controlling hypertension and tachycardia, whereas vasodilators are useful in controlling blood pressure in the setting of a slow heart rate. When the patient resumes oral intake, preoperative antihypertensive medications should be restarted.

**ISCHEMIC HEART DISEASE**

**Preoperative Considerations**
Myocardial ischemia results from a metabolic oxygen demand that exceeds the oxygen supply. Ischemia can therefore result from increased myocardial metabolic demand, reduced myocardial oxygen delivery, or a combination of both. Common causes include coronary arterial thrombosis or vasospasm; severe hypertension or tachycardia (particularly in the presence of ventricular hypertrophy); severe hypotension, hypoxemia, or anemia; and severe aortic stenosis or regurgitation.

By far, the most common cause of myocardial ischemia is atherosclerosis of the coronary arteries. CAD is responsible for about 25% of all deaths in Western societies and is a major cause of perioperative morbidity and mortality. The overall incidence of CAD in surgical patients is estimated to be between 5% and 10%. Major preoperative risk factors for CAD include hyperlipidemia, hypertension, diabetes, cigarette smoking, increasing age, male sex, and a positive family history. Other risk factors include obesity, a history of cerebrovascular or peripheral vascular disease, menopause, use of high-estrogen oral contraceptives by women who smoke, and a sedentary lifestyle.

CAD may be manifested by symptoms, characteristic electrocardiographic or echocardiographic findings, or biochemical evidence of myocardial necrosis (infarction); symptoms (usually angina) or characteristic echocardiographic or electrocardiographic findings of ischemia; or arrhythmias (including sudden death), symptoms (orthopnea, dyspnea on exertion), signs (rales, dependent edema, shock), or echocardiographic changes suggestive of ventricular dysfunction. An ambulatory patient presenting with risk factors for CAD and new symptoms would normally undergo some form of stress testing to confirm the suspected diagnosis.

**Unstable Angina**

Unstable angina is defined as (1) an abrupt increase in severity, frequency (more than three episodes per day), or duration of anginal attacks (crescendo angina); (2) angina at rest; or (3) new onset of angina (within the past 2 months) with severe or frequent episodes (more than three per day). Unstable angina may occur following MI or be precipitated by major surgery or by noncardiac medical conditions, including severe anemia, fever, infections, thyrotoxicosis, hypoxemia, and emotional distress in previously stable patients.

Unstable angina, particularly when it is associated with significant ST-segment changes at rest, usually reflects severe underlying coronary disease and may be followed by MI. Plaque disruption with platelet aggregates or thrombi
and vasospasm are frequent pathological correlates. Critical stenosis in one or more major coronary arteries is present in more than 80% of patients with these symptoms. Patients with unstable angina require evaluation and treatment, which may include admission to a coronary care unit and some form of coronary intervention.

**Chronic Stable Angina**

Anginal chest pains are most often substernal, exertional, radiating to the neck or arm, and relieved by rest or nitroglycerin. Variations are common, including epigastric, back, or neck pain, or transient shortness of breath from ventricular dysfunction (anginal equivalent). Nonexertional ischemia and silent (asymptomatic) ischemia are fairly common occurrences, particularly following surgery. Patients with diabetes have an increased incidence of silent ischemia.

Symptoms are generally absent until the atherosclerotic lesions cause 50% to 75% occlusion of the coronary circulation. When a stenotic segment reaches 70% occlusion, maximum compensatory dilation is usually present distally: blood flow may be adequate at rest, but inadequate with increased metabolic demand. An extensive collateral blood supply allows some patients to remain relatively asymptomatic despite severe disease. Coronary vasospasm is also a cause of transient transmural ischemia in some patients; most vasospastic episodes occur at preexisting stenotic lesions in epicardial vessels and may be precipitated by a variety of factors, including emotional upset and hyperventilation (Prinzmetal angina). Coronary spasm is more often observed in patients who have angina with varying levels of activity or emotional stress (variable-threshold); it is less common with classic exertional (fixed-threshold) angina.

The overall prognosis of patients with CAD is related to both the number and severity of coronary obstructions, as well as to the extent of ventricular dysfunction.

**Treatment of Ischemic Heart Disease**

The general approach in treating patients with ischemic heart disease is five-fold:

- Correction of risk factors, with the hope of slowing disease progression
- Modification of the patient’s lifestyle to reduce stress and improve exercise tolerance
• Correction of complicating medical conditions that can exacerbate ischemia (ie, hypertension, anemia, hypoxemia, hyperthyroidism, fever, infection, or adverse drug effects)
• Pharmacological manipulation of the myocardial oxygen supply–demand relationship
• Anticoagulation
• Correction of coronary lesions by percutaneous coronary intervention (angioplasty [with or without stenting] or atherectomy) or coronary artery bypass surgery

The most commonly used pharmacological agents for stable ischemic heart disease are nitrates, β-blockers, calcium channel blockers, and platelet inhibitors. Those drugs with circulatory effects are compared in Table 21–7.

**A. β-Adrenergic Blocking Agents**

These drugs are first-line agents for patients with stable ischemic heart disease. They decrease myocardial oxygen demand by reducing heart rate and contractility, and, in some cases, afterload (via their antihypertensive effect). In contrast to other agents, they increase survival in patients with impaired left ventricular function, they increase survival after MI, and they reduce the likelihood of a subsequent infarction. Optimal blockade results in a resting heart rate between 50 and 60 beats/min and prevents appreciable increases with exercise (<20 beats/min increase during exercise). Available agents differ in receptor selectivity, intrinsic sympathomimetic (partial agonist) activity, and membrane-stabilizing properties (Table 21–8). Membrane stabilization results in antiarrhythmic activity. Agents with intrinsic sympathomimetic properties are
better tolerated by patients with mild to moderate ventricular dysfunction. Certain β-blockers (bisoprolol, carvedilol, and extended-duration metoprolol) improve survival in patients with chronic heart failure. Blockade of β₂-adrenergic receptors also can mask hypoglycemic symptoms in patients with diabetes, delay metabolic recovery from hypoglycemia, and impair the handling of large potassium loads. Cardioselective (β₁-receptor-specific) agents, although generally better tolerated than nonselective agents in patients with reactive airways, must still be used cautiously in such patients. The selectivity of cardioselective agents tends to be dose dependent. Patients on long-standing β-blocker therapy should have these agents continued perioperatively. Acute β-blocker withdrawal in the perioperative period places patients at a markedly increased risk of cardiac morbidity and mortality. β-Blocker therapy should be continued perioperatively in patients who take these agents chronically.

† Also possesses unique antifibrhythmic properties.

**B. Calcium Channel Blockers**

These agents are chosen when a patient cannot take a β-blocker or when treatment with a β-blocker is insufficient. The effects and uses of the most commonly used calcium channel blockers are shown in Table 21–9. Calcium
channel blockers reduce myocardial oxygen demand by decreasing cardiac afterload and augment myocardial oxygen supply via coronary vasodilation. Verapamil and diltiazem also reduce demand by slowing the heart rate.

1Total oral dose per day divided into three doses unless otherwise stated.
2Also possess antiarrhythmic properties.

Nifedipine’s potent effects on the systemic blood pressure may precipitate hypotension, reflex tachycardia, or both. Its tendency to decrease afterload generally offsets any negative inotropic effect. Long-acting verapamil, diltiazem, amlodipine, or felodipine are preferred. Nicardipine and clevidipine generally have the same effects as nifedipine but are shorter acting, and clevidipine is particularly useful as a vasodilator infusion. Nimodipine is primarily used in preventing cerebral vasospasm following subarachnoid hemorrhage.

All calcium channel blockers potentiate depolarizing and nondepolarizing neuromuscular blocking agents and the circulatory effects of volatile agents. Verapamil and diltiazem can potentiate depression of cardiac contractility and conduction in the atrioventricular (AV) node by volatile anesthetics. Nifedipine and similar agents can potentiate systemic vasodilation by volatile and intravenous agents.

**C. Nitrates**

Nitrates decrease venous and arteriolar tone, increase vascular capacitance, and reduce ventricular wall tension. These effects tend to reduce myocardial oxygen
demand. Prominent venodilation makes nitrates excellent agents when congestive heart failure is also present.

Additionally, nitrates dilate the coronary arteries. Even minor degrees of dilation at stenotic sites may be sufficient to increase blood flow, because flow is directly related to the fourth power of the radius. Nitrate-induced coronary vasodilation preferentially increases subendocardial blood flow in ischemic areas. This favorable redistribution of coronary blood flow to ischemic areas may be dependent on the presence of collaterals in the coronary circulation.

Nitrates can be used for both the treatment of acute ischemia and prophylaxis against frequent anginal episodes.

D. Anticoagulants
Chronic aspirin therapy reduces coronary events in patients with CAD and prevents coronary and ischemic cerebral events in at-risk patients. Other platelet antagonists are generally also included in patients who have undergone percutaneous coronary stenting. Careful review of anticoagulant/antiplatelet medications is a mandatory element of preanesthetic assessment, especially if neuraxial anesthesia is being considered (see Chapter 45).

E. Other Agents and Other Treatments
ACE inhibitors prolong survival in patients with congestive heart failure or left ventricular dysfunction. Antiarrhythmic therapy in patients with complex ventricular ectopy who have significant CAD and left ventricular dysfunction should be guided by an electrophysiological study. Patients with inducible sustained ventricular tachycardia (VT) or ventricular fibrillation are candidates for an automatic internal cardioverter-defibrillator (ICD). Treatment of ventricular ectopy (with the exception of sustained VT) in patients with good ventricular function does not improve survival and may increase mortality. In contrast, ICDs have been shown to improve survival in patients with advanced cardiomyopathy (ejection fraction <30%), even in the absence of demonstrable arrhythmias.

E. Combination Therapy
Moderate to severe angina frequently requires combination therapy with two or more classes of agents. Patients with ventricular dysfunction may not tolerate the combined negative inotropic effect of a β-blocker and a calcium channel blocker together; an ACE inhibitor or ARB is better tolerated and seems to improve survival. Similarly, the additive effect of a β-blocker and a calcium channel
blocker on the AV node may precipitate heart block in susceptible patients.

PREOPERATIVE MANAGEMENT

The importance of ischemic heart disease—particularly a history of MI—as a risk factor for perioperative morbidity and mortality is reviewed earlier in this chapter. Most studies confirm that perioperative outcome is related to disease severity, ventricular function, and the type of surgery to be undertaken. Patients with extensive (three-vessel or left main) CAD, a recent history of MI, or ventricular dysfunction are at greatest risk of cardiovascular complications. As previously mentioned, current guidelines recommend revascularization only when such treatment would be indicated irrespective of the patient’s need for surgery.

Chronic stable (mild to moderate) angina does not seem to increase perioperative risk substantially. Similarly, a history of prior coronary artery bypass surgery or coronary angioplasty alone does not seem to substantially increase perioperative risk. In some studies, maintenance of chronic β-receptor blockers in the perioperative period has been shown to reduce perioperative mortality and the incidence of postoperative cardiovascular complications; however, other studies have shown an increase in stroke and death following preoperative introduction of β-blockers to at-risk patients. Consequently, initiating therapy with β-blockers in at-risk patients who will undergo surgery is no longer recommended. Like β-blockers, statins should be continued perioperatively in patients so routinely treated, as acute perioperative withdrawal of statins is associated with adverse outcomes. The ACC/AHA recommendations are summarized in a set of useful guidelines that also provide guidance on the timing of surgery following percutaneous coronary interventions and the deployment of coronary stents (Table 21–10).

History

The most important symptoms to elicit include chest pain, dyspnea, poor exercise tolerance, syncope, or near syncope. The relationship between symptoms and activity level should be established. Activity should be described in terms of everyday tasks, such as walking or climbing stairs. Patients may be relatively asymptomatic despite severe CAD if they have a sedentary lifestyle. Patients with diabetes are particularly prone to silent ischemia. Easy fatigability or shortness of breath suggests impaired ventricular function.

A history of unstable angina or MI should include the time of its occurrence and whether it was complicated by arrhythmias, conduction disturbances, or heart failure. Arrhythmias and conduction abnormalities are more common in patients with previous infarction and in those with poor ventricular function. This latter group of patients will often have ICDs.

Physical Examination & Routine Laboratory Evaluation

Evaluation of patients with CAD is similar to that of patients with hypertension. Laboratory evaluation in patients who have a history compatible with recent
unstable angina and are undergoing emergency procedures should include cardiac enzymes. Normal serum levels of troponins, creatine kinase (MB isoenzyme), and lactate dehydrogenase (type 1 isoenzyme) are useful in excluding MI.

The baseline ECG is normal in 25% to 50% of patients with CAD but no prior MI. Electrocardiographic evidence of ischemia often becomes apparent only during angina. The most common baseline abnormalities are nonspecific ST-segment and T-wave changes. Prior infarction may be manifested by Q waves or loss of R waves in the leads closest to the infarct. First-degree AV block, bundle-branch block, or hemiblock may be present. Persistent ST-segment elevation following MI may be indicative of a left ventricular aneurysm. A long rate-corrected QT interval (QTc > 0.44 s) may reflect the underlying ischemia, drug toxicity (usually class Ia antiarrhythmic agents, antidepressants, or phenothiazines), electrolyte abnormalities (hypokalemia or hypomagnesemia), autonomic dysfunction, mitral valve prolapse, or, less commonly, a congenital abnormality. Patients with a long QT interval are at risk of developing ventricular arrhythmias—particularly polymorphic VT (torsades de pointes), which can lead to ventricular fibrillation. The long QT interval reflects nonuniform prolongation of ventricular repolarization and predisposes patients to reentry phenomena. In contrast to polymorphic ventricular arrhythmias with a normal QT interval, which respond to conventional antiarrhythmics, polymorphic tachyarrhythmias with a long QT interval generally respond best to pacing or magnesium salts.

The chest radiograph can be used to exclude cardiomegaly or pulmonary vascular congestion secondary to ventricular dysfunction.

**Specialized Studies**

**A. Holter Monitoring**

Continuous ambulatory electrocardiographic (Holter) monitoring is useful in evaluating arrhythmias, antiarrhythmic drug therapy, and severity and frequency of ischemic episodes. Silent (asymptomatic) ischemic episodes are frequently found in patients with CAD. Frequent ischemic episodes on preoperative Holter monitoring correlate well with intraoperative and postoperative ischemia. Holter monitoring showing no ischemic episodes has an excellent negative predictive value for postoperative cardiac complications.

**B. Exercise Electrocardiography**
The usefulness of this test without associated cardiac imaging is limited in patients with baseline ST-segment abnormalities and those who are unable to increase their heart rate (>85% of maximal predicted) because of fatigue, dyspnea, or drug therapy. Overall sensitivity is 65%, and specificity is 90%. Exercise testing is most sensitive (85%) in patients with three-vessel or left main CAD. Disease that is limited to the left circumflex artery may also be missed because ischemia in its distribution may not be evident on the standard surface ECG. A normal test does not necessarily exclude CAD, but suggests that severe disease is not likely. The degree of ST-segment depression, its severity and configuration, the time of onset in the test, and the time required for resolution are important findings. A myocardial ischemic response at low levels of exercise is associated with a significantly increased risk of perioperative complications and long-term cardiac events. Other significant findings include changes in blood pressure and the occurrence of arrhythmias. Exercise-induced ventricular ectopy frequently indicates severe CAD associated with ventricular dysfunction. The ischemia presumably leads to electrical instability in myocardial cells. Given that risk seems to be associated with the extent of potentially ischemic myocardium, testing often includes perfusion scans or echocardiographic assessments; however, in ambulatory patients, exercise ECG testing alone is useful because it estimates functional capacity and detects myocardial ischemia.

C. Myocardial Perfusions Scans and Other Imaging Techniques

Myocardial perfusion imaging using thallium-201 or technetium-99m is used in evaluating patients who cannot exercise (eg, peripheral vascular disease) or who have underlying ECG abnormalities that preclude interpretation during exercise (eg, left bundle-branch block). If the patient cannot exercise, images are obtained before and after injection of an intravenous coronary dilator (eg, dipyridamole or adenosine) to produce a hyperemic response similar to exercise. Myocardial perfusion studies following exercise or injection of dipyridamole or adenosine have a high sensitivity, but only fairly good specificity for CAD. They are best for detecting two- or three-vessel disease. These scans can locate and quantitate areas of ischemia or scarring and differentiate between the two. Perfusion defects that fill in on the redistribution phase represent ischemia, not previous infarction. The negative predictive value of a normal perfusion scan is approximately 99%.

Magnetic resonance imaging, positron emission tomography, and computed tomography scans are increasingly being used to define coronary artery anatomy and determine myocardial viability.
D. Echocardiography
This technology provides information about both regional and global ventricular function and may be carried out at rest, following exercise, or with administration of dobutamine. Detectable regional wall motion abnormalities and the derived left ventricular ejection fraction correlate well with angiographic findings. Moreover, dobutamine stress echocardiography seems to be a reliable predictor of adverse cardiac complications in patients who cannot exercise. New or worsening wall motion abnormalities following dobutamine infusion are indicative of significant ischemia. Patients with an ejection fraction of less than 50% tend to have more severe disease and increased perioperative morbidity. Dobutamine stress echocardiography, however, may not be reliable in patients with left bundle-branch block because septal motion may be abnormal, even in the absence of left anterior descending CAD in some patients.

E. Coronary Angiography
Coronary angiography remains the definitive way to evaluate CAD and is associated with a low complication rate (<1%). The location and severity of occlusions can be defined, and coronary vasospasm may also be observed on angiography. In evaluating fixed stenotic lesions, occlusions greater than 50% to 75% are generally considered significant. The severity of disease is often expressed according to the number of major coronary vessels affected (one-, two-, or three-vessel disease). Significant stenosis of the left main coronary artery is of great concern because disruption of flow in this vessel will have adverse effects on almost the entire left ventricle.

Ventriculography, measurement of the ejection fraction, and measurement of intracardiac pressures, also provide important information. Indicators of significant ventricular dysfunction include an ejection fraction less than 50%, a left ventricular end-diastolic pressure greater than 18 mm Hg, a cardiac index less than 2.2 L/min/m², and marked or multiple wall motion abnormalities.

Premedication
Allaying fear, anxiety, and pain preoperatively are desirable goals in patients with CAD. Satisfactory premedication minimizes sympathetic activation, which adversely affects the myocardial oxygen supply–demand balance. Overmedication is equally detrimental and should be avoided because it may result in hypoxemia, respiratory acidosis, and hypotension. Most clinicians now limit premedication to small doses of intravenous midazolam (or the equivalent)
given immediately before invasive procedures or before transporting the patient
to the operating theater.

Preoperative medications should generally be continued until the time of
surgery. The sudden withdrawal of antianginal medication perioperatively—
particularly β-blockers—can precipitate a sudden, rebound increase in ischemic
episodes. Statins should also be continued in the perioperative period.
Prophylactic administration of nitrates intravenously or transdermally to patients
with CAD in the perioperative period provides no benefit to patients not
previously on long-term nitrate therapy and without evidence of ongoing
ischemia. Transdermal absorption of nitroglycerin may be erratic in the
perioperative period.

INTRAOPERATIVE MANAGEMENT

The intraoperative period is regularly associated with factors and events that can
adversely affect the myocardial oxygen demand–supply relationship. Activation
of the sympathetic system plays a major role. Hypertension and enhanced
contractility increase myocardial oxygen demand, whereas tachycardia increases
demand and reduces supply. Although myocardial ischemia is commonly
associated with tachycardia, ischemia can occur in the absence of any apparent
hemodynamic derangement.

Objectives

The overwhelming priority in managing patients with ischemic heart disease
is maintaining a favorable myocardial supply–demand relationship. Autonomic-
mediated increases in heart rate and blood pressure should be controlled with
deeper planes of general anesthesia, adrenergic blockade, vasodilators, or a
combination of these. Excessive reductions in coronary perfusion pressure or
arterial oxygen content must be avoided. Higher diastolic pressures may be
preferable in patients with high-grade coronary occlusions. Excessive increases
—such as those caused by fluid overload—in left ventricular end-diastolic
pressure should be avoided because they increase ventricular wall tension
(afterload) and can reduce subendocardial perfusion (see Chapter 20).
Transfusion carries its own risks and consequently there is no set transfusion
trigger in patients with CAD; however, most clinicians are reluctant to have
hemoglobin levels fall below 7 g/dL. Anemia can lead to tachycardia, worsening
the balance between myocardial oxygen supply and demand. The ACC/AHA
recommendations for the anesthetic management of the patient with CAD
disease for noncardiac surgery are summarized in Table 21–11.

²COR, class of recommendation; LOE, level of evidence; MI, myocardial infarction; TEE, transthoracic echocardiogram.

**MONITORING**

Intraarterial pressure monitoring is reasonable in most patients with severe CAD and major or multiple cardiac risk factors who are undergoing any but the most minor procedures. Central venous (or rarely pulmonary artery) pressure can be monitored during prolonged or complicated procedures involving large fluid shifts or blood loss. Noninvasive methods of cardiac output determination and volume assessment have been previously discussed in this text and we recommend them. Transesophageal echocardiography (TEE) and transthoracic echocardiography (TTE) can provide valuable information, both qualitative and quantitative, on contractility and ventricular chamber size (preload) perioperatively.

**A. Electrocardiography**
Early ischemic changes are subtle and involve changes in T-wave morphology, including inversion, tenting, or both (Figure 21–2). More obvious ischemia may be seen in the form of progressive ST-segment depression. Down-sloping and horizontal ST depressions are of greater specificity for ischemia than is upsloping depression. New ST-segment elevations are rare during noncardiac surgery and are indicative of severe ischemia, vasospasm, or infarction.

![Diagram of ischemia in the heart](image)

**FIGURE 21–2** Electrocardiographic signs of ischemia. Patterns of ischemia and injury. (Data from Schamroth L. *The 12 Lead Electrocardiogram.* Oxford, UK: Blackwell; 1989.)

It should be noted that an isolated minor ST elevation in the mid-precordial leads (V₃ and V₄) can be a normal variant in young patients. Ischemia may also present as an unexplained intraoperative atrial or ventricular arrhythmia or the onset of a new conduction abnormality. The sensitivity of the ECG in detecting ischemia is related to the number of leads monitored. Studies suggest that the V₅, V₄, II, V₂, and V₃ leads (in decreasing sensitivity) are most useful. Ideally, at least two leads should be monitored simultaneously. Usually, lead II is monitored for inferior wall ischemia and arrhythmias, and V₅ is monitored for anterior wall ischemia. When only one lead can be monitored, a modified V₅ lead provides the greatest sensitivity.
The increasing number of individuals treated with drug-eluting stents can be problematic perioperatively, especially when antiplatelet therapy must be discontinued (eg, emergency spinal surgery). Such patients are at very increased risk of thrombosis and perioperative MI. Anesthesia providers should never for nonsurgical reasons (eg, desire to perform a spinal anesthetic) discontinue antiplatelet or antithrombotic agents perioperatively without first discussing the risks and benefits of the proposed anesthetic requiring suspension of antiplatelet therapy with the patient and his or her cardiologist. The ACC/AHA guidelines offer recommendations on the approach of bringing patients to surgery following percutaneous coronary interventions and the type of interventions suggested when subsequent surgery is expected (Figure 21–3).

**FIGURE 21–3** Algorithm for antiplatelet management in patients with percutaneous coronary intervention (PCI) and noncardiac surgery. Colors correspond to the following classes of recommendations: class I, green; class IIa,
yellow; class IIb, orange; class III, red. (*Assuming the patient is currently on dual antiplatelet therapy [DAPT].) ASA, acetylsalicylic acid; ASAP, as soon as possible; BMS, bare-metal stent; DES, drug-eluting stent; P2Y, adenosine diphosphate receptor antagonist. (Reproduced with permission from Fleisher LA, Fleischman KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: A report of the American College of Cardiology/American Heart Association Task Force on practice guidelines. J Am Coll Cardiol. 2014 Dec 9;64(22):e77-e137.)

B. Hemodynamic Monitoring
The most common hemodynamic abnormalities observed during ischemic episodes are hypertension and tachycardia. They are almost always a cause (rather than the result) of ischemia. Hypotension is a late and ominous manifestation of progressive ventricular dysfunction. TEE readily will demonstrate a dysfunctional ventricle and ventricular wall motion changes associated with myocardial ischemia. Ischemia is frequently, but not always, associated with an abrupt increase in pulmonary capillary wedge pressure; however, it is rare for pulmonary capillary wedge pressure to be measured during general anesthesia.

C. Transesophageal Echocardiography
TEE can be helpful in detecting global and regional cardiac dysfunction, as well as valvular function, in surgical patients. Moreover, detection of new regional wall motion abnormalities is a more sensitive and earlier indication of myocardial ischemia than the ECG. In animal studies in which coronary blood flow is gradually reduced, regional wall motion abnormalities develop before the ECG changes. Although the occurrence of new intraoperative abnormalities correlates with postoperative MIs in some studies, not all such abnormalities are necessarily ischemic. Both regional and global abnormalities can be caused by changes in heart rate, altered conduction, preload, afterload, or drug-induced changes in contractility. Decreased systolic wall thickening may be a more reliable index for ischemia than endocardial wall motion alone.

Arrhythmias, Pacemakers, and Internal Cardioverter-Defibrillator Management
Electrolyte disorders, heart structure defects, inflammation, myocardial ischemia, cardiomyopathies, and conduction abnormalities can all contribute to the development of perioperative arrhythmias and heart block. Consequently,
anesthesia providers must be prepared to treat both chronic and new-onset cardiac rhythm abnormalities.

Supraventricular tachycardias (SVTs) can have hemodynamic consequences secondary to loss of AV synchrony and decreased diastolic filling time. Loss of the “P” wave on the ECG with a fast ventricular response is consistent with SVTs. Most SVTs occur secondary to a reentrant mechanism. Reentrant arrhythmias occur when conduction tissues in the heart depolarize or repolarize at varying rates. In this manner, a self-perpetuating loop of repolarization and depolarization can occur in the conduction pathways or AV node, or both. SVTs producing hemodynamic collapse are treated perioperatively with synchronized cardioversion. Adenosine can likewise be given to slow AV node conduction and potentially disrupt the reentrant loop. SVTs in patients without accessory conduction bundles (Wolff–Parkinson–White [WPW] syndrome) are treated with β-blockers and calcium channel blockers. In patients with known WPW, procainamide or ibutilide can be used to treat SVTs. Use of intravenous amiodarone, adenosine, digoxin, or non-dihydropyridine calcium channel antagonists is considered a class III recommendation by the AHA/ACC as these agents may harmfully increase the ventricular response in patients with preexcitation syndromes such as WPW. At times, SVTs manifest with a broad QRS complex and seem to be similar to VTs. Such rhythms, when they present, should be treated like VT, until proven otherwise.

Atrial fibrillation (AF) can complicate the perioperative period (Figure 21–4). Up to 35% of cardiac surgery patients develop postoperative AF.

**FIGURE 21–4** Posterior view of principal electrophysiological mechanisms of atrial fibrillation. **A:** Focal activation. The initiating focus (indicated by the dot) often lies within the region of the pulmonary veins. The resulting wavelets represent fibrillatory conduction, as in multiple-wavelet reentry. **B:** Multiple-wavelet reentry. Wavelets (arrows) randomly reenter tissue previously activated.
by the same or another wavelet. The routes the wavelets travel vary. LA, left atrium; PV, pulmonary vein; ICV, inferior vena cava; SCV, superior vena cava; RA, right atrium. (Reproduced with permission from Konings KT, Kirchhof CJ, Smeets JR, et al. High-density mapping of electrically induced atrial fibrillation in humans. *Circulation*. 1994 Apr;89(4):1665-1680.)

The ACC/AHA guidelines recommend antithrombotic therapy in patients with long-standing AF to prevent thromboembolic ischemic stroke. Consequently, many patients with AF will present to the operating room on some form of antithrombotic therapy (eg, warfarin, direct thrombin, or factor Xa inhibitors). Patients may require discontinuation of oral anticoagulation therapy prior to invasive procedures. Bridging with heparin is often utilized in patients at high risk for thromboembolism (eg, patients with mechanical heart valves).

When AF develops perioperatively, rate control with β-blockers can often be instituted. Chemical cardioversion can be attempted with amiodarone or procainamide. Of note, if the duration of AF is greater than 48 hours, or unknown, ACC/AHA guidelines recommend anticoagulation for 3 weeks prior to, and 4 weeks following, either electrical or chemical cardioversion. Additionally, TEE can be performed to rule out the presence of left atrial or left atrial appendage thrombus.

Should AF develop postoperatively, ventricular rate response can be controlled with AV nodal blocking agents, unless contraindicated. Should AF result in hemodynamic instability, synchronized cardioversion should be attempted. Patients at high risk of AF following cardiac surgery can be treated with prophylactic amiodarone. Many centers routinely administer β-blockers or amiodarone to all patients undergoing coronary artery surgery to reduce the risk of new onset AF.

AF is most frequently associated with loss of atrial muscle and the development of fibrosis. Fibrosis may contribute to reentrant mechanisms of AF as depolarization/repolarization becomes nonhomogeneous. AF may also develop from a focal source often located in the pulmonary veins. In patients with an accessory bundle, AF can produce rapid ventricular responses and hemodynamic collapse. Drugs that slow conduction across the AV node (eg, digitalis, verapamil, diltiazem) do not slow conduction across the accessory pathway, potentially leading to hemodynamic collapse. The ACC/AHA guidelines likewise recommend caution in the use of β-blockers for AF in patients with preexcitation syndromes.

Ventricular arrhythmias have been the subject of much review by the AHA (*Table 21–12*). Ventricular premature contractions (VPCs) can appear
perioperatively secondary to electrolyte abnormalities (hypokalemia, hypomagnesium, hypocalcemia), acidosis, ischemia, embolic phenomenon, mechanical irritation of the heart from central lines, cardiac manipulation, and drug effects. Correction of the underlying source of any arrhythmia should be addressed. Patients can likewise present with VPCs secondary to various cardiomyopathies.

</tr>
</tbody>
</table>
The incidence of sudden cardiac death (SCD) is estimated at 1 to 2/1000 per year. Consequently, some patients will experience an unexpected death in the perioperative period. All anesthesia providers must be prepared to resuscitate and manage patients with ventricular arrhythmias, including ventricular tachycardia (VT) (nonsustained and sustained) and ventricular fibrillation.

Nonsustained VT is a short run of ventricular ectopy that lasts <30 s and spontaneously terminates, whereas sustained VT persists longer than 30 s. VT is either monomorphic or polymorphic, depending on the QRS complex. If the QRS complex morphology changes, it is designated as polymorphic VT. Torsades des pointes is a form of VT associated with a prolonged QT interval, producing a sine wave-like VT pattern on the ECG. Ventricular fibrillation requires immediate resuscitative efforts and defibrillation.

Patients presenting with ventricular ectopy and nonsustained runs of VT routinely undergo investigation prior to surgery; however, patients with such rhythm abnormalities may not be at greater risk for nonfatal MI or cardiac death perioperatively. Supraventricular and ventricular arrhythmias constitute active cardiac conditions that warrant evaluation and treatment prior to elective, noncardiac surgery. Electrophysiological studies are undertaken to determine the possibility for catheter-mediated ablation of VTs.

Should VT present perioperatively, cardioversion is recommended whenever hemodynamic compromise occurs. Otherwise, treatment with amiodarone or procainamide can be attempted. At all times, therapy should also be directed at identifying any causative sources of the arrhythmia. β-Blockers are useful in the treatment of VT, especially if ischemia is a suspected causative factor in the
development of rhythm. The use of β-blockers following MI has reduced the incidence of post-MI ventricular fibrillation.

Torsades des pointes is associated with conditions that lengthen the QT interval. If the arrhythmia develops in association with pauses, pacing can be effective. Likewise, some patients may benefit from isoproterenol infusions, if they develop pause-dependent torsades des pointes. Magnesium sulfate may be useful in patients with long QT syndrome and episodes of torsades.

The development of perioperative ventricular fibrillation requires defibrillation and the use of resuscitation algorithms. Amiodarone can be used to stabilize the rhythm following successful defibrillation.

ICDs are recommended in patients with a history of survived SCD, decreased ventricular function following MI, and left ventricular ejection fractions less than 35%. Additionally, ICDs are used to treat potential sudden cardiac death in patients with dilated, hypertrophic, arrhythmogenic right ventricular and genetic cardiomyopathies. ICDs usually have a biventricular pacing function that improves the effectiveness of left ventricular contraction. Patients with heart failure frequently have a widened QRS complex greater than 120 ms. In such patients, ventricular systole is less efficient, as the lateral and septal left ventricular walls do not effectively contract because of the conduction delay. Cardiac resynchronization therapy has been shown to improve functional status in patients with heart failure.

Anesthetic management for the placement of ICDs and other electrophysiological procedures (eg, catheter ablation) depends on the patient’s underlying conditions. Many patients present with systolic and diastolic heart failure and depend on sympathetic tone to maintain blood pressure. Some patients tolerate ICD placement using deep sedation rather than general anesthesia. However, catheter-based electrophysiological studies can be quite time consuming, and patients can develop atelectasis and airway obstruction. Thus, general anesthesia is often used in the electrophysiology laboratory. Should the patient’s blood pressure suddenly decline during electrophysiologic studies, development of pericardial tamponade should be suspected. Emergent drainage of tamponade may be necessary.

Many patients present to surgery with ICDs in place. Published guidelines of the American Society of Anesthesiologists can provide assistance in the management of such patients. Management is a three-step process, as follows:

1. **Preoperative.** Identify the type of device and determine if it is used for antibradycardia functions. Consult with the patient’s cardiologist preoperatively as to the device’s function and use history.
2. **Intraoperative.** Determine what electromagnetic interference is likely to present intraoperatively and advise the use of bipolar electrocautery where possible. Assure the availability of temporary pacing and defibrillation equipment and apply pads as necessary. Patients who are pacemaker-dependent can be programmed to an asynchronous mode to mitigate electrical interference. Magnet application to ICDs may disable the antitachycardia function, but not convert to an asynchronous pacemaker. Consultation with the patient’s cardiologist and interrogation of the device is often necessary. Most patients will have a card on which the device model and manufacturer are provided. A telephone call to the device manufacturer can provide information about device performance and the best method for managing the device (eg, reprogramming or applying a magnet) prior to surgery. A large number of ICD models are in use; however, most suspend their antitachycardia function in response to a magnet.

3. **Postoperative.** The device must be interrogated to ensure that therapeutic functions have been restored. Patients should be continuously monitored until the antitachycardia functions of the device are restored and its function has been confirmed.

ICDs are particularly problematic intraoperatively when electrocautery is used because the device may (1) interpret cautery as ventricular fibrillation; (2) inhibit pacemaker function due to cautery artifact; (3) increase the pacing rate due to activation of a rate-responsive sensor; or (4) temporarily or permanently reset to a backup or reset mode. Use of bipolar cautery, placement of the grounding pad far from the ICD device, and limiting use of the cautery to only short bursts help to reduce the likelihood of problems, but will not eliminate them.

When there is greater risk of stray currents from the cautery, the ICD device should have the defibrillator function programmed off immediately before surgery and reprogrammed back on immediately afterward. External defibrillation pads should be applied and attached to a defibrillator machine intraoperatively. Careful monitoring of the arterial pulse with pulse oximetry or an arterial waveform is necessary to ensure that the pacemaker is not inhibited and that there is arterial perfusion during episodes of ECG artifact from surgical cautery.

**HEART FAILURE**

An increasing number of patients present for surgery with either systolic or
diastolic heart failure. Heart failure may be secondary to ischemia, valvular heart disease, infectious agents, or many forms of cardiomyopathy. Patients may experience heart failure symptoms with both a preserved and reduced ejection fractions. Most heart failure patients seek medical attention for complaints of dyspnea and fatigue. Heart failure develops over time, as symptoms worsen (Figure 21–5). Patients generally undergo echocardiography to diagnose structural heart defects, to detect signs of cardiac “remodeling,” to determine the left ventricular ejection fraction, and to assess the heart’s diastolic function. Laboratory evaluations of concentration of brain natriuretic peptide (BNP) are likewise obtained to distinguish heart failure from other causes of dyspnea. BNP is released from the heart, and its elevation is associated with impaired ventricular function.

![Figure 21–5](image)

**At risk for heart failure**
- **Stage A**
  - At high risk for HF but without structural heart disease or symptoms of HF
  - Goals: Prevent vascular, coronary disease
  - Therapy: ACEI or ARB in appropriate patients for vascular disease or DM

- **Stage B**
  - Structural heart disease but without signs or symptoms of HF
  - Goals: Prevent further cardiac remodeling
  - Therapy: ACEI or ARB as appropriate

- **Stage C**
  - Structural heart disease with prior or current symptoms of HF
  - Goals: Prevent mortality
  - Therapy:ACEI or ARB

- **Stage D**
  - Refractory HF of rest or despite GDMT
  - Goals: Reduce hospital readmissions
  - Therapy: ACEI or ARB

*FIGURE 21–5* Stages in the development of heart failure and recommended therapy by stage. ACEI, angiotensin-converting enzyme inhibitor; AF, atrial fibrillation; ARB, angiotensin-receptor blocker; CAD, coronary artery disease; CRT, cardiac resynchronization therapy; DM, diabetes mellitus; EF, ejection fraction; GDMT, guideline-directed medical therapy; HF, heart failure; HFpEF, heart failure with preserved ejection fraction; HFrEF, heart failure with reduced
The body attempts to compensate for LV systolic failure through activation of the sympathetic and renin–angiotensin–aldosterone system. Consequently, patients experience salt retention, volume expansion, sympathetic stimulation, and vasoconstriction. The heart dilates to maintain stroke volume in spite of decreased contractility. Over time, compensatory mechanisms fail and contribute to the symptoms associated with heart failure (eg, dependent edema, tachycardia, decreased tissue perfusion). Patients with systolic heart failure are likely to present to surgery having been previously treated with diuretics, β-blockers, ACE inhibitors or ARBs, and possibly aldosterone antagonists. Electrolytes must be measured, as diuretics frequently lead to hypokalemia. ARB or ACE inhibitor use may contribute to hypotension in the surgical patient with heart failure. ACE inhibitors are rarely associated with angioedema requiring emergent airway management.

Myocardial relaxation is a dynamic, not passive, process. The heart with preserved diastolic function accommodates volume during diastole, with minimal increases in left ventricular end-diastolic pressure. Conversely, the heart with diastolic dysfunction relaxes poorly and produces increased left ventricular end-diastolic pressure. The increased left ventricular end-diastolic pressure is transmitted to the left atrium and pulmonary vasculature resulting in symptoms of congestion. Patients with any form of heart failure have increased risk of perioperative morbidity.

**HYPERTROPHIC CARDIOMYOPATHY**

Hypertrophic cardiomyopathy (HCM) is an autosomal dominant trait that affects 1 in 500 adults. Many patients are unaware of the condition, and some will present with sudden cardiac death as the initial manifestation. Symptoms include dyspnea, exercise intolerance, palpitations, and chest pain. Clinically, HCM is detected by the murmur of dynamic left ventricular outflow tract (LVOT) obstruction in late systole. Symptomatic patients frequently have a thickened intraventricular septum of 20 to 30 mm. A variety of genetic variants have been identified as causative. The myocardium of the intraventricular septum is...
abnormal, and many patients can develop diastolic dysfunction without pronounced dynamic obstructive gradients. During systole, the anterior leaflet of the mitral valve abuts the intraventricular septum (Figure 21–6), producing obstruction and a late systolic murmur.

**FIGURE 21–6** The midesophageal long axis view is shown. As a consequence of the hypertrophied interventricular septum, flow patterns within the heart are altered so that the anterior leaflet of the mitral valve is drawn during ventricular systole into the left ventricular outflow tract (LVOT), producing obstruction. This is known as systolic anterior motion of the mitral valve. (Reproduced with permission from Wasnick J, Hillel Z, Kramer D, et al. Cardiac Anesthesia & Transesophageal Echocardiography. New York, NY: McGraw-Hill Education; 2011.)

Perioperative management is aimed at minimizing the degree of LVOT obstruction. This is accomplished by maintaining adequate intravascular volume, avoiding vasodilatation, and reducing myocardial contractility through the use of β-blockers.

**Valvular Heart Disease**

1. **General Evaluation of Patients**
Regardless of the lesion or its cause, preoperative evaluation should be primarily concerned with determining the identity and severity of the lesion and its hemodynamic significance, ventricular function, and the presence of any secondary effects on pulmonary, renal, or hepatic function. Concomitant CAD should not be overlooked, particularly in older patients and those with known risk factors (see earlier discussion). Myocardial ischemia may occur in the absence of significant coronary occlusion in patients with severe aortic stenosis or regurgitation.

**History**

One should evaluate exercise tolerance, fatigability, pedal edema, and shortness of breath in general (dyspnea), when lying flat (orthopnea), or at night (paroxysmal nocturnal dyspnea). The New York Heart Association functional classification of heart disease ([Table 21–13](#)) is useful for grading the severity of heart failure symptoms and estimating prognosis. Patients should also be questioned about chest pains and neurological symptoms. Some valvular lesions are associated with thromboembolic phenomena. Prior procedures, such as valvotomy or valve replacement and their effects, should also be well documented.

**TABLE 21–13** Modified New York Association functional classification of heart disease.

Medications commonly used by valvular heart disease patients include diuretics, vasodilators, ACE inhibitors, β-blockers, antiarrhythmics, and anticoagulants. Preoperative vasodilator therapy may be used to decrease preload, afterload, or both. Excessive vasodilation worsens exercise tolerance and is often first manifested as postural (orthostatic) hypotension.
**Physical Examination**

The most important signs to identify on physical examination are those of congestive heart failure. Left-sided (S₃ gallop or pulmonary rales) and right-sided (jugular venous distention, hepatojugular reflux, hepatosplenomegaly, or pedal edema) signs may be present. Auscultatory findings may suggest valvular dysfunction, but echocardiographic studies are more reliable. The ACC/AHA guidelines recommend that transthoracic echocardiography be performed as a class I indication in the initial evaluation of patients suspected of having valvular heart disease. Moreover, the ACC/AHA suggest that any change in symptoms or physical examination findings warrants a repeat transthoracic echocardiography exam. Neurological deficits, usually secondary to embolic phenomena, should be documented.

**Laboratory Evaluation**

In addition to the laboratory studies discussed for patients with hypertension and CAD, liver function tests may be useful in assessing hepatic dysfunction caused by passive hepatic congestion in patients with severe or chronic right-sided failure. Adequate reversal of warfarin or heparin anticoagulation may be documented with a prothrombin time and international normalized ratio (INR) or partial thromboplastin time, respectively, prior to surgery.

Electrocardiographic findings are generally nonspecific. The chest radiograph is useful to assess cardiac size and pulmonary vascular congestion.

**Special Studies**

Echocardiography, imaging studies, and cardiac catheterization should only be obtained if the results will change therapy or outcomes. In many instances, noninvasive studies obviate the need for cardiac catheterization, unless there are concerns about CAD. When advanced imaging procedures are performed, they generally address the following questions:

- Which valvular abnormality is most important hemodynamically?
- What is the severity of an identified lesion?
- What degree of ventricular impairment is present?
- What is the hemodynamic significance of other identified abnormalities?
- Is there any evidence of CAD?
The ACC/AHA have prepared detailed guidelines to assist in the management of patients with valvular heart disease. Although the evaluation of the patient with a heart murmur generally rests with the cardiologist, anesthesia providers will on occasion discover a previously undetected murmur on preanesthetic examination. In particular, anesthetists are concerned that undiagnosed, critical aortic stenosis might be present, which could potentially lead to hemodynamic collapse with either regional or general anesthesia. In the past, most valvular heart diseases were a consequence of rheumatic heart disease; however, with an aging surgical population, increasing numbers of patients have degenerative valve problems. More than one in eight patients older than age 75 years may manifest at least one form of moderate to severe valvular heart disease. A study conducted in the Netherlands reported that the prevalence of aortic stenosis was 2.4% in patients older than age 60 years who were scheduled for elective surgery.

Murmurs occur as a consequence of the accelerated blood flow through narrowed openings in stenotic and regurgitant lesions. Although systolic murmurs may be related to increased blood flow velocity, the ACC/AHA guidelines note that all diastolic and continuous murmurs reflect pathology. When new murmurs are detected in a preoperative evaluation, consultation with the patient’s personal physician is helpful to determine the need for echocardiographic evaluation. In many centers, immediate echocardiographic evaluation can be performed in the preoperative area, often by another member of the anesthesia department.

2. Specific Valvular Disorders

MITRAL STENOSIS

Preoperative Considerations

Mitral stenosis almost always occurs as a delayed complication of rheumatic fever. However, mitral stenosis can also occur in dialysis-dependent patients. Two-thirds of patients with mitral stenosis are female. The stenotic process is estimated to begin after a minimum of 2 years following rheumatic heart disease and results from progressive fusion and calcification of the valve leaflets. Symptoms generally develop after 20 to 30 years, when the mitral valve orifice is reduced from its normal 4 to 6 cm² opening to less than 1.5 cm². Less than 50% of patients have isolated mitral stenosis; the remaining patients also have
mitral regurgitation, and up to 25% of patients also have rheumatic involvement of the aortic valve (stenosis or regurgitation).

**Pathophysiology**

The rheumatic process causes the valve leaflets to thicken, calcify, and become funnel shaped; annular calcification may also be present. The mitral commissures fuse, the chordae tendineae fuse and shorten, and the valve cusps become rigid; as a result, the valve leaflets typically display bowing or doming during diastole on echocardiography.

Significant restriction of blood flow through the mitral valve results in a transvalvular pressure gradient that depends on cardiac output, heart rate (diastolic time), and cardiac rhythm. Increases in either cardiac output or heart rate (decreased diastolic time) necessitate higher flows across the valve and result in higher transvalvular pressure gradients. The left atrium is often markedly dilated, promoting SVTs, particularly AF. Blood flow stasis in the atrium promotes the formation of thrombi, usually in the left atrial appendage. Loss of normal atrial systole with AF (which is usually responsible for 20% to 30% of ventricular filling) necessitates even higher diastolic flow across the valve to maintain the same cardiac output and increases the transvalvular gradient.

Acute elevations in left atrial pressure are rapidly transmitted back to the pulmonary capillaries. If mean pulmonary capillary pressure acutely and significantly rises transudation of capillary fluid may result in pulmonary edema. Chronic elevations in pulmonary capillary pressure are partially compensated by increases in pulmonary lymph flow, but eventually result in pulmonary vascular changes, leading to irreversible increases in pulmonary vascular resistance (PVR) and pulmonary hypertension. Reduced lung compliance and a secondary increase in the work of breathing contribute to chronic dyspnea. Right ventricular failure is frequently precipitated by acute or chronic elevations in right ventricular afterload. Marked dilation of the right ventricle can result in tricuspid or pulmonary valve regurgitation.

Embolic events are common in patients with mitral stenosis and AF. Dislodgment of clots from the left atrium results in systemic emboli, commonly to the cerebral circulation. Patients also have an increased incidence of pulmonary emboli, pulmonary infarction, hemoptyisis, and recurrent bronchitis. Chest pain occurs in 10% to 15% of patients with mitral stenosis, even in the absence of CAD; its cause often remains unexplained but may be emboli in the
coronary circulation or acute right ventricular pressure overload. Patients may develop hoarseness as a result of compression of the left recurrent laryngeal nerve by the enlarged left atrium.

Left ventricular function is preserved in the majority of patients with pure mitral stenosis (Figure 21–7); however, impaired left ventricular function may be encountered in up to 25% of patients and presumably represents residual damage from rheumatic myocarditis or coexistent hypertensive or ischemic heart disease.

![Pressure-volume loops in patients with valvular heart disease.](image)

**FIGURE 21–7** Pressure–volume loops in patients with valvular heart disease. A, normal; B, mitral stenosis; C, aortic stenosis; D, mitral regurgitation (chronic); E, aortic regurgitation (chronic). LV, left ventricular. (Reproduced with permission from Jackson JM, Thomas SJ, Lowenstein E. Anesthetic management of patients with valvular heart disease. *Semin Anesth*. 1982;1:239.)

The left ventricle is chronically underloaded in the patient with mitral stenosis and the stroke volume may be reduced. At the same time, the left atrium, right ventricle, and right atrium are frequently dilated and dysfunctional. Vasodilation that occurs following both neuraxial and general anesthesia can lead to peripheral venous blood pooling and inadequate volume delivery to the left ventricle. This can precipitate hemodynamic collapse.

**Treatment**

The time from onset of symptoms to incapacitation averages 5 to 10 years. At
that stage, most patients die within 2 to 5 years. Surgical correction is therefore usually undertaken once significant symptoms develop. Percutaneous transseptal balloon valvuloplasty may be used in selected young or pregnant patients, as well as older patients who are poor surgical candidates. Medical management is primarily supportive and includes limitation of physical activity, sodium restriction, and diuretics. Small doses of a β-adrenergic blocking drug may also be useful in controlling heart rate in patients with mild to moderate symptoms. Patients with a history of emboli and those at high risk (age older than 40 years; a large atrium with chronic atrial fibrillation) are usually anticoagulated.

**Anesthetic Management**

**A. Objectives**

- The principal hemodynamic goals are to maintain a sinus rhythm (if present preoperatively) and to avoid tachycardia, large increases in cardiac output, and both hypovolemia and fluid overload by judicious administration of intravenous fluids.

**B. Monitoring**

Invasive hemodynamic monitoring is often used for major surgical procedures, particularly those associated with large fluid shifts. TEE and noninvasive cardiac output monitors can also be used to help guide perioperative management. Overzealous fluid replacement readily precipitates pulmonary edema in patients with severe disease. Pulmonary capillary wedge pressure measurements in the presence of mitral stenosis reflect the transvalvular gradient and not necessarily left ventricular end-diastolic pressure. Prominent α waves and a decreased y descent are typically present on the pulmonary capillary wedge pressure waveform in patients who are in sinus rhythm. A prominent cv wave on the central venous pressure waveform is usually indicative of secondary tricuspid regurgitation. The ECG typically shows a notched P wave in patients who are in sinus rhythm.

**C. Choice of Agents**

Patients may be very sensitive to the vasodilating effects of spinal and epidural anesthesia. In theory, epidural anesthesia may be easier to manage than spinal anesthesia because of the more gradual onset of sympathetic blockade. There is no “ideal” general anesthetic, and agents should be employed to achieve the desired effects of permitting sufficient diastolic time to adequately load the left
Ventricles. Vasopressors are often needed to maintain vascular tone following anesthetic induction.

Intraoperative tachycardia may be controlled by deepening anesthesia with an opioid (excluding meperidine) or β-blocker (esmolol or metoprolol). In the presence of atrial fibrillation, ventricular rate should be controlled. Marked hemodynamic deterioration from sudden SVT necessitates cardioversion. Phenylephrine is preferred over ephedrine as a vasopressor because the former lacks β-adrenergic agonist activity. Vasopressin can also be employed to restore vascular tone should hypotension develop secondary to anesthetic induction.

MITRAL REGURGITATION

Preoperative Considerations

Mitral regurgitation can develop acutely or insidiously as a result of a large number of disorders. Chronic mitral regurgitation is usually the result of rheumatic fever (often with concomitant mitral stenosis); congenital or developmental abnormalities of the valve apparatus; or dilation, destruction, or calcification of the mitral annulus. Acute mitral regurgitation is usually due to myocardial ischemia or infarction (papillary muscle dysfunction or rupture of a chorda tendinea), infective endocarditis, or chest trauma. The ACC/AHA indicate that primary mitral regurgitation is present when one or more of the components of the mitral valve apparatus contribute to valvular incompetence. Correction of the structure of the mitral valve corrects the underlying disease process. In contrast secondary mitral regurgitation, the ACC/AHA notes, is present when ventricular dilation prevents coaptation of the mitral valve leaflets. In this instance, repair of the valve is not curative according to the ACC/AHA’s valvular heart disease guidelines because the underlying disease process likewise must be addressed in addition to restoration of valvular competency.

Pathophysiology

The principal derangement is a reduction in forward stroke volume due to backward flow of blood into the left atrium during systole. The left ventricle compensates by dilating and increasing end-diastolic volume (Figure 21–7). Regurgitation through the mitral valve initially maintains a normal end-systolic volume in spite of an increased end-diastolic volume. However, as the disease progresses the end-systolic volume increases. By increasing end-diastolic volume, the volume-overloaded left ventricle can maintain a normal cardiac
output despite blood being ejected retrograde into the atrium. With time, patients with chronic mitral regurgitation eventually develop eccentric left ventricular hypertrophy and progressive impairment in contractility. In patients with severe mitral regurgitation, the regurgitant volume may exceed the forward stroke volume. In time, wall stress increases, resulting in an increased demand for myocardial oxygen supply.

The regurgitant volume passing through the mitral valve is dependent on the size of the mitral valve orifice (which can vary with ventricular cavity size), the heart rate (systolic time), and the left ventricular–left atrial pressure gradient during systole. The last factor is affected by the relative resistances of the two outflow paths from the left ventricle, namely, SVR and left atrial compliance. Thus, a decrease in SVR or an increase in mean left atrial pressure will reduce the regurgitant volume. Atrial compliance also determines the predominant clinical manifestations. Patients with normal or reduced atrial compliance (acute mitral regurgitation) have primarily pulmonary vascular congestion and edema. Patients with increased atrial compliance (long-standing mitral regurgitation resulting in a large dilated left atrium) primarily show signs of a reduced cardiac output. Most patients are between the two extremes and exhibit symptoms of both pulmonary congestion and low cardiac output. Patients with a regurgitant fraction of less than 30% of the total stroke volume generally have mild symptoms. Regurgitant fractions of 30% to 60% generally cause moderate symptoms, whereas fractions greater than 60% are associated with severe disease.

Echocardiography, particularly TEE, is useful in delineating the underlying pathophysiology of mitral regurgitation and guiding treatment. Mitral valve leaflet motion is often described as normal, prolapsing, or restrictive (Figure 21–8). Excessive motion or prolapse is defined by systolic movement of a leaflet beyond the plane of the mitral valve and into the left atrium (see later section on mitral valve prolapse).
FIGURE 21–8 Classification of mitral valve leaflet motion (as seen from transesophageal echocardiography). Note that with prolapse, the free edge of the leaflet(s) extends beyond the plane of the mitral annulus, producing an eccentric jet. With restricted motion, the leaflets fail to coapt, resulting in a central jet. LA, left atrium; LV, left ventricle.

**Treatment**
Reduction of SVR increases forward stroke volume and decreases the
regurgitant volume. Surgical treatment is usually reserved for patients with moderate to severe symptoms. Valvuloplasty or valve repair are performed whenever possible to avoid the problems associated with valve replacement (eg, thromboembolism, hemorrhage, and prosthetic failure). Catheter-mediated valve repairs are continually being refined, potentially reducing the need for “open” surgery. Anesthesiologists skilled in advanced perioperative echocardiography assist in correctly identifying the leaflet(s) to be repaired and determining the repair’s success. Three-dimensional echocardiography is increasingly employed to assist in the assessment of the mitral valve (see Figure 5–31).

**Anesthetic Management**

**A. Objectives**

Anesthetic management should be tailored to the severity of mitral regurgitation as well as the underlying left ventricular function. Factors that exacerbate the regurgitation, such as slow heart rates and acute increases in afterload, should be avoided. Bradycardia can increase the regurgitant volume by increasing left ventricular end-diastolic volume and acutely dilating the mitral annulus. The heart rate should ideally be kept between 80 and 100 beats/min. Acute increases in left ventricular afterload, such as with endotracheal intubation and surgical stimulation under “light” anesthesia, should be treated rapidly.

**B. Monitoring**

Monitors are based on the severity of ventricular dysfunction, as well as the procedure. Color-flow Doppler TEE can be invaluable in quantitating the severity of the regurgitation and guiding therapeutic interventions in patients with severe mitral regurgitation. Doppler echocardiography identifies the acceleration of blood as it is ejected through the regurgitant orifice during systole from the left ventricle into the left atrium (Figure 21–9).
FIGURE 21–9 Transesophageal echocardiography using color-flow Doppler demonstrates mitral regurgitation. The left atrium (LA), left ventricle (LV), right ventricle (RV), and ascending aorta (AscAo) are shown. The arrow indicates a jet of mitral regurgitation. (Reproduced with permission from Mathew JP, Swaminathan M, Ayoub CM. Clinical Manual and Review of Transesophageal Echocardiography. 2nd ed. New York, NY: McGraw-Hill Education; 2010.)

C. Choice of Agents

Patients with relatively well-preserved ventricular function tend to do well with most anesthetic techniques. Spinal and epidural anesthesia are well tolerated, provided bradycardia is avoided. Patients with compromised ventricular function can likewise be managed with a variety of anesthetic agents and techniques. Invasive monitoring (arterial line, TEE) can be used to guide perioperative management in patients with severe mitral regurgitation and poor ventricular function. Inodilators such as milrinone may be employed to improve ventricular function and reduce systemic resistance in patients with poor ventricular function and severe mitral regurgitation to promote the forward as opposed to regurgitant blood flow.

MITRAL VALVE PROLAPSE

Preoperative Considerations

Mitral valve prolapse (Barlow syndrome) is classically characterized by a midsystolic click, with or without a late apical systolic murmur on auscultation.
It is a relatively common abnormality that is present in up to 1% to 2.5% of the general population. The diagnosis is suggested by auscultatory findings and confirmed by echocardiography, which shows systolic prolapse of mitral valve leaflets into the left atrium. Patients with the murmur often have some element of mitral regurgitation. The posterior mitral leaflet is more commonly affected than the anterior leaflet. The mitral annulus may also be dilated. Pathologically, most patients have redundancy or some myxomatous degeneration of the valve leaflets. Most cases of mitral valve prolapse are sporadic or familial, affecting otherwise normal persons. A high incidence of mitral valve prolapse is found in patients with connective tissue disorders (particularly Marfan syndrome).

The overwhelming majority of patients with mitral valve prolapse are asymptomatic, but in a small percentage of patients, the myxomatous degeneration is progressive. Manifestations, when they occur, can include chest pains, arrhythmias, embolic events, florid mitral regurgitation, infective endocarditis, and, rarely, sudden death. The diagnosis can be made preoperatively by auscultation of the characteristic click, but must be confirmed by echocardiography. The prolapse is accentuated by maneuvers that decrease ventricular volume (preload). Both atrial and ventricular arrhythmias are common. Although bradyarrhythmias have been reported, paroxysmal supraventricular tachycardia is the most commonly encountered sustained arrhythmia. An increased incidence of abnormal AV bypass tracts is reported in patients with mitral valve prolapse.

Most patients have a normal life span. About 15% develop progressive mitral regurgitation. A smaller percentage develops embolic phenomena or infective endocarditis. Patients with both a click and a systolic murmur seem to be at greater risk of developing complications. Anticoagulation or antiplatelet agents may be used for patients with a history of emboli, whereas β-adrenergic blocking drugs are commonly used for arrhythmias.

**Anesthetic Management**

The management of these patients is based on their clinical course. Most patients are asymptomatic and do not require special care. Ventricular arrhythmias may occur intraoperatively, particularly following sympathetic stimulation, and will generally respond to lidocaine or β-adrenergic blocking agents. Mitral regurgitation caused by prolapse is generally exacerbated by decreases in ventricular size. Hypovolemia and factors that increase ventricular emptying or decrease afterload should be avoided. Vasopressors with pure α-adrenergic agonist activity (such as phenylephrine) may be preferable to those that are
primarily β-adrenergic agonists.

**AORTIC STENOSIS**

**Preoperative Considerations**

Valvular aortic stenosis is the most common cause of obstruction to left ventricular outflow. Left ventricular outflow obstruction is less commonly due to hypertrophic cardiomyopathy, discrete congenital subvalvular stenosis, or, rarely, supravalvular stenosis. Valvular aortic stenosis is typically congenital, rheumatic, or degenerative. Abnormalities in the number of cusps (most commonly a bicuspid valve) or their architecture produce turbulence that traumatizes the valve and eventually leads to stenosis. Rheumatic aortic stenosis is rarely isolated; it is more commonly associated with aortic regurgitation or mitral valve disease. In the most common degenerative form, calcific aortic stenosis, wear and tear results in the buildup of calcium deposits on normal cusps, preventing them from opening completely (**Figure 21–10**).

![Aortic Valve](image)

**FIGURE 21–10** A stenotic aortic valve is clearly seen in this midesophageal short axis aortic valve view. Calcification of the aortic valve is usually associated with senile degeneration. However, congenitally abnormal (bicuspid) and rheumatic presentations also occur. (Reproduced with permission from Wasnick J, Hillel Z, Kramer D, et al. Cardiac Anesthesia & Transesophageal Echocardiography. New York, NY: McGraw-Hill; 2011.)
**Pathophysiology**

Left ventricular outflow obstruction caused by valvular aortic stenosis is almost always gradual, allowing the ventricle, at least initially, to compensate and maintain stroke volume. Concentric left ventricular hypertrophy enables the ventricle to maintain stroke volume by generating the needed transvalvular pressure gradient and reducing ventricular wall stress.

Critical aortic stenosis is said to exist when the aortic valve orifice is reduced to 0.5 to 0.7 cm$^2$ (normal is 2.5–3.5 cm$^2$). With this degree of stenosis, patients generally have a transvalvular gradient of approximately 50 mm Hg at rest (with a normal cardiac output) and are unable to increase cardiac output in response to exertion. Moreover, further increases in the transvalvular gradient do not significantly increase stroke volume. With long-standing aortic stenosis, myocardial contractility progressively deteriorates, compromising left ventricular function.

Classically, patients with advanced (end-stage) aortic stenosis have the triad of heart failure, angina, and syncope. Initial diagnosis in the modern era is usually made earlier in the course of the disease when the more typical complaints are exercise-induced dyspnea, vertigo, or angina. A prominent feature of aortic stenosis is a decrease in left ventricular compliance as a result of hypertrophy. Diastolic dysfunction as a result of an increase in ventricular muscle mass, fibrosis, or myocardial ischemia is to be expected. In contrast to left ventricular end-diastolic volume, which remains normal until very late in the disease, left ventricular end-diastolic pressure is elevated early in the disease. The decreased diastolic pressure gradient between the left atrium and left ventricle impairs ventricular filling, which becomes quite dependent on a normal atrial contraction. Loss of atrial systole can precipitate congestive heart failure or hypotension in patients with aortic stenosis. Cardiac output may be normal in symptomatic patients at rest, but characteristically, it does not appropriately increase with exertion. Patients may experience angina even in the absence of CAD. Myocardial oxygen demand increases because of ventricular hypertrophy, whereas myocardial oxygen supply decreases as a result of the marked compression of intramyocardial coronary coronary vessels caused by high intracavitary systolic pressures (up to 300 mm Hg). Exertional syncope or near-syncope is thought to be due to an inability to tolerate the vasodilation in muscle tissue during exertion. Arrhythmias leading to severe hypoperfusion may also account for syncope and sudden death in some patients.
Treatment

Once symptoms develop, most patients without valve replacement will die within a few years. Percutaneous balloon valvuloplasty is generally used in younger patients with congenital aortic stenosis; it can also be used in elderly patients with calcific aortic stenosis who are poor candidates for aortic valve replacement. Its efficacy for the latter group is short-lived, however, and restenosis usually occurs within 6 to 12 months. Catheter-delivered aortic valves are increasingly being perfected and deployed in the treatment of aortic valve disease. Surgical replacement of the stenotic aortic valve remains the mainstay of therapy.

Anesthetic Management

A. Objectives

- Maintenance of normal sinus rhythm, heart rate, vascular resistance, and intravascular volume is critical in patients with aortic stenosis. Loss of a normally timed atrial systole often leads to rapid deterioration, particularly when associated with tachycardia. The combination of the two (AF with rapid ventricular response) seriously impairs ventricular filling and necessitates immediate cardioversion. Fortunately, AF is uncommon in patients with aortic stenosis. The reduced ventricular compliance also makes the patient very sensitive to abrupt changes in intravascular volume. Many patients behave as though they have a fixed stroke volume in spite of adequate hydration; under these conditions, cardiac output becomes very rate dependent. Extreme bradycardia (<50 beats/min) is therefore poorly tolerated. Heart rates between 60 and 90 beats/min are optimal in most patients.

B. Monitoring

Monitoring for ischemia is complicated by baseline ST-segment and T-wave abnormalities often seen in the aortic stenosis patient. Intraarterial pressure monitoring is desirable in patients with severe aortic stenosis, as many of these patients do not tolerate even brief episodes of hypotension. Vasodilators should be used cautiously, if at all, because patients are often very sensitive to these agents. TEE can be useful in these patients for monitoring ischemia, ventricular preload, contractility, valvular function, and the effects of therapeutic interventions.
C. Choice of Agents
Patients with mild to moderate aortic stenosis (generally asymptomatic) may tolerate spinal or epidural anesthesia. These techniques should be employed very cautiously, however, because hypotension readily occurs as a result of reductions in preload, afterload, or both. A vasoconstrictor medication must be immediately available. Epidural anesthesia may be preferable to single-shot spinal anesthesia because of its slower onset of hypotension, which allows more timely correction. Continuous spinal catheters can similarly be used to gradually increase the level of block and slow the onset of hypotension.

In the patient with severe aortic stenosis the choice of anesthetic agents and techniques is less important than effective management of their hemodynamic effects. Most general anesthetics can produce both vasodilation and hypotension, which require treatment postinduction. If a volatile agent is used, the concentration should be controlled to avoid excessive vasodilation, myocardial depression, or loss of normal atrial systole. Significant tachycardia and severe hypertension, which can precipitate ischemia, should be treated immediately by increasing anesthetic depth or administration of a β-adrenergic blocking agent. Most patients with aortic stenosis tolerate moderate hypertension and are sensitive to vasodilators. Use of vasoconstrictors (eg, vasopressin, phenylephrine, norepinephrine) is often necessary to preserve systemic blood pressure in the anesthetized aortic stenosis patient. Moreover, because of an already precarious myocardial oxygen demand–supply balance, aortic stenosis patients tolerate even mild degrees of hypotension poorly. Intraoperative SVTs with hemodynamic compromise should be treated with immediate synchronized cardioversion. Frequent ventricular ectopy (which often reflects ischemia) is usually poorly tolerated hemodynamically and should be treated.

AORTIC REGURGITATION
Preoperative Considerations
Aortic regurgitation usually develops slowly and is progressive (chronic), but it can also develop quickly (acute). Chronic aortic regurgitation may be caused by abnormalities of the aortic valve, the aortic root, or both. Abnormalities in the valve are usually congenital (bicupid valve) or due to rheumatic fever. Diseases affecting the ascending aorta cause regurgitation by dilating the aortic annulus; they include syphilis, annuloaortic ectasia, cystic medial necrosis (with or without Marfan syndrome), ankylosing spondylitis, rheumatoid and psoriatic
arthritis, and a variety of other connective tissue disorders. Acute aortic insufficiency most commonly follows infective endocarditis, trauma, or aortic dissection.

**Pathophysiology**

Regardless of the cause, aortic regurgitation produces volume overload of the left ventricle. The effective forward stroke volume is reduced because of backward (regurgitant) flow of blood into the left ventricle during diastole. Systemic arterial diastolic pressure and SVR are typically low. The decrease in cardiac afterload helps facilitate ventricular ejection. Total stroke volume is the sum of the effective stroke volume and the regurgitant volume. The regurgitant volume depends on the heart rate (diastolic time) and the diastolic pressure gradient across the aortic valve (diastolic aortic pressure minus left ventricular end-diastolic pressure). Slow heart rates increase regurgitation because of the associated disproportionate increase in diastolic time, whereas increases in diastolic arterial pressure favor regurgitant volume by increasing the pressure gradient for backward flow.

With chronic aortic regurgitation, the left ventricle progressively dilates and undergoes eccentric hypertrophy. Patients with severe aortic regurgitation have the largest end-diastolic volumes of any heart disease. The resulting increase in end-diastolic volume maintains an effective stroke volume. Any increase in the regurgitant volume is compensated by an increase in end-diastolic volume. Left ventricular end-diastolic pressure is usually normal or only slightly elevated, because ventricular compliance initially increases. Eventually, as ventricular function deteriorates, the ejection fraction declines, and impaired ventricular emptying is manifested as gradual increases in left ventricular end-diastolic pressure and end-systolic volume.

Sudden incompetence of the aortic valve does not allow compensatory dilation or hypertrophy of the left ventricle. Effective stroke volume rapidly declines because the normal-sized ventricle is unable to accommodate a sudden large regurgitant volume. The sudden rise in left ventricular end-diastolic pressure is transmitted back to the pulmonary circulation and causes acute pulmonary venous congestion.

Acute aortic regurgitation typically presents as the sudden onset of pulmonary edema and hypotension, whereas chronic regurgitation ultimately manifests as congestive heart failure. Symptoms are generally nil or minimal in the chronic form when the regurgitant volume remains under 40% of stroke volume, but
become severe when it exceeds 60%. Angina can occur even in the absence of coronary disease. The myocardial oxygen demand is increased from muscle hypertrophy and dilation; the myocardial blood supply is reduced by low diastolic pressures in the aorta as a result of the regurgitation, and peak myocardial blood flow occurs in systole rather than diastole.

**Treatment**

Most patients with chronic aortic regurgitation remain asymptomatic for 10 to 20 years. Once significant symptoms develop, the expected survival time is about 5 years without valve replacement. Diuretics and afterload reduction, particularly with ACE inhibitors, generally benefit patients with advanced chronic aortic regurgitation. The decrease in arterial blood pressure reduces the diastolic gradient for regurgitation. Patients with chronic aortic regurgitation should receive valve replacement before irreversible ventricular dysfunction occurs. Percutaneous aortic valve replacement is increasingly used for high-risk patients with aortic insufficiency.

Patients with acute aortic regurgitation typically require intravenous inotropic and vasodilator therapy. Early intervention is indicated in patients with acute aortic regurgitation; medical management alone is associated with a high mortality rate.

**Anesthetic Management**

**A. Objectives**

The heart rate should be maintained toward the upper limits of normal (80–100 beats/min). Bradycardia and increases in SVR increase the regurgitant volume in patients with aortic regurgitation, whereas tachycardia can contribute to myocardial ischemia. Excessive myocardial depression should also be avoided. The compensatory increase in cardiac preload should be maintained, but overzealous fluid replacement can readily result in pulmonary edema.

**B. Monitoring**

Invasive hemodynamic monitoring should be employed in patients with acute aortic regurgitation or those with severe chronic regurgitation. Premature closure of the mitral valve often occurs during acute aortic regurgitation and may cause pulmonary capillary wedge pressure to give a falsely high estimate of left ventricular end-diastolic pressure. The arterial pressure wave in patients with
aortic regurgitation characteristically has a very wide pulse pressure. *Pulsus bisferiens* may also be present in patients with moderate to severe aortic insufficiency and is thought to result from the rapid ejection of a large stroke volume. Color-flow Doppler TEE can be invaluable in quantitating the severity of the regurgitation and guiding therapeutic interventions (Figure 21–11).

![Echocardiography Image](image)

**FIGURE 21–11** Transesophageal echocardiography using color-flow Doppler demonstrates aortic regurgitation. The left ventricular outflow tract (LVOT), left atrium (LA), and ascending aorta (ASCAO) are seen. The *arrow* demonstrates an eccentrically directed jet of aortic regurgitation. (Reproduced with permission from Mathew JP, Swaminathan M, Ayoub CM. Clinical Manual and Review of Transesophageal Echocardiography. 2nd ed. New York, NY: McGraw-Hill Education; 2010.)

Severe aortic regurgitation rapidly raises left ventricular pressure during diastole. Echocardiography can also detect reversal of blood flow in the aorta during diastole in patients with severe aortic regurgitation. The more severe the regurgitation, the further distal in the aorta that diastolic flow reversal is identified.

**C. Choice of Agents**
Most patients with aortic insufficiency tolerate spinal and epidural anesthesia well, provided intravascular volume is maintained. When general anesthesia is required, inhalational agents may be ideal because of the associated vasodilation. Phenylephrine (25–50 mcg) can be used to treat hypotension secondary to
excessive anesthetic-induced vasodilation; however, large doses of phenylephrine may increase SVR (and arterial diastolic pressure) sufficiently to worsen the regurgitation.

**TRICUSPID REGURGITATION**

**Preoperative Considerations**

Most patients have trace to mild tricuspid regurgitation on echocardiography; the regurgitant volume in these cases is almost always trivial. Clinically significant tricuspid regurgitation, however, is most commonly due to dilation of the right ventricle from pulmonary hypertension that is associated with chronic left ventricular failure. Tricuspid regurgitation can also follow infective endocarditis, rheumatic fever, carcinoid syndrome, or chest trauma or may be due to Ebstein anomaly (downward displacement of the valve because of abnormal attachment of the valve leaflets).

**Pathophysiology**

Chronic left ventricular failure often leads to sustained increases in pulmonary vascular pressures. The chronic increase in afterload causes progressive dilation of the thin-walled right ventricle, and excessive dilation of the tricuspid annulus eventually results in regurgitation. An increase in end-diastolic volume allows the right ventricle to compensate for the regurgitant volume and maintain an effective forward flow. Because the right atrium and the vena cava are compliant and can usually accommodate the volume overload, mean right atrial and central venous pressures are generally only slightly elevated. Acute or marked elevations in pulmonary artery pressures increase the regurgitant volume and are reflected by an increase in central venous pressure. Moreover, sudden marked increases in right ventricular afterload sharply reduce the effective right ventricular output, reduce left ventricular preload, and can precipitate systemic hypotension.

Chronic venous hypertension leads to passive congestion of the liver and progressive hepatic dysfunction. Severe right ventricular failure with underloading of the left heart may also produce right-to-left shunting through a patent foramen ovale, which can result in marked hypoxemia.

The normal right ventricle does not extend to the apex of the heart when visualized using echocardiography. As the right heart dilates, it acquires a more spherical shape, the right ventricle extends to the apex of the heart, and the
Interventricular septum is flattened. These changes can impair left heart function.

**Treatment**

Tricuspid regurgitation is generally well tolerated by most patients. Because the underlying disorder is generally more important than the tricuspid regurgitation itself, treatment is aimed at the underlying disease process. Recent studies suggest that correction of significant tricuspid regurgitation with annuloplasty is beneficial when patients with moderate to severe tricuspid regurgitation are brought to surgery for replacement of another valve.

**Anesthetic Management**

**A. Objectives**

Hemodynamic goals should be directed primarily toward the underlying disorder. Hypovolemia and factors that increase right ventricular afterload, such as hypoxia and acidosis, should be avoided to maintain effective right ventricular stroke volume and left ventricular preload. Positive end-expiratory pressure and high mean airway pressures may also be undesirable during mechanical ventilation because they reduce venous return and increase right ventricular afterload.

**B. Monitoring**

Invasive monitoring may be useful. Pulmonary artery catheterization is rarely used and often not feasible; rarely a large regurgitant flow may make passage of a pulmonary artery catheter across the tricuspid valve difficult. Increasing central venous pressure implies worsening right ventricular dysfunction. The $x$ descent is absent, and a prominent $cv$ wave is usually present on the central venous pressure waveform. Thermodilution cardiac output measurements are falsely elevated because of the tricuspid regurgitation. Color-flow Doppler TEE is useful in evaluating the severity of the regurgitation and other associated abnormalities.

**C. Choice of Agents**

The selection of anesthetic agents should be based on the underlying disorder. Most patients tolerate spinal and epidural anesthesia well. Coagulopathy secondary to hepatic dysfunction should be excluded prior to any regional technique.
ENDOCARDITIS PROPHYLAXIS

The ACC/AHA guidelines regarding prophylactic antibiotic regimens in patients with prosthetic heart valves and other structural heart abnormalities have dramatically changed in recent years, decreasing the number of indications for antibiotic administration. The risk of antibiotic administration is often considered greater than the potential for developing perioperative endocarditis. At present, the ACC/AHA guidelines suggest the use of endocarditis prophylaxis in the highest risk patients undergoing dental procedures involving gingival manipulation or perforation of the oral mucosa (class IIa); see Table 21–14. Such conditions include:

**TABLE 21–14 Regimens for a dental procedure.**

<table>

</tbody>
</table>

2 IM, Intramuscular; IV, Intravenous.
3 Use other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.
4 Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.

- Patients with prosthetic cardiac valves or prosthetic heart materials
- Patients with a past history of endocarditis
- Patients with congenital heart disease that is either partially repaired or un repaired
- Patients with congenital heart disease with residual defects following repair
- Patients with congenital heart disease within 6 months of a complete repair, whether catheter-based or surgical
- Cardiac transplant patients with structurally abnormal valves

Class III recommendations indicate that prophylaxis is not necessary for nondental procedures, including TEE and esophagogastroduodenoscopy, except in the presence of an active infection.
Endocarditis is believed to occur in areas of cardiac endothelial damage, where in cases of bacteremia, bacteria can be deposited and multiply. Areas of increased myocardial blood flow velocity lead to damaged endothelium, providing a template for bacterial adherence and growth. Guidelines are ever changing, and not considered to be “standard of care.” Nevertheless, deviation from guidelines often requires explanation as being outside of “evidence-based” practice. Review of the ACC/AHA guidelines is recommended when high-risk patients are encountered.

**ANTICOAGULATION**

Patients with mechanical prosthetic heart valves require anticoagulation, which is currently accomplished with warfarin. Aspirin is also indicated in this population, as well as in patients with bioprosthetic valves, to prevent thrombus formation. Warfarin is sometimes also used initially for mitral bioprosthetic valves.

Patients with prosthetic valves often present for noncardiac surgery that will require temporary discontinuation of anticoagulation. The ACC/AHA guidelines indicate that patients at low risk of thrombosis, such as those with bileaflet mechanical valves in the aortic position with no additional problems (eg, no AF or no hypercoagulable state) can discontinue warfarin 48 to 72 hours preoperatively so that the INR falls below 1.5. In patients at greater risk of thrombosis, warfarin should be discontinued and heparin, either unfractionated or low molecular weight, started when the INR falls below 2.0. Heparin can be discontinued 4 to 6 hours prior to surgery and then restarted as soon as surgical bleeding permits, until the patient can be restarted on warfarin therapy. Fresh frozen plasma or prothrombin complex concentrates may be given, if needed, in an emergency situation to interrupt warfarin therapy. Anesthesia providers should always consult with the patient's surgeon and the physician responsible for prescribing the anticoagulation before adjusting anticoagulation or antiplatelet regimens perioperatively.

---

**Congenital Heart Disease**

**Preoperative Considerations**

Congenital heart disease encompasses a seemingly endless list of abnormalities that may be detected in infancy, early childhood, or, less commonly, adulthood.
The incidence of congenital heart disease in all live births approaches 1%. The natural history of some defects is such that patients often survive to adulthood (Table 21–15). Moreover, the number of surviving adults with corrected or palliated congenital heart disease is steadily increasing with advances in surgical and medical treatment. Patients with congenital heart disease may therefore be encountered during noncardiac surgery and obstetric deliveries. Knowledge of the anatomy of the original heart structure defect and of any corrective repairs is essential prior to anesthetizing the patient with congenital heart disease.

**TABLE 21–15** Common congenital heart defects in which patients typically survive to adulthood without treatment.

The complex nature and varying pathophysiology of congenital heart defects make classification difficult. A commonly used scheme is presented in Table 21–16. Most patients present with cyanosis, congestive heart failure, or an asymptomatic abnormality. Cyanosis is typically the result of an abnormal intracardiac communication that allows unoxygenated blood to reach the systemic arterial circulation (right-to-left shunting). Congestive heart failure is most prominent with defects that either obstruct left ventricular outflow or markedly increase pulmonary blood flow. The latter is usually due to an abnormal intracardiac communication that returns oxygenated blood to the right heart (left-to-right shunting). Whereas right-to-left shunts generally decrease pulmonary blood flow, some complex lesions increase pulmonary blood flow—even in the presence of right-to-left shunting. In many cases, more than one lesion is present. Survival prior to surgical correction with some anomalies (eg, transposition, total anomalous venous return, pulmonary atresia) depends on the simultaneous presence of another shunting lesion (eg, patent ductus arteriosus, patent foramen ovale, ventricular septal defect). Chronic hypoxemia in patients with cyanotic heart disease typically results in erythrocytosis. This increase in red cell mass, which is due to increased erythropoietin secretion from the kidneys, serves to restore tissue oxygen concentration to normal. Unfortunately,
blood viscosity can also rise to the point at which it may interfere with oxygen delivery. When tissue oxygenation is restored to normal, the hematocrit is stable (usually <65%), and symptoms of the hyperviscosity syndrome are absent, the patient is said to have compensated erythrocytosis. Patients with uncompensated erythrocytosis do not establish this equilibrium; they have symptoms of hyperviscosity and may be at risk of thrombotic complications, particularly stroke. The risk of stroke is aggravated by dehydration. Children younger than age 4 years seem to be at greatest risk of stroke. Phlebotomy is generally not recommended if symptoms of hyperviscosity are absent and the hematocrit is less than 65%.

Coagulation abnormalities are common in patients with cyanotic heart disease. Platelet counts tend to be low-normal, and many patients have defects in the coagulation cascade. Hyperuricemia often occurs because of increased urate reabsorption secondary to renal hypoperfusion, and can result in progressively impaired kidney function.

Preoperative echocardiography is invaluable in defining the anatomy of the defect(s) and to confirm or exclude the existence of other lesions or complications, their physiological significance, and the effects of any therapeutic interventions.

**Anesthetic Management**

This population of patients includes four groups: (1) those who have undergone corrective cardiac surgery and require no further operations, (2) those who have had only palliative surgery, (3) those who have not yet undergone any cardiac surgery, and (4) those whose conditions are inoperable and may be awaiting cardiac transplantation. Although the management of the first group of patients may be the same as that of normal patients (except for consideration of prophylactic antibiotic therapy), the care of others requires familiarity with the complex pathophysiology of these defects (Tables 21–17 and 21–18).

1. Table references
Pulmonary hypertension, primary or secondary
Cyanotic congenital heart disease
New York Heart Association class III or IV
Severe systemic ventricular dysfunction (ejection fraction less than 35%)
Severe left-sided heart obstructive lesions

**Moderate risk**
- Prosthetic valve or conduit
- Intracardiac shunt
- Moderate left-sided heart obstruction
- Moderate systemic ventricular dysfunction

For the purpose of anesthetic management, congenital heart defects may be divided into obstructive lesions, predominantly left-to-right shunts, or predominantly right-to-left shunts. Shunts can also be bidirectional and may reverse under certain conditions.

### 1. Obstructive Lesions

**Pulmonic Stenosis**
Pulmonary valve stenosis obstructs right ventricular outflow and causes concentric right ventricular hypertrophy. Severe obstruction presents in the neonatal period, whereas lesser degrees of obstruction may go undetected until adulthood. The valve is usually deformed and is either bicuspid or tricuspid. Valve leaflets are often partially fused and display systolic doming on echocardiography. The right ventricle undergoes hypertrophy, and poststenotic dilation of the pulmonary artery is often present. Symptoms are those of right ventricular heart failure. Symptomatic patients readily develop fatigue, dyspnea, and peripheral cyanosis with exertion as a result of the limited pulmonary blood flow and increased oxygen extraction by tissues. With severe stenosis, the pulmonic valve gradient exceeds 60 to 80 mm Hg, depending on the age of the patient. Right-to-left shunting may also occur in the presence of a patent foramen ovale or atrial septal defect. Cardiac output is very dependent on an elevated heart rate, but excessive increases in the latter can compromise ventricular filling. Percutaneous balloon valvuloplasty is generally considered
the initial treatment of choice in most patients with symptomatic pulmonic stenosis. Anesthetic management for patients undergoing surgery should maintain a normal or slightly high heart rate, augment preload, and avoid factors that increase PVR (such as hypoxemia or hypercarbia).

2. Predominantly Left-to-Right (Simple) Shunts

Simple shunts are isolated abnormal communications between the right and left sides of the heart. Because pressures are normally higher on the left side of the heart, blood usually flows across from left to right, and blood flow through the right heart and the lungs increases. Depending on the size and location of the communication, the right ventricle may also be subjected to the higher left-sided pressures, resulting in both pressure and volume overload. Right ventricular afterload is normally 5% that of the left ventricle, so even small left-to-right pressure gradients can produce large increases in pulmonary blood flow. The ratio of pulmonary (Qp) to systemic (Qs) blood flow is useful to determine the directionality of the shunt.

A ratio greater than 1 usually indicates a left-to-right shunt, whereas a ratio less than 1 indicates a right-to-left shunt. A ratio of 1 indicates either no shunting or a bidirectional shunt of opposing magnitudes.

Large increases in pulmonary blood flow produce pulmonary vascular congestion and increase extravascular lung water. The latter interferes with gas exchange, decreases lung compliance, and increases the work of breathing. Left atrial distention also compresses the left bronchus, whereas distention of pulmonary vessels compresses smaller bronchi.

Over the course of several years, chronic increases in pulmonary blood flow produce vascular changes that irreversibly increase PVR. Elevation of right ventricular afterload produces hypertrophy and progressively raises right-sided cardiac pressures. With advanced disease, the pressures within the right heart can exceed those within the left heart. Under these conditions, the intracardiac shunt reverses and becomes a right-to-left shunt (Eisenmenger syndrome).

When a communication is small, shunt flow depends primarily on the size of the communication (restrictive shunt). When the communication is large (nonrestrictive shunt), shunt flow depends on the relative balance between PVR and SVR. An increase in SVR relative to PVR favors left-to-right shunting, whereas an increase in PVR relative to SVR favors right-to-left shunting. Common chamber lesions (eg, single atrium, single ventricle, truncus arteriosus) represent the extreme form of nonrestrictive shunts; shunt flow with these lesions is bidirectional and totally dependent on relative changes in the
ventricular afterload.

The presence of shunt flow between the right and left hearts, regardless of the direction of blood flow, mandates the meticulous exclusion of air bubbles and particulate material from intravenous fluids to prevent paradoxical embolism into the cerebral or coronary circulations.

**Atrial Septal Defects**

Ostium secundum atrial septal defects (ASDs) are the most common form and usually occur as isolated lesions in the area of the fossa ovalis. The defect is sometimes associated with partial anomalous pulmonary venous return, most commonly of the right upper pulmonary vein. A secundum ASD may result in single or multiple (fenestrated) openings between the atria. The less common sinus venosus and ostium primum ASDs are typically associated with other cardiac abnormalities. Sinus venosus defects are located in the upper interatrial septum close to the superior vena cava; one or more of the right pulmonary veins often abnormally drains into the superior vena cava. In contrast, ostium primum ASDs are located in the lower interatrial septum and overlie the mitral and tricuspid valves; most patients also have a cleft in the anterior leaflet of the mitral valve, and some have an abnormal septal leaflet in the tricuspid valve.

Most children with ASDs are minimally symptomatic; some have recurrent pulmonary infections. Congestive heart failure and pulmonary hypertension are more commonly encountered in adults with ASDs. Patients with ostium primum defects often have large shunts and may also develop significant mitral regurgitation. In the absence of heart failure, anesthetic responses to inhalation and intravenous agents are generally not significantly altered in patients with ASDs. **Large increases in SVR should be avoided because they may worsen the left-to-right shunting.**

**Ventricular Septal Defects**

Ventricular septal defect (VSD) is a common congenital heart defect, accounting for up to 25% to 35% of congenital heart disease. The defect is most frequently found in the membranous part of the interventricular septum (membranous or infracristal VSD) in a posterior position and anterior to the septal leaflet of the tricuspid valve. Muscular VSDs are the next most frequent type and are located in the mid or apical portion of the interventricular septum, where there may be a single defect or multiple openings (resembling Swiss cheese). Defects in the subpulmonary (supracristal) septum are often associated with aortic regurgitation.
because the right coronary cusp can prolapse into the VSD. Septal defects at the ventricular inlet are usually similar in development and location to AV septal defects (see the following section).

The resulting functional abnormality of a VSD is dependent on the size of the defect, PVR, and the presence or absence of other abnormalities. Small VSDs, particularly of the muscular type, may close during childhood. Restrictive defects are associated with only small left-to-right shunts. Patients with small VSDs are treated medically and followed with electrocardiography (for signs of right ventricular hypertrophy) and echocardiography. Surgical closure is usually undertaken in patients with large VSDs before pulmonary vascular disease and Eisenmenger physiology develop. In the absence of heart failure, anesthetic responses to inhalation and intravenous agents are generally not significantly altered. Similarly, increases in SVR worsen the left-to-right shunting. **When right-to-left shunting is present, abrupt increases in PVR or decreases in SVR are poorly tolerated.**

**Atrioventricular Septal Defects**

Endocardial cushion (AV canal) defects produce contiguous atrial and ventricular septal defects, often with very abnormal AV valves. This is a common lesion in patients with Down syndrome. The defect can produce large shunts both at the atrial and ventricular levels. Mitral and tricuspid regurgitation exacerbate the volume overload on the ventricles. Initially, shunting is predominately left to right; however, with increasing pulmonary hypertension, Eisenmenger syndrome with obvious cyanosis develops.

**Patent Ductus Arteriosus**

Persistence of the communication between the main pulmonary artery and the aorta can produce restrictive or nonrestrictive left-to-right shunts. This abnormality is commonly responsible for the cardiopulmonary deterioration of premature infants and occasionally presents later in life when it can be corrected thoracoscopically. Anesthetic goals should be similar to atrial and ventricular septal defects.

**Partial Anomalous Venous Return**

This defect is present when one or more pulmonary veins drains into the right side of the heart; the anomalous veins are usually from the right lung. Possible
anomalous entry sites include the right atrium, the superior or inferior vena cava, and the coronary sinus. The resulting abnormality produces a variable amount of left-to-right shunting. The clinical course and prognosis are usually excellent and similar to that of a secundum ASD. Obstructed total anomalous pulmonary venous return is emergently corrected immediately after birth.

3. Predominantly Right-to-Left (Complex) Shunts
Lesions within this group (some also called mixing lesions) often produce both ventricular outflow obstruction and shunting. The obstruction favors shunt flow toward the unobstructed side. When the obstruction is relatively mild, the amount of shunting is affected by the ratio of SVR to PVR, but increasing degrees of obstruction fix the direction and magnitude of the shunt. Atresia of any one of the cardiac valves represents the extreme form of obstruction. Shunting occurs proximal to the atretic valve and is completely fixed; survival depends on another distal shunt (usually a patent ductus arteriosus [PDA], patent foramen ovale, ASD, or VSD), where blood flows in the opposite direction. This group of defects may also be divided according to whether they increase or decrease pulmonary blood flow.

Tetralogy of Fallot
This anomaly classically includes right ventricular outflow obstruction, right ventricular hypertrophy, and a VSD with an overriding aorta. Right ventricular obstruction in most patients is due to infundibular stenosis, which is due to hypertrophy of the subpulmonic muscle (crista ventricularis). At least 20% to 25% of patients also have pulmonic stenosis, and a small percentage of patients has some element of supravalvular obstruction. The pulmonic valve is often bicuspid, or, less commonly, atretic. Infundibular obstruction may be increased by sympathetic tone and is therefore dynamic; this obstruction is likely responsible for the hypercyanotic spells observed in very young patients. The combination of right ventricular outflow obstruction and a VSD results in ejection of unoxygenated right ventricular blood, as well as oxygenated left ventricular blood into the aorta. The right-to-left shunting across the VSD has both fixed and variable components. The fixed component is determined by the severity of the right ventricular obstruction, whereas the variable component depends on SVR and PVR.

Surgical palliation with a left-to-right systemic shunt or complete correction is usually undertaken. For the former, a modified Blalock–Thomas–Taussig
(systemic–pulmonary artery) shunt is most often used to increase pulmonary blood flow. In this procedure, a synthetic graft is anastomosed between a subclavian artery and an ipsilateral pulmonary artery. Complete correction involves closure of the VSD, removal of obstructing infundibular muscle, and pulmonic valvulotomy or valvuoplasty, when necessary.

The goals of anesthetic management in patients with tetralogy of Fallot should be to maintain intravascular volume and SVR. Increases in PVR, such as might occur from acidosis or excessive airway pressures, should be avoided. **Ketamine (intramuscular or intravenous) is a commonly used induction agent because it maintains or increases SVR and therefore does not aggravate the right-to-left shunting.** Patients with milder degrees of shunting generally tolerate inhalation induction. The right-to-left shunting tends to slow the uptake of inhalation anesthetics; in contrast, it may accelerate the onset of intravenous agents. Oxygenation often improves following induction of anesthesia. Muscle relaxants that release histamine should be avoided. Hypercyanotic spells may be treated with intravenous fluid and phenylephrine (5 mcg/kg). β-Blockers (eg, propranolol) may also be effective in relieving infundibular spasm.

**Tricuspid Atresia**

With tricuspid atresia, blood can flow out of the right atrium only via a patent foramen ovale (or an ASD). Moreover, a PDA (or VSD) is necessary for blood to flow from the left ventricle into the pulmonary circulation. Cyanosis is usually evident at birth, and its severity depends on the amount of pulmonary blood flow that is achieved. Early survival is dependent on prostaglandin E₁ infusion (to maintain PDA patency), with or without a percutaneous balloon atrial septostomy. Severe cyanosis requires a modified Blalock–Thomas–Taussig shunt early in life. The preferred surgical management is a modified Fontan procedure, in which the venous drainage is directed to the pulmonary circulation. In some centers, a superior vena cava to the main pulmonary artery (bidirectional Glenn) shunt may be employed before or instead of a Fontan procedure. With both procedures, blood from the systemic veins flows through the pulmonary circulation to the left atrium without the assistance of the right ventricle. Success of the procedure depends on a high systemic venous pressure and maintaining both low PVR and a low left atrial pressure. Heart transplantation may be necessary for a failed Fontan procedure.
Transposition of the Great Arteries

In patients with transposition of the great arteries, pulmonary and systemic venous return flows normally back to the right and left atrium, respectively, but the aorta arises from the right ventricle, and the pulmonary artery arises from the left ventricle. Thus, deoxygenated blood returns back into the systemic circulation, and oxygenated blood returns back to the lungs. Survival is possible only through mixing of oxygenated and deoxygenated blood across the foramen ovale and a PDA. The presence of a VSD increases mixing and reduces the level of hypoxemia. Prostaglandin E₁ infusion is usually necessary. Corrective surgical treatment involves an arterial switch procedure in which the aorta is divided and reanastomosed to the left ventricle, and the pulmonary artery is divided and reanastomosed to the right ventricle. The coronary arteries must also be reimplanted into the old pulmonary artery root. A VSD, if present, is closed. Less commonly, an atrial switch (Senning) procedure may be carried out if an arterial switch is not possible. In this latter procedure, an intraatrial baffle is created from the atrial wall, and blood from the pulmonary veins flows across an ASD to the right ventricle, from which it is ejected into the systemic circulation.

Transposition of the great vessels may occur with a VSD and pulmonic stenosis. This combination of defects mimics tetralogy of Fallot; however, the obstruction affects the left ventricle, not the right ventricle. Corrective surgery involves patch closure of the VSD, directing left ventricular outflow into the aorta, ligation of the proximal pulmonary artery, and connecting the right ventricular outflow to the pulmonary artery with a valved conduit (Rastelli procedure).

Truncus Arteriosus

With a truncus arteriosus defect, a single arterial trunk supplies the pulmonary and systemic circulation. Both ventricles eject into the truncus as it always overrides a VSD. As PVR gradually decreases after birth, pulmonary blood flow increases greatly, resulting in heart failure. If left untreated, PVR increases, and cyanosis develops again, along with Eisenmenger physiology. Surgical correction closes the VSD, separates the pulmonary artery from the truncus, and connects the right ventricle to the pulmonary artery with a conduit (Rastelli repair).

Hypoplastic Left Heart Syndrome
This syndrome describes a group of defects characterized by aortic valve atresia and marked underdevelopment of the left ventricle. The right ventricle is the main pumping chamber for both systemic and pulmonary circulations. It ejects normally into the pulmonary artery, and all (or nearly all) blood flow entering the aorta is usually derived from a PDA. Surgical treatment includes both the Norwood repair and a hybrid approach to palliation. In the Norwood repair, a new aorta is created from the hypoplastic aorta and the main pulmonary artery. Pulmonary blood flow is delivered via a Blalock–Thomas–Taussig shunt. The right ventricle becomes the heart’s systemic pumping ventricle. A hybrid approach has also been advocated for the palliation of hypoplastic left heart syndrome. In this approach, the pulmonary arteries are banded to reduce pulmonary blood flow, and the PDA is stented to provide for systemic blood flow.

The Patient with a Transplanted Heart

Preoperative Considerations

The number of patients with cardiac transplants is increasing because of both the increasing frequency of transplantation and improved posttransplant survival rates. These patients may present to the operating room early in the postoperative period for mediastinal exploration or retransplantation, or they may appear later for incision and drainage of infections, orthopedic surgery, or unrelated procedures.

The transplanted heart is totally denervated, so direct autonomic influences are absent. Cardiac impulse formation and conduction are normal, but the absence of vagal influences causes a relatively high resting heart rate (100–120 beats/min). Although sympathetic fibers are similarly interrupted, the response to circulating catecholamines is normal or even enhanced because of denervation sensitivity (increased receptor density). Cardiac output tends to be low-normal and increases relatively slowly in response to exercise because the response is dependent on an increase in circulating catecholamines. Because the Starling relationship between end-diastolic volume and cardiac output is normal, the transplanted heart is also often said to be preload dependent. Coronary autoregulation is preserved.

Preoperative evaluation should focus on evaluating the functional status of the transplanted organ and detecting complications of immunosuppression. Rejection may be heralded by arrhythmias (in the first 6 months) or decreased
exercise tolerance from a progressive deterioration of myocardial performance. Periodic echocardiographic evaluations are commonly used to monitor for rejection, but the most reliable technique is endomyocardial biopsy. Accelerated atherosclerosis in the graft is a very common and serious problem that limits the life of the transplant. Moreover, myocardial ischemia and infarction are almost always silent because of the denervation. Because of this, patients must undergo periodic evaluations, including angiography, for assessment of coronary atherosclerosis.

Immunosuppressive therapy may include cyclosporine, tacrolimus, and prednisone. Important side effects include nephrotoxicity, bone marrow suppression, hepatotoxicity, opportunistic infections, and osteoporosis. Hypertension and fluid retention are common and typically require treatment with a diuretic and an ACE inhibitor.

**Anesthetic Management**

Almost all anesthetic techniques, including regional anesthesia, have been used successfully for transplanted patients. The preload-dependent function of the graft makes maintenance of a normal or high cardiac preload desirable. Moreover, the absence of reflex increases in heart rate can make patients particularly sensitive to rapid vasodilation. Indirect vasopressors, such as ephedrine, are less effective than direct-acting agents because of the absence of catecholamine stores in myocardial neurons. Isoproterenol or epinephrine infusions should be readily available to increase the heart rate if necessary.

Electrocardiographic monitoring for ischemia is necessary. The ECG usually demonstrates two sets of P waves, one representing the recipient’s own sinoatrial (SA) node (which is left intact), and the other representing the donor’s SA node. The recipient’s SA node may still be affected by autonomic influences, but it does not affect cardiac function. Direct arterial pressure monitoring should be used for major operations; strict asepsis should be observed during placement.

In a recently transplanted patient, the right ventricle of the transplanted heart may not be able to overcome the resistance of the pulmonary vasculature. Right ventricular failure can occur perioperatively, requiring the use of inhaled nitric oxide, inotropes, and, at times, right ventricular assist devices.

Because the number of transplantable hearts is limited, patients are increasingly treated with left ventricular assist devices (LVADs). LVADs drain blood from the apex of the left ventricular and in a nonpulsatile manner pump oxygenated blood into the aorta, restoring blood delivery to the tissues (Figure
Patients require anticoagulation to prevent pump thrombosis. Maintenance of right heart function is essential to adequately supply the left side of the heart with sufficient blood for the device to eject. Hypovolemia, pulmonary hypertension, and right heart failure can lead to inadequate loading of the left heart, resulting in reduced LVAD pump flows. LVAD patients presenting for noncardiac procedures are routinely managed by cardiac anesthesiologists familiar with LVAD operations and skilled in advanced perioperative echocardiography.
CASE DISCUSSION

Hip Fracture in an Elderly Woman Who Fell
A 71-year-old woman presents for open reduction and internal fixation of a left hip fracture. She gives a history of two episodes of lightheadedness several days prior to her fall today. When questioned about her fall, she can only recall standing in her bathroom while brushing her teeth and then awakening on the floor with hip pain. The preoperative ECG shows a sinus rhythm with a P–R interval of 220 ms and a right bundle-branch block (RBBB) pattern.

Why should the anesthesiologist be concerned about a history of syncope?

A history of syncope in elderly patients should always raise the possibility of arrhythmias and underlying organic heart disease. Although arrhythmias can occur in the absence of organic heart disease, the two are commonly related. Cardiac syncope usually results from an abrupt arrhythmia that suddenly compromises cardiac output and impairs cerebral perfusion. Lightheadedness and presyncope, may reflect lesser degrees of cerebral impairment. Both bradyarrhythmias and tachyarrhythmias (see Chapter 20) can produce syncope. Table 21–19 lists other cardiac and noncardiac causes of syncope.

How do bradyarrhythmias commonly arise?

Bradyarrhythmias may arise from either SA node dysfunction or abnormal AV conduction of the cardiac impulse. A delay or block of the impulse can occur anywhere between the SA node and the distal His-Purkinje system). Reversible abnormalities may be due to abnormal vagal tone, electrolyte abnormalities, drug toxicity, hypothermia, or myocardial ischemia. Irreversible abnormalities, which initially may be only
intermittent before they become permanent, reflect either isolated conduction system abnormalities or underlying heart disease (most commonly hypertensive, coronary artery, or valvular heart disease).

**What is the pathophysiology of sinus node dysfunction?**

Patients with sinus node dysfunction may have a normal baseline 12-lead ECG but abrupt pauses in SA node activity (sinus arrest) or intermittent block of conduction of the SA impulse to the surrounding tissue (exit block). Symptoms are usually present when pauses are prolonged (>3 s) or the effective ventricular rate is less than 40 beats/min. Patients may experience intermittent dizziness, syncope, confusion, fatigue, or shortness of breath. Symptomatic SA node dysfunction, or sick sinus syndrome, is often unmasked by β-adrenergic blocking agents, calcium channel blockers, digoxin, or quinidine. The term tachycardia–bradycardia syndrome is often used when patients experience paroxysmal tachyarrhythmias (usually atrial flutter or fibrillation) followed by sinus pauses or bradycardia. The latter, bradycardia, probably represents failure of the SA node to recover normal automaticity following suppression by the tachyarrhythmia.

**How are AV conduction abnormalities manifested on the surface 12-lead ECG?**

AV conduction abnormalities are usually manifested by abnormal ventricular depolarization (bundle-branch block), prolongation of the P–R interval (first-degree AV block), failure of some atrial impulses to depolarize the ventricles (second-degree AV block), or AV dissociation (third-degree AV block; also called complete heart block).

**What determines the significance of these conduction abnormalities?**

The significance of a conduction system abnormality depends on its location, its likelihood for progression to complete heart block, and the likelihood that a more distal pacemaker site will be able to maintain a stable and adequate escape rhythm (>40 beats/min). The His bundle is normally the lowest area in the conduction system that can maintain a stable rhythm (usually 40–60 beats/min). When conduction fails anywhere above it, a normal His bundle can take over the pacemaker function of the heart and maintain a normal QRS complex, unless a distal intraventricular conduction defect is present. When the escape rhythm arises farther down the His-
Purkinje system, the rhythm is usually slower (<40 beats/min) and is often unstable; it results in a wide QRS complex.

**What is the significance of isolated bundle-branch block with a normal P–R interval?**

A conduction delay or block in the right bundle-branch results in a typical RBBB QRS pattern on the surface ECG (M-shape or rSR' in V1) and may represent a congenital abnormality or underlying organic heart disease. In contrast, a delay or block in the main left bundle-branch results in a left bundle-branch block (LBBB) QRS pattern (wide R with a delayed upstroke in V5) and nearly always represents underlying heart disease. The term *hemiblock* is often used if only one of the two fascicles of the left bundle-branch is blocked (left anterior or left posterior hemiblock). When the P–R interval is normal—and in the absence of an acute MI—a conduction block in either the left or right bundle rarely leads to complete heart block.

**Can the site of an AV block always be determined from a 12-lead ECG?**

No. A first-degree AV block (P–R interval >200 ms) can reflect abnormal conduction anywhere between the atria and the distal His-Purkinje system. Mobitz type I second-degree AV block, which is characterized by progressive lengthening of the P–R interval before a P wave is not conducted (a QRS does not follow the P wave), is usually due to a block in the AV node itself, and can be caused by digitalis toxicity or myocardial ischemia; progression to a third-degree AV block is uncommon.

In patients with Mobitz type II second-degree AV block, atrial impulses are periodically not conducted into the ventricle without progressive prolongation of the P–R interval. The conduction block is nearly always in or below the His bundle and frequently progresses to complete (third-degree) AV block, particularly following an acute anteroseptal MI. The QRS is typically wide.

In patients with a third-degree AV block, the atrial rate and ventricular depolarization rates are independent (AV dissociation) because atrial impulses completely fail to reach the ventricles. If the site of the block is in the AV node, a stable His bundle rhythm will result in a normal QRS complex, and the ventricular rate will often increase following
administration of atropine. If the block involves the His bundle, the origin of the ventricular rhythm is more distal, resulting in wide QRS complexes. A wide QRS complex does not necessarily exclude a normal His bundle, as it may represent a more distal block in one of the bundle branches.

*Can AV dissociation occur in the absence of AV block?*

Yes. AV dissociation may occur during anesthesia with volatile agents in the absence of AV block and results from sinus bradycardia or an accelerated AV junctional rhythm. During isorhythmic dissociation, the atria and ventricles beat independently at nearly the same rate. The P wave often just precedes or follows the QRS complex, and their relationship is generally maintained. In contrast, interference AV dissociation results from a junctional rhythm that is faster than the sinus rate—such that sinus impulses always find the AV node refractory.

*How do bifascicular and trifascicular blocks present?*

A bifascicular block exists when two of the three major His bundle-branches (right, left anterior, or left posterior) are partially or completely blocked. If one fascicle is completely blocked and the others are only partially blocked, a bundle-branch block pattern will be associated with either first-degree or second-degree AV block. If all three are affected, a trifascicular block is said to exist. A delay or partial block in all three fascicles results in either a prolonged P–R interval (first-degree AV block) or alternating LBBB and RBBB. Complete block in all three fascicles results in third-degree AV block.

*What is the significance of the electrocardiographic findings in this patient?*

The electrocardiographic findings (first-degree AV block plus RBBB) suggest a bifascicular block. Extensive disease of the conduction system is likely. Moreover, the patient’s syncopal and near-syncopal episodes suggest that she may be at risk of life-threatening bradyarrhythmias (third-degree AV block). Intracardiac electrocardiographic recordings would be necessary to confirm the site of the conduction delay.

*What is appropriate management for this patient?*

Cardiac evaluation is required because of the symptomatic bifascicular block. One of two approaches can be recommended, depending on the
urgency of the surgery. If the surgery is truly emergent, a temporary transvenous pacing catheter or a transcutaneous pacemaker is indicated prior to induction of general or regional anesthesia. If the surgery can be postponed 24 to 48 h (as in this case), continuous electrocardiographic monitoring, echocardiography, serial 12-lead ECGs, and measurements of cardiac biomarkers can be obtained to exclude myocardial ischemia or infarction, valvular heart disease, or congestive heart failure, in addition to other pathological conditions that might adversely affect the patient’s surgical outcome.

**What are general perioperative indications for temporary pacing?**

Suggested indications include any documented symptomatic bradyarrhythmia, second-degree (type II) AV block, or third-degree AV block and refractory supraventricular tachyarrhythmias. The first three indications generally require ventricular pacing, whereas the fourth requires atrial pacing electrodes and a programmable rapid atrial pulse generator.

**How can temporary cardiac pacing be established?**

Pacing can be established by transvenous, transcutaneous, epicardial, or transesophageal electrodes. The most reliable method is generally via a transvenous pacing electrode in the form of a pacing wire or a balloon-tipped pacing catheter. A pacing wire should always be positioned fluoroscopically, but a flow-directed pacing catheter can also be placed in the right ventricle under pressure monitoring. If the patient has a rhythm, an intracardiac electrocardiographic recording showing ST-segment elevation when the electrode comes in contact with the right ventricular endocardium confirms placement of either type of electrode. Transcutaneous ventricular pacing is also possible via large stimulating adhesive pads placed on the chest and should be used whenever transvenous pacing is not readily available. Epicardial electrodes are usually used during cardiac surgery. Pacing the left atrium via an esophageal electrode is a simple, relatively noninvasive technique, but it is useful only for symptomatic sinus bradycardias and for terminating some supraventricular tachyarrhythmias.

Once positioned, the pacing electrodes are attached to an electrical pulse generator that periodically delivers an impulse at a set rate and magnitude. Most pacemaker generators can also sense the heart’s spontaneous (usually ventricular) electrical activity: when activity is detected, the generator
suppresses its next impulse. By altering the generator’s sensing threshold, the pacemaker generator can function in a fixed (asynchronous) mode or in a demand mode (by increasing sensitivity). The lowest current through the electrode that can depolarize the myocardium is called the threshold current (usually $<2$ mA for transvenous electrodes).

**What is AV sequential pacing?**

Ventricular pacing often reduces cardiac output because the atrial contribution to ventricular filling is lost. When the AV conducting system is diseased, atrial contraction can still be maintained by sequential stimulation by separate atrial and ventricular electrodes. The P–R interval can be varied by adjusting the delay between the atrial and ventricular impulses (usually set at 150–200 ms).

**How are pacemakers classified?**

Pacemakers are categorized by a five-letter code, according to the chambers paced, chambers sensed, response to sensing, programmability, and arrhythmia function (Table 21–20). The two most commonly used pacing modes are VVI and DDD (the last two letters are frequently omitted).

**If a pacemaker is placed in this patient, how can its function be evaluated?**

If the patient’s underlying rhythm is slower than the rate of a demand pacemaker, pacing spikes should be seen on the ECG. The spike rate should be identical to the programmed (permanent pacemaker—usually 72/min) or set (temporary) pacemaker rate; a slower rate may indicate a low battery. Every pacing spike should be followed by a QRS complex (100% capture). Moreover, every impulse should be followed by a palpable arterial pulse. If the patient has a temporary pacemaker, the escape rhythm can be
established by temporarily slowing the pacing rate.

When the patient’s heart rate is faster than the set pacemaker rate, pacing spikes should not be observed if the generator is sensing properly. In this instance, ventricular capture cannot be evaluated unless the pacemaker rate increases or the spontaneous heart rate decreases.

**What intraoperative conditions may cause the pacemaker to malfunction?**

*Electrical interference from surgical electrocautery units can be interpreted as myocardial electrical activity and can suppress the pacemaker generator.* Problems with electrocautery may be minimized by limiting its use to short bursts, limiting its power output, placing its grounding plate as far from the pacemaker generator as possible, and using bipolar cautery. Moreover, continuous monitoring of an arterial pulse wave (pressure, plethysmogram, or oximetry signal) is mandatory to ensure continuous perfusion during electrocautery.

Both hypokalemia and hyperkalemia can alter the pacing electrodes’ threshold for depolarizing the myocardium and can result in failure of the pacing impulse to depolarize the ventricle. Myocardial ischemia, infarction, or scarring can also increase the electrodes’ threshold and cause failure of ventricular capture.

**What are appropriate measures if a pacemaker fails intraoperatively?**

If a temporary pacemaker fails intraoperatively, the inspired oxygen concentration should be increased to 100%. All connections and the generator battery should be checked. Most units have a battery-level indicator and a light that flashes with every impulse. The generator should be set into the asynchronous mode, and the ventricular output should be set on maximum. Failure of a temporary transvenous electrode to capture the ventricle is usually due to displacement of the electrode away from the ventricular endocardium; careful slow advancement of the catheter or wire while pacing often results in capture. Pharmacological management (atropine, isoproterenol, or epinephrine) may be useful until the problem is resolved. If an adequate arterial blood pressure cannot be maintained with adrenergic agonists, cardiopulmonary resuscitation should be instituted until another pacing electrode is placed or a new generator box is obtained. Transcutaneous pacing can be employed.
If a permanent pacemaker malfunctions (as with electrocautery), it should generally be converted to an asynchronous mode. Some units will automatically reprogram themselves to the asynchronous mode if malfunction is detected. Other pacemaker units must be reprogrammed by placing either an external magnet, or, preferably, a programming device over the generator. The effect of an external magnet on some pacemakers—particularly during electrocautery—may be unpredictable and should generally be determined prior to surgery.

**Which anesthetic agents are appropriate for patients with pacemakers?**

All anesthetic agents have been safely used in patients who already have pacemakers. Even volatile agents seem to have no effect on pacing electrode thresholds. Local anesthesia with moderate to deep intravenous sedation is usually used for placement of permanent pacemakers.

**SUGGESTED READINGS**

W.B. Saunders; 2009.
Anesthesia for Cardiovascular Surgery

KEY CONCEPTS

1. Cardiopulmonary bypass (CPB) diverts venous blood away from the heart (most often via one or more cannulas in the right atrium), adds oxygen, removes CO₂, and returns the blood through a cannula in a large artery (usually the ascending aorta or a femoral artery). As a result, nearly all blood bypasses the heart and lungs.

2. The fluid level in the reservoir is critical. If a “roller” pump is used and the reservoir is allowed to empty, air can enter the main pump and be propelled into the patient where it may cause organ damage or fatality.

3. Initiation of CPB is associated with a variable increase in stress hormones and systemic inflammation.

4. Establishing the adequacy of the patient’s preoperative cardiac function should be based on exercise (activity) tolerance, measurements of myocardial contractility such as ejection fraction, severity and location of coronary stenoses, ventricular wall motion abnormalities, cardiac end-diastolic pressures, cardiac output, and valvular areas and gradients.

5. Blood should be immediately available for transfusion if the patient has had previous cardiac surgery (a “redo”); when there has been a previous sternotomy, the right ventricle or coronary grafts may be adherent to the sternum and may be accidentally entered during the repeat sternotomy.

6. Transesophageal echocardiography (TEE) provides valuable information about cardiac anatomy and function during surgery. Two-dimensional, multiplane TEE can detect regional and global ventricular
abnormalities, chamber dimensions, valvular anatomy, and the presence of intracardiac air.

Anesthetic dose requirements are variable. Severely compromised patients should be given anesthetic agents in incremental, small doses. Patient tolerance of inhaled anesthetics generally declines with declining ventricular function.

Anticoagulation must be established before CPB to prevent acute disseminated intravascular coagulation and formation of clots in the CPB pump.

Antifibrinolytic therapy may be particularly useful for patients who are undergoing a repeat operation; who refuse blood products, such as Jehovah’s Witnesses; who are at high risk for postoperative bleeding because of recent administration of glycoprotein IIb/IIIa inhibitors (abciximab, eptifibatide, or tirofiban); who have preexisting coagulopathy; or who are undergoing long and complicated procedures.

Hypotension from impaired ventricular filling may occur during manipulation of the venae cavae and the heart.

Hypothermia (<34°C) potentiates general anesthetic potency, but failure to give anesthetic agents, particularly during rewarming on CPB, may result in awareness and recall.

Protamine administration can result in a number of adverse hemodynamic effects, some of which are immunological in origin. Protamine given slowly (5–10 min) usually has few effects; when given more rapidly it produces a fairly consistent vasodilation that is easily treated with blood from the pump oxygenator and small doses of phenylephrine. Catastrophic protamine reactions often include myocardial depression and marked pulmonary hypertension. Diabetic patients previously maintained on protamine-containing insulin (such as NPH) may be at increased risk for adverse reactions to protamine.

Persistent bleeding often follows prolonged durations of bypass (>2 h) and in most instances has multiple causes. Inadequate surgical control of bleeding sites, incomplete reversal of heparin, thrombocytopenia, platelet dysfunction, hypothermia-induced coagulation defects, undiagnosed preoperative hemostatic defects, or newly acquired factor deficiency or hypofibrinogenemia may be responsible.

Chest tube drainage in the first 2 h of more than 250 to 300 mL/h (10 mL/kg/h)—in the absence of a hemostatic defect—is excessive and may require surgical reexploration. Intrathoracic bleeding at a site not
adequately drained may cause cardiac tamponade, requiring immediate reopening of the chest.

Factors known to increase pulmonary vascular resistance (PVR), such as acidosis, hypercapnia, hypoxia, enhanced sympathetic tone, and high mean airway pressures, are to be avoided for patients with right-to-left shunting; hyperventilation (hypocapnia) with 100% oxygen is usually effective in lowering PVR. Conversely, patients with left-to-right shunting may benefit from systemic vasodilation and increases in PVR.

Induction of general anesthesia in patients with cardiac tamponade can precipitate severe hypotension and cardiac arrest.

The sudden increase in left ventricular afterload after application of the aortic cross-clamp during aortic surgery may precipitate acute left ventricular failure and myocardial ischemia, particularly in patients with underlying ventricular dysfunction or coronary disease. The period of greatest hemodynamic instability follows the release of the aortic cross-clamp; the abrupt decrease in afterload together with bleeding and the release of vasodilating acid metabolites from the ischemic lower body can precipitate severe systemic hypotension.

The emphasis of anesthetic management during carotid surgery is on maintaining adequate perfusion to the brain and heart.

To provide anesthesia for cardiovascular surgery, ideally one will have an understanding of circulatory physiology, pharmacology, and pathophysiology; cardiopulmonary bypass (CPB) pumps, filters, and circuitry; transesophageal echocardiography (TEE); and techniques of myocardial preservation. Because surgical manipulations of the heart and great vessels will often have a profound impact on circulatory function, the anesthesiologist must understand the rationale behind the surgical techniques and follow the progress of the surgery closely, so that he or she can anticipate potential problems associated with each sequential step of the procedure.

This chapter presents an overview of anesthesia for cardiovascular surgery and of the principles, techniques, and physiology of CPB. Surgery on the aorta, the carotid arteries, and the pericardium presents special problems, which are also discussed herein.

---

**Cardiopulmonary Bypass**
CPB diverts venous blood away from the heart (most often via one or more cannuas in the right atrium), adds oxygen, removes CO₂, and returns the blood through a cannula in a large artery (usually the ascending aorta or a femoral artery). As a result, nearly all blood bypasses the heart and lungs. When CPB is fully established, it provides both artificial ventilation and perfusion via the systemic circulation. This technique provides distinctly nonphysiological conditions, because mean arterial pressure is usually less than normal and blood flow is usually nonpulsatile. To minimize organ damage during this stressful period, varying degrees of systemic hypothermia may be employed. Topical hypothermia (an ice-slush solution) and cardioplegia (a chemical solution for arresting myocardial electrical activity) may also be used to protect the heart.

The operation of the CPB machine is a complex task requiring the attention of a perfusionist—a specialized, certified technician. Optimal results with CPB require close cooperation and clear, continuing communication among the surgeon, anesthesiologist, and perfusionist.

**BASIC CIRCUIT**

The typical CPB machine has six basic components: a venous reservoir, an oxygenator, a heat exchanger, a main pump, an arterial filter, tubing that conducts venous blood to the venous reservoir, and tubing that conducts oxygenated blood back to the patient (Figure 22–1). Modern CPB machines use a single disposable unit that includes the reservoir, oxygenator, and heat exchanger. Most machines also have separate accessory pumps that can be used for blood salvage (cardiotomy suction), venting (draining) the left ventricle, and administration of cardioplegia solutions. A number of other filters, alarms, and in-line pressure, oxygen-saturation, and temperature monitors are also typically used.
Prior to use, the CPB circuit must be primed with fluid (typically 1200–1800 mL for adults) that is devoid of bubbles. A balanced salt solution, such as lactated Ringer solution, is generally used, but other components are frequently added, including colloid (albumin or starch), mannitol (to promote diuresis), heparin (500–5000 units), and bicarbonate. At the onset of bypass in adults, when using a crystalloid priming solution, hemodilution typically decreases the hematocrit to about 22% to 27%. Blood is included in priming solutions for smaller children and severely anemic adults to prevent excessive hemodilution.

**Reservoir**

The reservoir of the CPB machine receives blood from the patient via one or two venous cannulas placed in the right atrium, the superior and inferior vena cava, or a femoral vein. With most circuits blood returns to the reservoir by gravity drainage. During extracorporeal circulation the patient’s venous pressure is normally low. Thus, the driving force for flow into the pump is directly related to the difference in height between the patient and the reservoir and inversely proportional to the resistance of the cannulas and tubing. An appropriately primed CPB machine draws in blood like a siphon. Entrainment of air in the venous line can produce an air lock that may prevent blood flow. With some circuits (eg, use of an unusually small venous cannula) assisted venous drainage may be required; a regulated vacuum together with a hard shell venous reservoir or centrifugal pump (see below) is used in such instances. The fluid level in
the reservoir is critical. If a “roller” pump is used and the reservoir is allowed to empty, air can enter the main pump and be propelled into the patient where it may cause organ damage or fatality. A low reservoir level alarm is typically present. Centrifugal pumps will not pump air but have the disadvantage of not impelling a well-defined volume with each revolution of the head (unlike roller pumps).

**Oxygenator**

Blood is drained by gravity from the bottom of the venous reservoir into the oxygenator, which contains a blood–gas interface that allows blood to equilibrate with the gas mixture (primarily oxygen). A volatile anesthetic is frequently added to the oxygenator gas mixture. The blood–gas interface in a modern, membrane-type oxygenator is a very thin, gas-permeable silicone membrane. Arterial CO$_2$ tension during CPB is dependent on total gas flow past the oxygenator. A membrane oxygenator permits the perfusion to have independent control of PaO$_2$ and PacO$_2$ by varying the inspired oxygen concentration and the gas flow rate.

**Heat Exchanger**

Blood from the oxygenator enters the heat exchanger and can either be cooled or warmed, depending on the temperature of the water flowing through the exchanger; heat transfer occurs by conduction. Because gas solubility decreases as blood temperature rises, a filter or trap is built into the unit to catch any bubbles that may form during rewarming.

**Main Pump**

Modern CPB machines use either an electrically driven double-arm roller (positive displacement) or a centrifugal pump to propel blood through the CPB circuit.

**A. Roller Pumps**

Roller pumps produce flow by compressing large-bore tubing in the main pumping chamber as the roller heads turn. Subtotal occlusion of the tubing prevents excessive red cell trauma. The rollers pump blood regardless of the resistance encountered, and produce a nearly continuous nonpulsatile flow. Flow
is directly proportional to the number of revolutions per minute. In some pumps, an emergency backup battery provides power in case of an electrical power failure. All roller pumps have a hand crank to allow manual pumping, but those who have hand cranked a roller pump head will confirm that this is not a good long-term solution to an electric power failure.

B. Centrifugal Pumps
Centrifugal pumps consist of a series of cones in a plastic housing. As the cones spin, the centrifugal forces created propel the blood from the centrally located inlet to the periphery. In contrast to roller pumps, blood flow with centrifugal pumps is pressure sensitive and must be monitored by an electromagnetic flowmeter. Increases in distal pressure will decrease flow and must be compensated for by increasing the pump speed. Because these pumps are nonocclusive, they are less traumatic to blood than roller pumps. Unlike roller pumps, which are placed after the oxygenator (Figure 22–1), centrifugal pumps are normally located between the venous reservoir and the oxygenator. Centrifugal (unlike roller) pumps have the advantage of not being able to pump air into the patient.

C. Pulsatile Flow
Pulsatile blood flow is possible with some roller pumps. Pulsations can be produced by instantaneous variations in the rate of rotation of the roller heads; they can also be added after flow is generated. Pulsatile flow is not available with centrifugal pumps. Although there is no consensus and the data are contradictory, some clinicians believe that pulsatile flow improves tissue perfusion, enhances oxygen extraction, attenuates the release of stress hormones, and results in lower systemic vascular resistance during CPB.

Arterial Filter
Particulate matter (eg, thrombi, fat globules, tissue debris) may enter the CPB circuit via the cardiotomy suction line. A final, in-line, arterial filter (that passes particles smaller than 27–40 μm) helps to reduce systemic embolism. Once filtered, the propelled blood returns to the patient, usually via a cannula in the ascending aorta, or less commonly in the femoral artery. A competent aortic valve prevents blood from regurgitating into the left ventricle.

Arterial inflow pressure is measured before the filter. Arterial inflow pressure is measured before the filter so as to monitor the filter for clogging. The filter is
always in parallel with a (normally clamped) bypass limb. The filter is also designed to trap gas bubbles, which can be bled out through a built-in stopcock.

**Accessory Pumps & Devices**

**A. Cardiotomy Suction**
The cardiotomy suction pump aspirates blood from the surgical field during CPB and returns it directly to the main pump reservoir. This is a potential portal for fat and other debris to enter the pump and embolize to organs. A red cell salvage suction device may also be used to aspirate blood from the surgical field, in which case blood is returned to a separate reservoir. When sufficient blood has accumulated (or at the end of the procedure), the salvaged blood is centrifuged, washed, and returned to the patient. Excessive suction pressure can theoretically contribute to red cell trauma. Extensive use of cell salvage suction (instead of cardiotomy suction) during bypass will deplete CPB circuit volume when blood loss is brisk. The high negative pressure of ordinary wall suction devices produces excessive red cell trauma precluding blood salvage from that source.

**B. Left Ventricular Vent**
Over time, even with “total” CPB, blood reaccumulates in the left ventricle as a result of residual pulmonary flow via the bronchial arteries (which arise directly from the aorta or the intercostal arteries) or thebesian vessels (see Chapter 20), or sometimes as a result of aortic valvular regurgitation. Aortic regurgitation can occur as a result of either structural valvular abnormalities or surgical manipulation of the heart. Distention of the left ventricle compromises myocardial preservation (see below) and requires decompression (venting). Surgeons may “vent” the left ventricle by inserting a catheter via the right superior pulmonary vein, through the left atrium, and across the mitral valve into the left ventricle, or by inserting a catheter in the left ventricular apex or across the aortic valve. The blood aspirated by the vent pump normally passes through a filter before being returned to the venous reservoir.

**C. Cardioplegia Pump**
Cardioplegic solutions are most often administered via an accessory pump on the CPB machine. This technique allows optimal control over the infusion pressure, rate, and temperature. A separate heat exchanger ensures control of the temperature of the cardioplegia solution. Less commonly, cardioplegic solutions may be infused from a cold intravenous fluid bag under pressure or by gravity.
D. Ultrafiltration

Ultrafiltration can be used during CPB to increase the patient’s hematocrit without transfusion. Ultrafilters consist of hollow capillary fibers that can function as membranes, allowing separation of the aqueous phase of blood from its cellular and proteinaceous elements. Blood can be diverted to pass through the fibers either from the arterial side of the main pump or from the venous reservoir using an accessory pump. Hydrostatic pressure forces water and electrolytes across the fiber membrane. Effluents of up to 40 mL/min may be removed.

SYSTEMIC HYPOTHERMIA

Intentional hypothermia is often used following the initiation of CPB. Core body temperature may be reduced to 20°C to 32°C. In recent years, so-called tepid bypass has been used; this may be accomplished by allowing the patient’s temperature to “drift” downward to 30°C to 35°C. Metabolic oxygen requirements are generally halved with each reduction of 10°C in body temperature. Some of the adverse effects of hypothermia include platelet dysfunction, coagulopathy, and depression of myocardial contractility. At the end of the surgical procedure, rewarming via the heat exchanger restores normal body temperature.

For complex repairs, profound hypothermia to temperatures of 15°C to 18°C allows total circulatory arrest for durations of as long as 60 min. During that time, both the heart and the CPB machine are stopped.

MYOCARDIAL PRESERVATION

Optimal results in cardiac surgery require an expeditious and complete surgical repair with minimal physical trauma to the heart. Meanwhile, several techniques are used to prevent myocardial damage and maintain normal cellular integrity and function during CPB. Nearly all patients sustain at least minimal myocardial injury during cardiac surgery. With good preservation techniques, however, most of the injury is reversible. Although myocardial injury can be related to hemodynamic instability or surgical technique, it most commonly appears to be related to incomplete myocardial preservation during CPB. Injury related to hemodynamic instability results from an imbalance between oxygen demand and supply, producing cell ischemia. Reperfusion following a period of ischemia may produce excess oxygen-derived free radicals, intracellular calcium overload,
abnormal endothelial–leukocyte interactions, and myocardial cellular edema. Patients at greatest risk are those with poor preoperative ventricular function (see Table 21–13), ventricular hypertrophy, diffuse severe coronary artery disease, or a combination of these. Inadequate myocardial preservation is usually manifested at the end of bypass as a persistently reduced cardiac output, worsened ventricular function as assessed by TEE, or cardiac arrhythmias. Electrocardiographic signs of myocardial ischemia are often difficult to detect due to frequent use of electrical pacing. Myocardial “stunning,” resulting from ischemia and reperfusion, produces systolic and diastolic dysfunction that is reversible with time. The stunned myocardium usually responds to positive inotropic drugs. Myocardial necrosis, on the other hand, produces irreversible injury.

Aortic cross-clamping during CPB completely excludes the coronary arteries from the generalized bypass machine flow to the body, halting coronary blood flow. Although it is difficult to estimate a safe time period for cross-clamping or CPB duration because of differing vulnerabilities among patients and differing techniques for myocardial preservation, CPB times longer than 120 min (while often unavoidable) increase risk. Myocardial ischemia during bypass may occur not only during aortic clamping, but also after release of the cross-clamp. Low arterial pressures, obstruction of the bypass graft ostium, coronary artery embolism (from thrombi, platelets, air, fat, or atheromatous debris), reperfusion injury, coronary artery or bypass graft vasospasm, and contortion of the heart—causing compression or kinking of the coronary vessels—are all possible causes. Areas of the myocardium distal to a high-grade coronary obstruction are at greatest risk.

Ischemia causes depletion of high-energy phosphate compounds and accumulation of intracellular calcium. When coronary blood flow ceases, anaerobic metabolism becomes the principal source of cellular energy, and fatty acid oxidation is impaired. Unfortunately, these high energy phosphate stores are rapidly depleted, producing a progressive acidosis.

Cardioplegic solutions maintain normal cellular integrity and function during CPB by reducing energy expenditure and preserving availability of high-energy phosphate compounds. Although measures directed at increasing or replenishing energy substrates in the form of glucose or glutamate/aspartate infusions are used, the emphasis of myocardial preservation is on reducing cellular energy requirements to minimal levels. This is accomplished initially by the use of potassium cardioplegia (described below). The initial dose of cardioplegic solution may be hypothermic or may start warm (“hot shot”) and progress to
cold. Maintenance of myocardial protection may be facilitated by systemic and topical cardiac hypothermia (ice slush). Myocardial hypothermia reduces basal metabolic oxygen consumption, and potassium cardioplegia minimizes energy expenditure by arresting both electrical and mechanical activity. Myocardial temperature is often monitored directly; 10°C to 15°C is usually considered desirable. Cardioplegic solutions can be administered either antegrade through a catheter placed in the proximal aorta between the aortic clamp and the aortic valve, or retrograde through a catheter placed through the right atrium into the coronary sinus.

Ventricular fibrillation and distention (previously discussed) are important causes of myocardial damage. Ventricular fibrillation can dangerously increase myocardial oxygen demand, whereas distention not only increases oxygen demand but also reduces oxygen supply by interfering with subendocardial blood flow. The combination of the two is particularly bad. Other factors that might contribute to perioperative myocardial damage include the use of excessive doses of positive inotropes or calcium salts. In open heart procedures, de-airing of cardiac chambers and venting before and during initial cardiac ejection are critically important in preventing cerebral or coronary air embolism (and strokes—see later discussion). Removing air from coronary grafts during bypass procedures is similarly important. Depending on the amount and the location of coronary emboli, even small air bubbles can cause varying degrees of ventricular dysfunction at the end of CPB. Air emboli may preferentially find their way into the right (versus left) coronary ostium because of its superior location on the aortic root in the supine patient.

**Potassium Cardioplegia**

The most widely used method of arresting myocardial electrical activity is the administration of potassium-rich crystalloid or blood–crystalloid solutions. Following initiation of CPB and aortic cross-clamping, the coronary circulation is perfused intermittently with (usually cold) cardioplegic solutions. The resulting increase in extracellular potassium concentration reduces transmembrane potential. Eventually, the heart is arrested in diastole. Usually, cold cardioplegia must be repeated at intervals (about every 30 min) because of gradual washout and rewarming of the myocardium. The heart is subject to warming by contact with blood in the adjacent descending aorta and by contact with warmer ambient air in the surgical theater. Moreover, multiple doses of cardioplegia solutions may improve myocardial preservation by preventing an excessive accumulation of metabolites that inhibit anaerobic metabolism.
Although the exact recipe varies from center to center, the essential ingredient of the induction dose of cardioplegic solution is the same: an elevated potassium (10–40 mEq/L) concentration in the initial dose. Potassium concentration is kept below 40 mEq/L because higher levels can be associated with an excessive potassium load and excessive potassium concentrations at the end of termination of bypass perfusion. Sodium concentration in cardioplegic solutions is usually less than in plasma (<140 mEq/L) because ischemia tends to increase intracellular sodium content. A small amount of calcium (0.7–1.2 mmol/L) is needed to maintain cellular integrity, whereas magnesium (1.5–15 mmol/L) is usually added to control excessive intracellular influxes of calcium. A buffer—most commonly bicarbonate—is necessary to prevent excessive buildup of acid metabolites; in fact, alkalotic perfusates are reported to produce better myocardial preservation. Alternative buffers include histidine and tromethamine (also known as THAM). Other components may include hypertonic agents to control cellular edema (mannitol) and agents thought to have membrane-stabilizing effects (lidocaine or glucocorticoids). Energy substrates are provided as glucose, glutamate, or aspartate. The question of whether to use crystalloid or blood as a vehicle for achieving cardioplegia remains controversial, although blood cardioplegia has become very common in North America. Evidence suggests that at least some groups of high-risk patients may do better with blood cardioplegia. Certainly, oxygenated blood cardioplegia may contain more oxygen than crystalloid cardioplegia.

Because cardioplegia may not reach areas distal to high-grade coronary obstructions (the areas that need it most), many surgeons administer retrograde cardioplegia through a coronary sinus catheter. Some centers have reported that the combination of antegrade plus retrograde cardioplegia is superior to either technique alone. Others have suggested that continuous warm blood cardioplegia is superior to intermittent hypothermic cardioplegia for myocardial preservation, but many surgeons avoid continuous cardioplegia so that they can operate in a “bloodless” surgical field. Cardiac surgery performed with true normothermia (rather than tepid bypass) raises additional concerns about loss of the potentially protective effects of systemic hypothermia against cerebral injury.

As discussed previously, with prolonged myocardial ischemic times (cross-clamp time), reperfusion of the myocardium can lead to extensive cell injury, rapid accumulation of intracellular calcium, and potentially irreversible cellular necrosis. This process has long been attributed to accumulation of oxygen-derived free radicals. Free radical scavengers, such as mannitol, may help decrease reperfusion injury and are typical constituents of cardioplegic solutions.
and bypass “priming” solutions. Several steps may help limit reperfusion injury before unclamping of the aorta. Just prior to reperfusion, the heart may be perfused by a reduced potassium cardioplegic solution that serves to wash out accumulated metabolic byproducts. Alternatively, a “hot shot” or warm blood cardioplegic solution may be administered to wash out byproducts and replenish metabolic substrates. Hypercalcemia should be avoided in the immediate reperfusion period. Reperfusion pressures should be controlled closely because of altered coronary autoregulation. Systemic perfusion pressure is reduced just prior to clamp release; it is then brought up initially to about 40 mm Hg before gradually being increased and maintained at about 70 mm Hg. To further minimize metabolic requirement, the heart should have the opportunity to recover and resume contracting in an empty state for some additional time (5–10 min), and acidosis and hypoxia should be corrected before attempting to wean the patient from CPB.

Inadequate myocardial protection or inadequate washout and recovery from cardioplegia can result in asystole, atrioventricular conduction block, or a poorly contracting heart at the end of bypass. Excessive volumes of hyperkalemic cardioplegic solutions may produce persisting systemic hyperkalemia. Although calcium salt administration partially offsets hyperkalemia, excessive calcium can promote and enhance myocardial damage. In the usual patient, myocardial performance improves with time as the contents of the cardioplegia are cleared from the heart.

**PHYSIOLOGICAL EFFECTS OF CARDIOPULMONARY BYPASS**

**Hormonal, Humoral, & Immunological Responses**

- Initiation of CPB is associated with a variable increase in stress hormones and systemic inflammation. Elevated concentrations of catecholamines, cortisol, arginine vasopressin, and angiotensin are observed. These neurohormonal responses are variably influenced by depth of anesthesia, blood pressure, type of surgical repair, or presence of pulsatile CPB.

  Multiple humoral systems are also activated, including complement, coagulation, fibrinolysis, and the kallikrein system. Contact of blood with the internal surfaces of the CPB system activates complement via the alternate pathway (C3) as well as the classic pathway; the latter also activates the coagulation cascade, platelets, plasminogen, and kallikrein. Mechanical trauma
from blood contact with the bypass apparatus also activates platelets and leukocytes. Increased amounts of oxygen-derived free radicals are generated. A systemic inflammatory response similar to that seen with sepsis and trauma can develop. When this response is intense or prolonged, patients can develop the same complications as are seen with sepsis or trauma, including generalized edema, acute respiratory distress syndrome, coagulopathy, and acute kidney failure.

CPB alters and depletes glycoprotein receptors on the surface of platelets. The resulting platelet dysfunction likely increases perioperative bleeding and potentiates other coagulation abnormalities (activation of plasminogen and the inflammatory response previously described).

The inflammatory response to CPB can be modulated by various therapies. Leukocyte depletion reduces inflammation and may similarly reduce complications. Leukocyte-depleted blood cardioplegia has been shown to improve myocardial preservation in some studies. Hemofiltration (ultrafiltration) during CPB, which presumably removes inflammatory cytokines, appears beneficial to pediatric patients. Administration of free radical scavengers such as high-dose vitamins C and E and mannitol has improved outcome in some studies, but remains investigational. Systemic corticosteroids before and during CPB can modulate the inflammatory response during CPB but improved outcome is not well established. Randomized clinical trials failed to find an outcome benefit to the routine use of systemic corticosteroids or statins in patients undergoing CPB.

One once-promising agent, aprotinin, a protease inhibitor, reduced inflammation and surgical bleeding following CPB. Unfortunately, it increased mortality and is no longer available in North America.

**CPB Effects on Pharmacokinetics**

Plasma and serum concentrations of most water-soluble drugs (eg, nondepolarizing muscle relaxants) acutely decrease at the onset of CPB, but the change can be minimal and inconsequential for most lipid-soluble drugs (eg, fentanyl and sufentanil). The effects of CPB are complex because of the sudden increase in volume of distribution with hemodilution, decreased protein binding, and changes in perfusion and redistribution between peripheral and central compartments. Some drugs, such as opioids, also bind CPB components, but this is also minimal and inconsequential. Heparin potentially alters protein binding of drugs and ions by releasing and activating lipoprotein lipase, which hydrolyzes
plasma triglycerides into free fatty acids; the latter can competitively inhibit drug binding to plasma proteins and bind free calcium ions. With the possible exception of propofol, constant infusion of a drug during CPB, even when adjusted to maintain a constant “effect site” concentration (“target controlled infusion”) using data from patients not undergoing CPB, generally causes progressively increasing blood levels as a result of reduced hepatic and renal perfusion (reduced elimination) and hypothermia (reduced metabolism).

Anesthetic Management of Cardiac Surgery

ADULT PATIENTS

The preoperative evaluation and anesthetic management of common cardiovascular diseases are discussed in Chapter 21. The same principles apply whether these patients are undergoing cardiac or noncardiac surgery. An important distinction is that patients undergoing cardiac procedures will by definition have advanced disease. Establishing the adequacy of the patient’s preoperative cardiac function should be based on exercise (activity) tolerance, measurements of myocardial contractility such as ejection fraction, severity and location of coronary stenoses, ventricular wall motion abnormalities, cardiac end-diastolic pressures, cardiac output, and valvular areas and gradients. Fortunately, unlike noncardiac surgery, cardiac surgery improves cardiac function in the majority of patients, and these patients have usually been extensively evaluated before being offered surgical repair. The anesthetic preoperative evaluation should also include a focus on pulmonary, neurological, and kidney function, as preoperative impairment of these organ systems predisposes patients to myriad postoperative complications.

1. Preinduction Period

Premedication

The prospect of heart surgery is frightening, and relatively “heavy” premedication was often given in the past (see Chapter 21). Benzodiazepine sedative-hypnotics (diazepam, 5–10 mg orally), alone or in combination with an opioid (morphine, 5–10 mg intramuscularly or hydromorphone, 1–2 mg intramuscularly), were often used. However, in current practice most patients receive no sedative-hypnotic premedication until their arrival on the surgical
unit, at which time many will receive small doses of intravenous midazolam. Longer acting premedicant agents (eg, lorazepam) are avoided by most practitioners to permit fast-tracking of patients through their recovery.

**Preparation**

The best practitioners of cardiac anesthesia formulate a simple anesthetic plan that includes adequate preparations for contingencies. In an emergency one cannot wait for an assistant to search for drugs and equipment. Preparation, organization, and attention to detail permit one to deal more efficiently with unexpected intraoperative problems. The anesthesia machine, monitors, infusion pumps, and blood warmer should all be checked before the patient arrives. Drugs—including anesthetic and vasoactive agents—should be immediately available. Many clinicians prepare one vasoconstrictor and one vasodilator infusion before the start of the procedure.

**Venous Access**

Cardiac surgery is sometimes associated with large and rapid blood loss, and with the need for multiple drug infusions. Ideally, two large-bore (16-gauge or larger) intravenous catheters should be placed. One of these should be in a large central vein, usually an internal or external jugular or subclavian vein. Central venous cannulations may be accomplished while the patient is awake but sedated or after induction of anesthesia. Studies show no benefit from placing either central venous or pulmonary arterial catheters in awake (versus anesthetized) patients undergoing cardiovascular surgery.

Drug infusions should ideally be given into a central catheter, preferably directly into the catheter or into the injection port closest to the catheter (to minimize dead space). Multilumen central venous catheters and multilumen pulmonary artery catheter introducer sheaths allow for multiple drug infusions with simultaneous measurement of vascular pressures. One intravenous port should be solely for drug infusions; drug and fluid boluses should be administered through another site.

Blood should be immediately available for transfusion if the patient has had previous cardiac surgery (a “redo”); when there has been a previous sternotomy, the right ventricle or coronary grafts may be adherent to the sternum and may be accidentally entered during the repeat sternotomy.
Monitoring

A. Electrocardiography
The electrocardiogram (ECG) is continuously monitored with two leads, usually leads II and V₅. Baseline tracings of all leads may be recorded for future reference. Computerized ST-segment analysis and the use of TEE have greatly improved detection of ischemic episodes.

B. Arterial Blood Pressure
In addition to all basic monitoring, arterial cannulation is always performed either prior to or immediately after induction of anesthesia. Radial arterial catheters may occasionally give falsely low readings following sternal retraction as a result of compression of the subclavian artery between the clavicle and the first rib. They may also provide falsely low values early after CPB due to the opening of atroventricular shunts in the hand during rewarming. The radial artery on the side of a previous brachial artery cutdown should be avoided, because its use is associated with a greater incidence of arterial thrombosis and wave distortion. Obviously, if a radial artery will be harvested for a coronary bypass conduit, it cannot be used as a site for arterial pressure monitoring. Other useful catheterization sites include the brachial, femoral, and axillary arteries. A backup manual or automatic blood pressure cuff should also be used.

C. Central Venous and Pulmonary Artery Pressure
Central venous pressure is not terribly useful for diagnosis of hypovolemia but has been customarily monitored in nearly all patients undergoing cardiac surgery. The pulmonary artery occlusion pressure provides a better measure of left ventricular filling pressure. Pulmonary artery catheterization has declined precipitously in nearly all circumstances except adult cardiac surgery due to lack of evidence of a positive effect on patient outcomes. In theory the decision about whether to use a pulmonary artery catheter should be based on the patient and the procedure; however, in most centers, it is the preferences of the anesthetic, surgical, and critical care teams that really matter. In many centers, either every or almost no cardiac surgery patient receives pulmonary artery catheterization. In general, pulmonary artery catheterization has been most often used in patients with compromised ventricular function, pulmonary hypertension, or those undergoing complicated procedures. The most useful data are pulmonary artery pressures, the pulmonary artery occlusion (“wedge”) pressure, and thermodilution cardiac outputs. Specialized catheters provide extra infusion
ports, continuous measurements of mixed venous oxygen saturation and cardiac output, and the capability for right ventricular or atrioventricular sequential pacing. Given the risk associated with placing any pulmonary artery catheter, some clinicians opine that it makes sense to insert only those devices that offer these advanced capabilities. Intraoperatively and postoperatively, when pulmonary artery occlusion pressure measurements are not available, left ventricular filling pressures can be measured with a left atrial pressure line inserted by the surgeon during bypass.

The right internal jugular vein is a preferred approach for intraoperative central venous cannulation, particularly when the line will be removed after a day or two. Catheters placed through the other sites, particularly on the left side, are more likely to kink following sternal retraction (as noted earlier) and are less likely to pass into the superior vena cava as those placed through the right internal jugular vein.

Pulmonary artery catheters migrate distally during CPB and may spontaneously wedge without balloon inflation. Inflation of the balloon under these conditions can rupture a pulmonary artery causing lethal hemorrhage. Pulmonary artery catheters should be routinely retracted 2 to 3 cm during CPB and the balloon subsequently inflated slowly. If the catheter wedges with less than 1.5 mL of air in the balloon, it should be withdrawn farther.

D. Urinary Output
Once the patient is anesthetized, an indwelling urinary catheter is placed to monitor the hourly output. Bladder temperature is often monitored as a measure of core temperature but may not track core temperature well with reduced urinary flow. The sudden appearance of reddish urine may indicate excessive red cell hemolysis caused by CPB or a transfusion reaction.

E. Temperature
Multiple temperature monitors are usually placed once the patient is anesthetized. Bladder (or rectal), esophageal, and pulmonary artery (blood) temperatures are often simultaneously monitored. Because of the heterogeneity of readings during cooling and rewarming, bladder and rectal readings are generally taken to represent an average body temperature, whereas esophageal represents core temperature. Pulmonary artery temperature provides an accurate estimate of blood temperature, which should be the same as core temperature in the absence of active cooling or warming. Nasopharyngeal and tympanic probes may most closely approximate brain temperature. Myocardial temperature is
often measured directly during instillation of cardioplegia.

**F. Laboratory Parameters**
Laboratory testing is mandatory during cardiac surgery. Blood gases, hemoglobin, potassium, ionized calcium, and glucose measurements should be immediately available. The **activated clotting time (ACT)** approximates the Lee–White clotting time and is used to monitor heparin anticoagulation and its reversal with protamine. Some centers routinely use thromboelastography (TEG) to identify causes of bleeding after CPB.

**G. Surgical Field**
One of the most important forms of intraoperative monitoring is inspection of the surgical field. Once the sternum is opened, lung expansion can be observed through the pleura. When the pericardium is opened, the heart (primarily the right ventricle) is visible; thus cardiac rhythm, volume, and contractility can often be judged visually. Blood loss and surgical maneuvers must be closely watched and related to changes in hemodynamics and rhythm.

**H. Transesophageal Echocardiography**
TEE provides valuable information about cardiac anatomy and function during surgery. Two-dimensional, multiplane TEE can detect regional and global ventricular abnormalities, chamber dimensions, valvular anatomy, and the presence of intracardiac air. TEE can also be helpful in confirming cannulation of the coronary sinus for cardioplegia. Multiple views should be obtained from the upper esophagus, mid-esophagus, and transgastric positions in the transverse, sagittal, and in-between planes (Figure 22–2). The two views most commonly used for monitoring during cardiac surgery are the four-chamber view (Figure 22–3) and the transgastric (short-axis) view (Figure 22–4). Three-dimensional echocardiography offers better visualization of complex anatomic features, particularly of cardiac valves. The following represent the most important applications of intraoperative TEE.
FIGURE 22–2 Useful views during transesophageal echocardiography. A: The relationship between the angle of the ultrasound beam and image orientation relative to the patient. B–D: Echocardiographic views from the upper mid-esophagus, lower mid-esophagus, and transgastric position (C). Note that different views can be obtained in each position as the tip of the probe is tilted either upward (anteflexion) or backward (retroflexion) and the angle of the beam is changed from 0° to 180°. The angle of the beam is shown in the upper left-
hand corner of each image. The probe is also rotated clockwise or
counterclockwise to optimize viewing of the various structures. AO, aorta; AV,
aortic valve; CS, coronary sinus; IVC, inferior vena cava; LA, left atrium; LAA,
left atrial appendage; LUPV, left upper pulmonary vein; LV, left ventricle; MPA,
main pulmonary artery; MV, mitral valve; PA, pulmonary artery; RA, right
atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena
cava.

**FIGURE 22–3** Transesophageal echocardiogram of the mid-esophageal four-
chamber view, showing the right and left atria and ventricles.
FIGURE 22–4 Transesophageal echocardiogram at the lower esophageal/transgastric level looking up at the left ventricle at the level of the papillary muscles.

1. **Assessment of valvular function**—Valvular morphology can be assessed by multiplane and three-dimensional TEE. Pressure gradients, area and severity of stenosis, and severity of valvular regurgitation can be assessed by Doppler echocardiography and color-flow imaging (Figure 22–5). Colors are usually adjusted so that flow toward the probe is red and flow in the opposite direction is blue. TEE also can detect prosthetic valve dysfunction in the forms of obstruction, regurgitation, paravalvular leak, or vegetations from endocarditis. The TEE images in the upper mid-esophagus at 40° to 60° and 110° to 130° are useful for examining the aortic valve and ascending aorta (Figure 22–6). The diameter of the aortic valve annulus can be estimated accurately. Doppler flow across the aortic valve must be measured looking up from the deep transgastric view (Figure 22–7). The anatomic features of the mitral valve relevant to TEE are shown in Figure 22–8. The mitral valve is examined from the mid-esophageal position, looking at the mitral valve apparatus with and without color in the 0° through 180° views (Figure 22–9). TEE is an invaluable aid to guide and assess the completeness of mitral valve repair surgery. The commissural view (at about 60°) is particularly helpful because it cuts across many scallops of the mitral valve.
FIGURE 22–5 Transesophageal echocardiography Doppler and color-flow imaging. A: Pulse-wave Doppler recording of mitral valve inflow showing two phases, E (early filling) and A (atrial filling). B: Color-flow imaging demonstrates backward flow (regurgitant jet) across the mitral valve during systole (mitral regurgitation).
FIGURE 22–6 Two views of the aortic valve. A: Between 40° and 60°, all three leaflets are usually visualized. B: Between 110° and 130°, the left ventricular outflow, aortic valve, and ascending aorta are clearly visualized.
FIGURE 22–7 Transesophageal echocardiographic recording of continuous-wave Doppler from the transgastric view looking up at the aortic valve, demonstrating severe aortic stenosis. Peak velocity of 409 cm/s indicates a gradient of 66.9 mm Hg.
The anatomy of the mitral valve and its anatomic relationships to the aortic valve and left circumflex coronary artery. The posterior leaflet has three scallops, P₁, P₂, and P₃. The anterior leaflet is usually divided into A₁ and A₂ regions; in some classifications the anterior leaflet is divided into three areas (A₁, A₂, A₃), corresponding to the opposing corresponding areas of the posterior leaflet.
FIGURE 22–9 Multiplane imaging cuts across different segments of the mitral valve apparatus between 0° and 180° (A). Images of the mitral valve at 0°, 71°, and 142° (B, C, and D, respectively).

2. Assessment of ventricular function—Ventricular function can be assessed by global systolic function, estimated by means of ejection fraction (often calculated using Simpson’s method of disks) and left ventricular end-diastolic
volume; diastolic function (ie, looking for abnormal relaxation and restrictive diastolic patterns by checking mitral flow velocity or by measuring movements of the mitral valve annulus using tissue Doppler techniques); and regional systolic function (by assessing wall motion and thickening abnormalities). Regional wall abnormalities from myocardial ischemia often appear before ECG changes. Regional wall motion abnormalities can be classified into three categories based on severity (Figure 22–10): hypokinesis (reduced wall motion), akinesis (no wall motion), and dyskinesis (paradoxical wall motion). The location of a regional wall motion abnormality can indicate which coronary artery is experiencing reduced flow. The left ventricular myocardium is supplied by three major arteries: the left anterior descending artery, the left circumflex artery, and the right coronary artery (Figure 22–11). The approximate areas of distribution of these arteries on echocardiographic views are shown in Figure 22–12. Increasingly it is recognized that areas classically presented as the distribution of the circumflex artery may receive blood flow from the right coronary artery or the left anterior descending artery. The ventricular short-axis mid view at the mid-papillary muscle level contains all three blood supplies from the major coronary arteries.

FIGURE 22–10 Classification of regional wall motion abnormalities.
FIGURE 22–11  Standard angiographic views of the left (A) and right (B) coronary arteries. Note the left main coronary artery quickly divides into the left
anterior descending and the left circumflex arteries. 

A: (1) Left anterior descending artery with septal branches; (2) ramus medianus; (3) diagonal artery; (4) first septal branch; (5) left circumflex artery; (6) left atrial circumflex artery; (7) obtuse marginal artery. 

B: (1) Conus artery; (2) sinoatrial node artery; (3) acute marginal artery; (4) posterior descending artery with septal branches; (5) atroventricular node artery; (6) posterior left ventricular artery. LAO, left anterior oblique; RAO, right anterior oblique.

**FIGURE 22–12** Coronary artery supply of the left and right ventricles in three views: the short-axis view (A), the four-chamber view (B), and the three-chamber view (C). Green, right coronary artery; blue, left anterior descending artery; pink, left circumflex artery.

3. **Assessment of other cardiac structures and abnormalities**—In adults undergoing elective cardiac surgery we have used TEE to diagnose previously undetected congenital defects such as an atrial or ventricular septal defect; pericardial effusions and constrictive pericarditis; and cardiac tumors. Doppler color-flow imaging helps delineate abnormal intracardiac blood flows and shunts. TEE can assess the extent of myomectomy in patients with hypertrophic cardiomyopathy (idiopathic hypertrophic subaortic stenosis). Upper-, mid-, and lower-esophageal views are valuable in diagnosing aortic disease processes such as dissection, aneurysm, and atheroma (Figure 22–13). The extent of dissections in the ascending and descending aorta can be accurately defined; however, airway structures prevent complete visualization of the aortic arch with TEE. The presence of protruding atheroma in the ascending aorta increases the risk of postoperative stroke and should prompt the use of epiaortic scanning to identify
an atheroma-free cannulation site or a change in surgical plans.

![Diagram of the aortic arch and descending aorta with views from different angles.]

**FIGURE 22–13** Upper esophageal views of the aortic arch and descending aorta. The ascending aorta can be visualized in the upper mid-esophagus at 110° to 130° with anteflexion at the aortic valve level (see Figures 22–2B and 22–6B). LAX, long axis; PA, pulmonary artery; SAX, short axis.

4. **Examination for residual air**—Air is introduced into the cardiac chambers during all “open” heart procedures, such as valve surgery. Residual amounts of air often remain in the left ventricular apex even after the best deairing maneuvers. TEE is helpful in defining the volume of residual air, to determine whether additional surgical maneuvers need to be undertaken to help avoid cerebral or coronary embolism.

I. **Electroencephalography**

Computer-processed electroencephalographic (EEG) recordings can be used to assess anesthetic depth during cardiac surgery, and either the processed or “raw” EEG can be used to ensure complete drug-induced electrical silence (for brain protection) prior to circulatory arrest. These recordings are generally not useful in detecting neurological insults during CPB. Progressive hypothermia (or progressively deepened anesthesia) is typically associated with EEG slowing, burst suppression, and, finally, an isoelectric recording. Most strokes during CPB are due to small emboli that are not likely to produce changes in the EEG. Artifacts from the CPB roller pump may be seen on the raw EEG (due to
piezoelectric effects from compression of the pump tubing) but can usually be identified as such by computer processing.

**J. Transcranial or Carotid Doppler**

Transcranial Doppler (TCD) provides noninvasive measurements of blood flow velocity in the middle cerebral artery, which is insonated through the temporal bone. TCD and carotid Doppler are useful for detecting cerebral emboli. Increased numbers of emboli detected by TCD or carotid Doppler have been associated with an increased risk of postoperative neurobehavioral dysfunction.

**K. Near-Infrared Cerebral Oximetry (NIRS)**

Cerebral oximetry (see Chapter 6) is increasingly employed during cardiac surgery. A baseline value is established for each patient prior to preoxygenation. Decreased cerebral oxygen saturation may be seen when oxygen delivery is impaired secondary to decreased PaCO$_2$ tension, anemia, decreased arterial oxygen saturation, and diminished cardiac output.

**Induction of Anesthesia**

Cardiac operations usually require general anesthesia, endotracheal intubation, and controlled ventilation. Some centers have used thoracic epidural anesthesia alone for minimally invasive surgery without CPB or combined thoracic epidural with light general endotracheal anesthesia for other forms of cardiac surgery. These techniques have never been popular in North America due to concerns about the risk of spinal hematomas following heparinization, the associated medical–legal consequences, and the limited evidence of an outcome benefit. Some centers use a single intrathecal opioid injection to provide postoperative analgesia.

Induction of general anesthesia should be performed in a smooth, controlled (but not necessarily “slow”) fashion—often referred to as a “cardiac induction” when it is used for other types of surgery. The principles are discussed in Chapter 21. Selection of anesthetic agents is generally less important than the way they are used. Indeed, studies have failed to show differences in long-term outcome with various anesthetic techniques. Anesthetic dose requirements are variable. Severely compromised patients should be given anesthetic agents in incremental, small doses. Patient tolerance of inhaled anesthetics generally declines with declining ventricular function. Blood pressure and heart rate are continuously evaluated following unconsciousness, insertion of an oral airway,
urinary catheterization, and tracheal intubation. A sudden increase in heart rate or blood pressure may indicate light anesthesia and the need for more anesthetic prior to the next challenge, whereas a decrease or no change suggests that the patient is ready for the subsequent stimulus. Reductions in blood pressure greater than 20% generally call for administration of a vasopressor (as described later). A series of challenges may be used to judge when anesthetic depth will allow intubation without a marked hypertensive response, while also avoiding hypotension from excessive anesthetic dosing.

The period following intubation is often characterized by a gradual decrease in blood pressure resulting from the anesthetized state (often associated with vasodilation and decreased sympathetic tone) and a lack of surgical stimulation. Patients will usually respond to fluid boluses or a vasoconstrictor. Nevertheless, the administration of large amounts of intravenous fluids prior to the bypass may serve to accentuate the hemodilution associated with CPB (as described below). Small doses of phenylephrine (25–100 mcg), vasopressin (1–3 units), or ephedrine (5–10 mg) may be useful to avoid excessive hypotension. Following intubation and institution of controlled ventilation; arterial blood gases, hematocrit, serum potassium, and glucose concentrations are measured. The baseline ACT (normal <130 s) is best measured after skin incision.

**Choice of Anesthetic Agents**

Anesthetic techniques for cardiac surgery have evolved over the years. Successful techniques range from primarily inhalation anesthesia to high-dose opioid totally intravenous techniques. In recent years, total intravenous anesthesia with short-acting agents and combinations of intravenous and volatile agents have become most popular.

**A. “High-Dose” Opioid Anesthesia**

This technique was originally developed to circumvent the myocardial depression associated with older volatile anesthetics, particularly halothane. But pure high-dose opioid anesthesia (eg, fentanyl, 50–100 mcg/kg, or sufentanil, 15–25 mcg/kg) produces prolonged postoperative respiratory depression (12–24 h), is associated with an unacceptably high incidence of patient awareness (recall) during surgery, and often fails to control the hypertensive response to stimulation in many patients with preserved left ventricular function. Other undesirable effects include skeletal muscle rigidity during induction and prolonged postoperative ileus. Moreover, simultaneous administration of
benzodiazepines with large doses of opioids can produce hypotension and myocardial depression. Patients anesthetized with sufentanil and other shorter acting agents generally regain consciousness and can be extubated sooner than those anesthetized with comparable doses of fentanyl.

B. Total Intravenous Anesthesia (TIVA)
The drive for cost containment in cardiac surgery was a major impetus for development of anesthesia techniques with short-acting agents. Although the drugs may be costlier, large economic benefits resulted from earlier extubation, decreased intensive care unit (ICU) stays, earlier ambulation, and earlier hospital discharge (“fast-track” management). One technique employs induction with propofol (0.5–1.5 mg/kg followed by 25–100 mcg/kg/min), and modest doses of fentanyl (total doses of 5–7 mcg/kg) or remifentanil (0–1 mcg/kg bolus followed by 0.25–1 mcg/kg/min). Target controlled infusion (TCI) employs software and hardware (computerized infusion pump) to deliver a drug and achieve a set concentration at the effect site based on pharmacokinetic modeling. For propofol, the clinician sets only the patient’s age and weight, and the desired blood concentration on the Diprifusor™, a TCI device widely available in countries outside North America. During cardiac surgery, a target propofol concentration of 1.5 to 2 mcg/mL is often used. When remifentanil (rather than a longer persisting agent) is used during cardiac anesthesia one must anticipate the need for postoperative analgesia after its discontinuation.

C. Mixed Intravenous/Inhalation Anesthesia
Selection of anesthetic agents is oriented to hemodynamic stability as well as early extubation (1–6 h). Propofol (0.5–1.5 mg/kg) or etomidate (0.1–0.3 mg/kg) is often used for induction. Induction usually follows sedation with small doses of midazolam (0.05 mg/kg). Renewed interest in volatile agents came about following studies demonstrating the protective effects of volatile agents on ischemic myocardium and the utility of these agents for fast-track recovery of cardiac patients. Opioids are given in small doses together with a volatile agent (0.5–1.5 minimum alveolar concentration [MAC]) to maintain anesthesia and to blunt the sympathetic response to stimulation. The opioid may be given by intermittent bolus injections, by continuous infusion, or both (Table 22–1). To facilitate fast-track management, typical total doses of fentanyl and sufentanil generally do not exceed 15 and 5 mcg/kg, respectively, and some clinicians combine smaller doses of fentanyl or sufentanil with an analgesic dose of hydromorphone or morphine administered toward the end of CPB. Some
clinicians also administer propofol in a low-dose infusion (25–50 mcg/kg/min) or TCI (1.5–2.0 mcg/mL) for maintenance. The major advantage of volatile agents or infusions of remifentanil or propofol is the ability to change the anesthetic concentration and depth rapidly. Isoflurane, sevoflurane, and desflurane are the most commonly used volatile anesthetics. Early laboratory reports of isoflurane inducing intracoronary steal have been overshadowed by later reports of myocardial protection. Isoflurane remains a commonly used volatile agent. Nitrous oxide is generally not used. Nitrous is particularly disadvantageous during the time interval between cannulation and decannulation, because of its tendency to expand any intravascular air bubbles that may form. Moreover, it cannot be given conveniently during CPB.

**D. Other Techniques**
The combination of ketamine with midazolam (or propofol) for induction and maintenance of anesthesia is a useful technique, particularly in frail patients with hemodynamic compromise. It is associated with stable hemodynamics, reliable amnesia and analgesia, minimal postoperative respiratory depression, and rare (if any) psychotomimetic side effects. For induction, ketamine, 1 to 2 mg/kg, with midazolam, 0.05 to 0.1 mg/kg, is given as a slow intravenous bolus. Anesthesia can then be maintained by infusion of ketamine, 1.3 to 1.5 mg/kg/h, and midazolam, 0.065 to 0.075 mg/kg/h, or more easily with an inhaled agent. Hypertension following intubation or surgical stimulation can be treated with propofol, opioids, β-blockers, or a volatile agent.

**E. Muscle Relaxants**
Muscle relaxation is helpful for intubation, to facilitate sternal retraction, and to
prevent patient movement and shivering. Unless airway difficulties are expected, intubation may be accomplished after administration of a nondepolarizing muscle relaxant. The choice of muscle relaxant in the past was often based on the desired hemodynamic response. Modern, shorter acting agents such as rocuronium, vecuronium, and cisatracurium are commonly used and have almost no hemodynamic side effects of their own. Vecuronium, however, has been reported to markedly enhance bradycardia associated with large doses of opioids, particularly sufentanil. Because of its vagolytic effects, pancuronium was often used in patients with marked bradycardia who were taking β-blocking agents, Succinylcholine remains appropriate for endotracheal intubation, particularly for rapid sequence induction. Judicious dosing, appropriate use of a peripheral nerve stimulator, and reversal (if needed) allow fast-tracking with any of these agents.

2. Prebypass Period

Following induction and intubation, the anesthetic course is typically characterized by an initial period of minimal stimulation (skin preparation and draping) that is frequently associated with hypotension, followed by discrete periods of intense stimulation that can produce tachycardia and hypertension. These periods of stimulation include the skin incision, sternotomy and sternal retraction, opening the pericardium, and, sometimes, aortic dissection. The anesthetic agent should be adjusted appropriately in anticipation of these events.

Accentuated vagal responses resulting in marked bradycardia and hypotension may occasionally be seen during sternal retraction or opening of the pericardium, perhaps more commonly in patients who have been taking β-adrenergic blocking agents or diltiazem.

Myocardial ischemia in the prebypass period is not always associated with hemodynamic perturbations such as tachycardia, hypertension, or hypotension. Prophylactic infusion of nitroglycerin (1–2 mcg/kg/min) has been studied many times and continues to be used in some centers, but it has never been shown to reduce the incidence of ischemia or improve outcomes.

Anticoagulation

Anticoagulation must be established before CPB to prevent acute disseminated intravascular coagulation and formation of clots in the CPB pump. In most centers the adequacy of anticoagulation will be confirmed by measuring the ACT. An ACT longer than 400 to 480 s is considered adequate. Heparin, 300 to 400 units/kg, is usually given before aortic cannulation. Some surgeons prefer
to administer the heparin themselves directly into the right atrium. If heparin is administered by the anesthesiologist, it should be given through a reliable (usually central) intravenous line, and the ACT should be measured 3 to 5 min later. If the ACT is less than 400 s, additional heparin (100 units/kg) is given. Some drugs (eg, aprotinin) prolong the celite-activated ACT but not the kaolin-activated ACT; the kaolin-ACT should be used to assess adequacy of anticoagulation in these circumstances. Heparin concentration assays (see Reversal of Anticoagulation, later) measure heparin levels and not necessarily effect; these assays are therefore not reliable for measuring the degree of anticoagulation but can be used as an adjunct. A whole blood heparin concentration of 3 to 4 units/mL is usually sufficient for CPB. The high-dose thrombin time (HiTT) is not influenced by aprotinin but is more complicated to perform than a kaolin-ACT. HiTT cannot provide a preheparin control and does not provide an index for the adequacy of reversal with protamine (as discussed later).

**Resistance to heparin is occasionally encountered; many such patients have antithrombin III deficiency (acquired or congenital).** Antithrombin III is a circulating serine protease that irreversibly binds and inactivates thrombin (as well as the activated forms of factors X, XI, XII, and XIII). When heparin complexes with antithrombin III, the anticoagulant activity of antithrombin III is enhanced 1000-fold. Patients with antithrombin III deficiency will achieve adequate heparin anticoagulation following infusion of antithrombin III (or fresh frozen plasma). Milder forms of heparin resistance can be managed by administration of a modestly larger than normal dose of heparin.

Patients with a history of heparin-induced thrombocytopenia (HIT) require special consideration. These patients produce heparin-dependent (platelet factor 4) antibodies that agglutinate platelets and produce thrombocytopenia, sometimes associated with thromboembolism. If the history of HIT is remote and antibodies can no longer be demonstrated, heparin may safely be used for CPB. When significant antibody titers are detected, alternative anticoagulants including hirudin, bivalirudin, anacrod, and argatroban may be considered.

**Bleeding Prophylaxis**

Bleeding prophylaxis with antifibrinolytic agents may be initiated before or after anticoagulation. Some clinicians prefer to administer antifibrinolytic agents after heparinization to reduce the possible incidence of thrombotic complications; others fear that delayed administration may reduce antifibrinolytic efficacy. Antifibrinolytic therapy may be particularly useful for patients who are
undergoing a repeat operation; who refuse blood products (such as Jehovah’s Witnesses); who are at high risk for postoperative bleeding because of recent administration of glycoprotein IIb/IIIa inhibitors (abciximab [RheoPro], eptifibatide [Integrilin], or tirofiban [Aggrastat]); who have preexisting coagulopathy; or who are undergoing long and complicated procedures. The antiplatelet effect of abciximab typically lasts 24 to 48 h; those of eptifibatide and tirofiban are 2 to 4 h and 4 to 8 h, respectively. The frequent combination of aspirin and the adenosine diphosphate receptor antagonist clopidogrel (Plavix) is also associated with excessive bleeding.

The antifibrinolytic agents currently available, ε-aminocaproic acid and tranexamic acid, do not affect the ACT and only rarely induce allergic reactions. ε-Aminocaproic acid is usually administered as a 50 to 75 mg/kg loading dose followed by a 20 to 25 mg/kg/h maintenance infusion (some clinicians use a standard 5–10 g loading dose followed by 1 g/h). Tranexamic acid is often dosed at 10 mg/kg followed by 1 mg/kg/h, although pharmacokinetic studies suggest that larger doses may more reliably maintain effective blood concentrations. Intraoperative collection of platelet-rich plasma by pheresis prior to CPB is employed by some centers; reinfusion following bypass may decrease bleeding and reduce transfusion requirements.

**Cannulation**

Placement of venous and arterial cannulas for CPB is a critical time. *After heparinization*, aortic cannulation is usually done first because of the hemodynamic problems sometimes associated with venous cannulation and to allow convenient and rapid transfusion from the pump oxygenator. The inflow cannula is most often placed in the ascending aorta. The small opening of most arterial cannulas produces a jet stream that, when not positioned properly, can cause aortic dissection or preferential flow of blood to the innominate artery. The systemic arterial pressure is customarily reduced to 90 to 100 mm Hg systolic during placement of the aortic cannula to reduce the likelihood of dissection. Air bubbles should be absent from the arterial cannula and inflow line, and adequacy of the connection between the arterial inflow line and the patient must be demonstrated before bypass is initiated. Failure to remove all air bubbles will result in air emboli, possibly into the coronary or cerebral circulations, whereas failure of the cannula tip to fully enter the aorta may result in aortic dissection. Some clinicians routinely hand compress the carotid arteries during aortic cannulation to decrease the likelihood of cerebral emboli, but the efficacy of this technique is doubtful.
One or two venous cannulas are placed in the right atrium, usually through the right atrial appendage. One cannula is usually adequate for most coronary artery bypass and aortic valve operations. The single cannula used often has two portals (two-stage); when it is properly positioned, one opening is in the right atrium and the other is in the inferior vena cava.

Separate cannulas in the superior and inferior venae cavae are used for other forms of open-heart procedures (other forms of valve surgery and congenital repairs). Hypotension from impaired ventricular filling may occur during manipulation of the venae cavae and the heart. Venous cannulation also frequently precipitates atrial or, less commonly, ventricular arrhythmias. Premature atrial contractions and transient bursts of a supraventricular tachycardia are common and need no treatment if they are not sustained. Sustained paroxysmal atrial tachycardia or atrial fibrillation frequently leads to hemodynamic deterioration, which may be treated pharmacologically, electrically, or by immediate initiation of bypass (provided that full anticoagulation has been confirmed). Malpositioning of the venous cannulas can interfere with venous return or impede venous drainage from the head and neck (superior vena cava syndrome). Upon initiation of CPB, the former is manifested as inadequate volume in the venous reservoir, whereas the latter produces engorgement of the head and neck.

3. Bypass Period

Initiation

Once the cannulas are properly placed and secured, the ACT is acceptable, and the perfusionist is ready, CPB is initiated. The main CPB pump is started and with satisfactory arterial inflow the venous cannula(s) is unclamped. Establishing the adequacy of venous return to the pump reservoir is critical. Normally, the reservoir level rises and CPB pump flow is gradually increased. If venous return is poor, the level of blood in the reservoir will decline, potentially allowing air to enter the pump circuit. When the venous reservoir volume declines the cannulas should be checked for proper placement and for forgotten clamps, kinks, or an air lock. Under these circumstances, pump flow should be slowed until the problem is resolved. Adding volume (blood or colloid) to the reservoir may be necessary. With full CPB and unimpeded venous drainage, the heart should empty; failure to empty or progressive distention may result from malpositioning of the venous cannula or aortic regurgitation. In the rare case of
severe aortic insufficiency that limits the extent of peripheral perfusion, immediate aortic cross-clamping (and cardioplegia) may be necessary.

**Flow & Pressure**

Systemic mean arterial pressure is closely monitored as pump flow is gradually increased to 2 to 2.5 L/min/m². At the onset of CPB, systemic arterial pressure usually decreases abruptly. Initial mean systemic arterial (radial) pressures of 30 to 40 mm Hg are not unusual. This decrease is usually attributed to abrupt hemodilution, which reduces blood viscosity and effectively lowers SVR. It is often treated with increased flow and vasopressors.

Persistent and excessive hypotension (<30 mm Hg) should prompt a search for unrecognized aortic dissection. If dissection is present, CPB must be temporarily stopped until a cannula can be placed distally in the “true” aortic lumen. Other possible causes for hypotension include inadequate pump flow from poor venous return or a pump malfunction, or pressure transducer error. Factitious hypertension has been reported when the right radial artery is used for monitoring and the aortic cannula is directed toward the innominate artery.

The relationship between pump flow, SVR, and mean systemic arterial blood pressure may be conceptualized as follows:

\[ \text{Mean arterial pressure} = \text{Pump flow} \cdot \text{SVR} \]

Consequently, with a constant SVR, mean arterial pressure is proportional to pump flow. Similarly, at any given pump flow, mean arterial pressure is proportional to SVR. To maintain both adequate arterial pressures and blood flows one can manipulate pump flow and SVR. Most centers strive for blood flows of 2 to 2.5 L/min/m² (50–60 mL/kg/min) and mean arterial pressures between 50 and 80 mm Hg in adults. Metabolic flow requirements decline with decreasing core body temperature. Evidence also suggests that during deep hypothermia (20–25°C), mean blood pressures as low as 30 mm Hg may still be consistent with adequate cerebral blood flow and cerebral oxygen delivery. Moderately decreased SVR can be increased with phenylephrine, vasopressin, or norepinephrine.

Increased mean arterial pressures (>150 mm Hg) are deleterious and may promote aortic dissection or cerebral hemorrhage. Generally, when mean arterial pressure exceeds 100 mm Hg, hypertension is said to exist and is treated by decreasing pump flow or increasing the concentration of a volatile agent to the oxygenator inflow gas. If the hypertension is refractory to these maneuvers or if
pump flow is already low, a vasodilator such as clevidipine, nicardipine, or nitroprusside is used.

**Monitoring**

Additional monitoring during CPB includes the pump flow rate, venous reservoir level, arterial inflow line pressure (as noted earlier), blood (perfusionate and venous) and myocardial temperatures, and in-line (arterial and venous) oxygen saturations. In-line pH, CO$_2$ tension, and oxygen tension sensors are also available. Blood gas tensions and pH should be confirmed by direct measurements. In the absence of hypoxemia, low venous oxygen saturations (<70%), a progressive metabolic acidosis, or reduced urinary output may indicate inadequate flow rates.

During bypass, arterial inflow line pressure is almost always greater than the systemic arterial pressure recorded from a radial artery or even an aortic catheter. The difference in pressure represents the pressure drop across the arterial filter, the arterial tubing, and the narrow opening of the aortic cannula. Nonetheless, monitoring this pressure is important for detecting problems with an arterial inflow line. Inflow pressures should remain below 300 mm Hg; higher pressures may indicate a clogged arterial filter, obstruction of the arterial tubing or cannula, or aortic dissection.

Serial ACT, hematocrit, and potassium measurements are performed during CPB. Blood glucose should be checked even in patients without a history of diabetes. The ACT is measured immediately after bypass and then every 20 to 30 min thereafter. Cooling generally increases the half-life of heparin and prolongs its effect. Some centers calculate a heparin dose–response curve to guide calculation of heparin dosing and protamine reversal (Figure 22–14). The hematocrit is usually not allowed fall much below 22%. Red cell transfusions into the pump reservoir may be necessary. Marked increases in serum potassium concentrations (secondary to cardioplegia) are usually treated with a furosemide-induced diuresis.
**FIGURE 22–14** Heparin dose–response curve; activated clotting time (ACT) in seconds versus total heparin dose in milligrams per kilogram. (1) Plot the initial ACT on the x-axis (point A). (2) Plot the ACT after heparinization (point B). (3) Draw the line defined by these two points. (4) If additional anticoagulation is needed, find the desired ACT on that line. The amount of additional heparin needed is the difference on the y-axis between the present ACT and the desired ACT (point C). (5) If the third point does not lie on the original line, a new line is drawn originating from the baseline ACT and passing midway between the other two points. (6) For reversal of anticoagulation, the protamine dose is based on the remaining heparin activity, estimated to be the heparin dose corresponding to the latest ACT on the dose–response line.

**Hypothermia & Cardioplegia**

Moderate (26–32°C) or deep (20–25°C) hypothermia is used routinely for some procedures, particularly those involving the aortic root and great vessels. The lower the temperature, the longer the time required to achieve cooling and rewarming. Lower temperatures, however, permit lower CPB flows to be used safely. At a temperature of 20°C, flows as low as 1.2 L/min/m² may be adequate.

Hypothermia produces characteristic changes in the ECG including the Osborne wave, a positive deflection between the QRS and ST segments. Ventricular fibrillation often occurs as the heart is cooled below 28°C to 29°C.
Cardioplegia should be established immediately, as fibrillation consumes high-energy phosphates at a greater rate than slower rhythms. Cardioplegia is achieved by cross-clamping the ascending aorta proximal to the aortic inflow cannula and (as previously described) infusing cardioplegia solution through a small catheter proximal to the cross-clamp or directly into the coronary ostia if the aorta is opened (eg, for aortic valve replacement). Many surgeons routinely employ retrograde cardioplegia via a catheter in the coronary sinus (see earlier discussion). During aortocoronary bypass grafting, cardioplegia solution may also be given through the graft when the surgeon elects to perform the distal anastomosis first.

**Ventilation**

Ventilation of the lungs is discontinued when adequate pump flows are reached and the heart stops ejecting blood. Following institution of full CPB, ventricular ejection continues briefly until the left ventricular volume reaches a critically low level. Discontinuing ventilation prematurely when there is any remaining pulmonary blood flow acts as a right-to-left shunt that can promote hypoxemia. The importance of this mechanism depends on the relative ratio of remaining pulmonary blood flow to pump flow. At some centers, once ventilation is stopped, oxygen flow is continued in the anesthesia circuit with a small amount of continuous positive airway pressure (5 cm H₂O) in the hope of preventing postoperative pulmonary dysfunction. Most centers either stop all gas flow or continue a low flow of oxygen (1–2 L/min) in the anesthesia circuit. Ventilation is resumed at the conclusion of CPB in anticipation of the heart beginning to eject blood.

**Management of Respiratory Gases**

There formerly was controversy about whether to use temperature-corrected (pH stat) or uncorrected (α-stat) arterial blood gas tensions during hypothermic CPB in adults. The controversy stemmed from the fact that the solubility of a gas increases and the neutral pH (ie, the pH at which concentrations of H⁺ and OH⁻ ions are the same) of water increases with hypothermia. As a result of the former effect, although total CO₂ content does not change (in a closed system), the partial pressure of CO₂ will decrease as blood temperature drops. The problem is most significant for arterial CO₂ tension because of its effect on arterial pH and cerebral blood flow. As the temperature decreases, the plasma bicarbonate
concentration does not change, but the decreased arterial CO₂ tension increases pH to what would be alkalotic values at normothermia. Blood with a CO₂ tension of 40 mm Hg and a pH of 7.40 at 37°C, when cooled to 25°C, will have a CO₂ tension of about 23 mm Hg and a pH of 7.60, yet will have an unchanged ratio of H⁺ to OH⁻ ions.

Normally—regardless of the patient’s temperature—blood samples are heated to 37°C in blood gas analyzers before gas tensions are measured. If a temperature-corrected reading is desired, a table or a program in the blood gas machine can be used to estimate what the gas tension and pH would have been if they had been measured at the patient’s temperature. The practice of temperature correcting gas tensions with the goal of maintaining a constant CO₂ tension of 40 mm Hg and a constant pH of 7.40 during hypothermia is referred to as **pH-stat management.** During hypothermic CPB, pH-stat management, which may require adding CO₂ to the oxygenator gas inflow, increases total blood CO₂ content. Under these conditions, cerebral blood flow increases (due to increased CO₂ tension relative to α-stat management) more than is required based on oxygen consumption. Increased cerebral blood flow is useful to increase uniformity of brain cooling prior to deep hypothermic circulatory arrest (more often used in children than adults). On the other hand, increased cerebral blood flow can also direct a greater fraction of atheromatous arterial emboli to the brain—a greater concern than uniformity of brain cooling during most cardiac surgery in adults.

The use of uncorrected gas tensions during hypothermia—**α-stat management**—is the rule in adults and is common in children when circulatory arrest will not be used. The basis of this approach is that preservation of normal protein function depends on maintaining a constant state of intracellular electroneutrality (the balance of charges on proteins). At physiological pH, these charges are primarily located on the imidazole rings of histidine residues (referred to as α residues). Moreover, as temperature decreases, $K_w$—the dissociation constant for water—also decreases ($pK_w$ increases). Therefore, at lower temperatures, the electroneutrality of aqueous solutions, where $[H^+] = [OH^-]$, corresponds to a lower $[H^+]$ (a higher pH). Hypothermic “alkalosis” thus does not necessarily reflect $[OH^-] > [H^+]$ but rather an absolute decrease in both $[H^+]$ and $[OH^-]$. Hypothermic CPB with α-stat management does not require addition of CO₂ to the oxygenator: The total CO₂ content of blood and the electroneutrality are unchanged. In contrast to pH-stat management, α-stat
management appears to preserve cerebral autoregulation of blood flow. Despite the theoretical and observed differences, in most studies comparisons between the two techniques fail to reveal appreciable differences in patient outcomes except in children undergoing circulatory arrest.

**Anesthesia**

- Hypothermia (<34°C) potentiates general anesthetic potency, but failure to give anesthetic agents, particularly during rewarming on CPB, may result in awareness and recall. With light anesthesia hypertension may be seen and, if muscle paralysis is also allowed to wear off, the patient may move. Consequently, additional doses of anesthetic agents may be necessary during CPB. Reduced concentrations of a volatile agent (eg, 0.5–0.75% isoflurane) via the oxygenator are frequently used. The volatile agent concentration may need to be reduced to a value that does not depress contractility immediately prior to termination of bypass if residual myocardial depression is apparent. Those relying on opioids and benzodiazepines for anesthesia during CPB may need to administer additional doses of these agents or commence a propofol infusion. Some clinicians routinely administer a benzodiazepine (eg, midazolam) when rewarming is initiated. Alternatively, a propofol, opioid, or ketamine–midazolam infusion may be continued throughout CPB. Sweating during rewarming is common and usually indicates a hypothalamic response to perfusion with warm blood (rather than “light” anesthesia). During rewarming, blood temperature should not exceed core temperature by more than 2°C.

**Cerebral Protection**

The incidence of neurobehavioral deficits after CPB varies widely, depending on how long after surgery the examination is performed and the criteria for diagnosis. In the first week after surgery the incidence may be as high as 80%. Fortunately, in most instances, these deficits are transient. Neurobehavioral deficits detectable 8 weeks or more (20–25%) after operation or strokes (2–6%) are less common. Factors that have been associated with neurological sequelae include increased numbers of cerebral emboli, combined intracardiac (valvular) and coronary procedures, advanced age, and preexisting cerebrovascular disease. During open-heart procedures, deairing of cardiac chambers, assumption of a head-down position, and venting before and during initial cardiac ejection are important in preventing gas emboli. Some centers fill the surgical field with CO₂, a gas that if entrained and embolized will more rapidly be reabsorbed. TEE
can detect residual air within the heart and the need for further deairing procedures. During coronary bypass procedures, minimizing the amount of aortic manipulation, the number of aortic clampings, and the number of graft sites on the surface of the aorta, and using sutureless proximal anastomotic devices may help reduce atheromatous emboli. Palpation of the aorta, TEE, and especially epi-aortic echocardiography can help identify high-risk patients and guide management. Epi-aortic echocardiography is the most sensitive and specific technique.

The relative contributions of emboli versus cerebral hypoperfusion in causing neurological deficits remains unclear. The data are controversial and sparse that prophylactic drug infusions immediately before and during intracardiac (open ventricle) procedures will decrease the incidence and severity of neurological deficits. Prior to circulatory arrest with very deep hypothermia, some clinicians administer a corticosteroid (methylprednisolone, 30 mg/kg, or the equivalent dose of dexamethasone) and mannitol (0.5 g/kg). The head is also covered with ice bags (avoiding the eyes). Surface cooling delays rewarming and may also facilitate adequacy of brain cooling. A long list of drugs has been tested and has failed to improve cerebral outcomes after heart surgery. Human studies during cardiac surgery have not shown improved neurobehavioral outcomes with prophylactic administration of calcium channel blockers (nimodipine), N-methyl-D-aspartate (NMDA) antagonists (remacemide), free radical scavengers (pegorgotein), sedative-hypnotics (thiopental, propofol, or clomethiazole), or lazaroids (tirilazad).

4. Termination of CPB
Discontinuation of bypass is accomplished by a series of necessary procedures and conditions, the first of which is adequate rewarming. The surgeon’s decision about when to rewarm is important; adequate rewarming requires time, but rewarming too soon removes the protective effects of hypothermia. Rapid rewarming often results in large temperature gradients between well-perfused organs and peripheral vasoconstricted tissues; subsequent equilibration following separation from CPB decreases core temperature again. An excessive gradient between the infusate temperature and the patient’s core temperature can result in deleterious brain hyperthermia. Infusion of a vasodilator drug (e.g., isoflurane) allows higher pump flows and will often speed the rewarming process. Allowing some pulsatile flow (ventricular ejection) may also speed rewarming. Excessively rapid rewarming, however, can result in the formation of gas bubbles in the bloodstream as the solubility of gases rapidly decreases. If the
heart fibrillates during rewarming, direct electrical defibrillation (5–10 J) may be necessary. Administration of lidocaine, 100 to 200 mg, and magnesium sulfate, 1 to 2 g, prior to removal of aortic cross-clamping is a common protocol and may decrease the likelihood of fibrillation. Many clinicians advocate a head-down position while intracardiac air is being evacuated to decrease the likelihood of cerebral emboli. Lung inflation facilitates expulsion of (left-sided) intracardiac air by compressing pulmonary vessels and returning blood into the left heart. TEE is useful in detecting residual intracardiac air. Initial reinflation of the lungs requires greater than normal airway pressure and should generally be done under direct visualization of the surgical field because excessive lung expansion can interfere with internal mammary artery grafts.

General guidelines for separation from CPB include the following:

- The core body temperature should be at least 37°C.
- A stable rhythm must be present. Pacing is often used and confers the benefit of a properly timed atrial systole. Persistence of atrioventricular block should prompt measurement of serum potassium concentration. If hyperkalemia is present, it can be treated with calcium, NaHCO$_3$, furosemide, or glucose and insulin.
- The heart rate must be adequate (generally 80–100 beats/min). Slow heart rates are generally treated by pacing. Many inotropic agents will also increase heart rate. Supraventricular tachycardias generally require cardioversion.
- Laboratory values must be within acceptable limits. Significant acidosis (pH <7.20), hypocalcemia (ionized), and hyperkalemia (>5.5 mEq/L) should be treated; ideally the hematocrit should exceed 22%; however, a hematocrit <22% should not by itself trigger transfusion of red blood cells at this time. When CPB reservoir volume and flow are adequate, ultrafiltration may be used to increase the hematocrit.
- Adequate ventilation with 100% oxygen must have been resumed.
- All monitors should be rechecked for proper function and recalibrated if necessary.

**Weaning from CPB**

CPB should be discontinued as systemic arterial pressure, ventricular volumes and filling pressures, and cardiac function (on TEE) are assessed. Central aortic pressure may be measured directly and compared with the radial artery pressure.
and cuff pressure (if there is concern about radial artery hypotension). A reversal of the normal systolic pressure gradient, with aortic pressure being greater than radial pressure, is often seen immediately postbypass. This has been attributed to opening of arteriovenous connections in the hand as a consequence of rewarming. Central aortic root pressure can also be estimated by palpation by an experienced surgeon. Right ventricular volume and contractility can be estimated visually, whereas filling pressures are measured directly by central venous, pulmonary artery, or left atrial catheters. Cardiac output can be measured by thermodilution. TEE can define adequacy of end-diastolic volumes, right and left ventricular contractility, and valvular function.

Weaning is typically accomplished by progressively clamping the venous return line (tubing). As the beating heart fills, ventricular ejection resumes. Pump flow is gradually decreased as arterial pressure rises. Once the venous line is completely occluded and systolic arterial pressure is judged to be adequate (>80–90 mm Hg), pump flow is stopped and the patient is evaluated. Some surgeons wean by clamping the venous line and then progressively “filling” the patient with arterial inflow.

Most patients fall into one of four groups when coming off bypass (Table 22–2). Patients with good ventricular function are usually quick to develop good blood pressure and cardiac output and can be separated from CPB immediately. Hyperdynamic patients can also be rapidly weaned. These patients emerge from CPB with a very low SVR, demonstrating good contractility and adequate volume, but have low arterial pressure; their hematocrit is often reduced (<22%). Diuresis (off CPB) or red blood cell transfusions increase arterial blood pressure.

1 CPB, cardiopulmonary bypass; LV, left ventricular; RV, right ventricular; IABP, intraaortic balloon pump; LVAD, left ventricular assist device; RVAD, right ventricular assist device; TEE, transesophageal echocardiography.
Hypovolemic patients include those with normal ventricular function and those with varying degrees of impairment. Those with preserved myocardial function quickly respond to infusion of blood via the aortic cannula. Blood pressure and cardiac output rise with each bolus, and the increase becomes progressively more sustained. Most of these patients maintain good blood pressure and cardiac output with a left ventricular filling pressure below 10 to 15 mm Hg. Ventricular impairment should be suspected (when definitive diagnosis using TEE is not available) in hypovolemic patients whose filling pressures rise during volume infusion without appreciable changes in blood pressure or cardiac output or in those who require filling pressures above 10 to 15 mm Hg. Ventricular dysfunction is easily diagnosed by TEE.

Patients with pump failure emerge from CPB with a sluggish, poorly contracting heart that progressively distends. In such cases, CPB may need to be reinstituted while inotropic therapy is initiated; alternatively, if the patient is less unstable, a positive inotrope (epinephrine, dopamine, dobutamine) can be administered while the patient is observed for improvement. If the patient does not respond to reasonable doses of one of these three agents, milrinone can be added. In patients with poor preoperative ventricular function milrinone may be administered as the first-line agent prior to separation from CPB. In the rare instance that SVR is increased, afterload reduction with nitroprusside or milrinone can be tried. The patient should be evaluated for unrecognized ischemia (kinked graft or coronary vasospasm), valvular dysfunction, shunting, or right ventricular failure (the distention is primarily right sided). TEE will facilitate the diagnosis in these cases.

If drug therapies fail, intraaortic balloon pump (IABP) counterpulsation should be initiated while the heart is “rested” on CPB. The efficacy of IABP depends on proper timing of inflation and deflation of the balloon (Figure 22–15). The balloon should inflate just after the dicrotic notch is seen on the intraaortic pressure tracing to augment diastolic blood pressure and coronary flow after closure of the aortic valve. Inflation too early increases afterload and exacerbates aortic regurgitation, whereas late inflation reduces diastolic augmentation. Balloon deflation should be timed just prior to left ventricular ejection to decrease its afterload. Early deflation makes diastolic augmentation and afterload reduction less effective. Use of a left or right ventricular assist device (LVAD or RVAD, respectively) may be necessary for patients with refractory pump failure. If myocardial stunning is a major contributor or there are areas of hibernating myocardium, a delayed improvement in contractile function may allow complete weaning from all drugs.
and support devices only after 12 to 48 h of therapy. Ventricular assist devices can be used as a bridge to cardiac transplantation.

FIGURE 22–15 A central arterial waveform during 1:2 inraaortic balloon pump counterpulsation. Ideally the balloon, which is positioned in the descending aorta just distal to the left subclavian artery, should inflate at the dicrotic notch (1) and be completely deflated just as the left ventricle begins to eject (2). Note the lower end-diastolic pressures after balloon augmentation and slightly lower systolic pressure in the following beat. N, nonaugmented beat; A, augmented beat; B, balloon augmentation.

Many clinicians believe that positive inotropes should not routinely be used in patients coming off CPB because positive inotropes increase myocardial oxygen demand. The routine use of calcium similarly may worsen ischemic injury and may contribute to coronary spasm (particularly in patients who were taking calcium channel blockers preoperatively). Nevertheless, there are centers that administer calcium salts or a positive inotrope (eg, dobutamine), or both, to every patient at the conclusion of CPB. Commonly used positive inotropes and vasopressors are listed in Table 22–3. Epinephrine, dopamine, and dobutamine are the most commonly used agents. Epinephrine is the most potent inotrope and is often effective in increasing both cardiac output and systemic blood pressure when others agents have failed. In lower doses, it has predominantly β-agonist activity. Dobutamine, unlike dopamine, does not increase filling pressures and may be associated with less tachycardia than dopamine; unfortunately, cardiac output often increases without significant changes in blood pressure. On the other hand, dopamine is sometimes more effective in increasing blood pressure than in increasing cardiac output. Interestingly, when infused to increase cardiac output to similar extents, epinephrine is associated with no more increase (and perhaps less) in heart rate than dobutamine. Inamrinone, enoximone, milrinone, and olprinone are selective phosphodiesterase inhibitors, and inotropes with
arterial and venous dilator properties. Only inamrinone and milrinone are available in North America. In studies of patients with chronic heart failure inamrinone and milrinone, unlike other inotropes, did not appreciably increase myocardial oxygen consumption. The combination of an inodilator (usually milrinone) and a β-adrenergic agonist results in at least additive (and possibly synergistic) inotropic effects. Norepinephrine is useful for increasing SVR but may compromise splanchic and renal blood flow at increased doses. Some clinicians use norepinephrine in combination with phosphodiesterase inhibitors to prevent excessive reductions in systemic arterial pressure. Arginine vasopressin may be used in patients with refractory hypotension, a low SVR, and resistance to norepinephrine. There are experimental reports in which doses of methylene blue or vitamin C have successfully counteracted vasodilation that could not be overcome with norepinephrine, vasopressin, or both. Inhaled nitric oxide and prostaglandin E₁ (or even inhaled milrinone) may also be helpful for refractory pulmonary hypertension and right ventricular failure (Table 22–4); nitric oxide has the added advantage of not decreasing systemic arterial pressure. Studies have not confirmed outcome benefits to the use of thyroid hormone (T₃) or glucose–insulin–potassium infusions for vasoactive/inotropic support after CPB.

### Table 22–4 Vasodilators
5. Postbypass Period

Following CPB, bleeding is controlled, bypass cannulas are removed, anticoagulation is reversed, and the chest is closed. Systolic arterial pressure is generally maintained at less than 140 mm Hg to minimize bleeding. Checking for bleeding, particularly from the posterior surface of the heart, requires lifting the heart, which can cause periods of precipitous hypotension. Some surgeons will need to be informed of the extent and duration of the hypotension; others have greater situational awareness. The atrial cannula(s) is removed before the aortic cannula in case the latter must be used to rapidly administer volume to the patient. Most patients need additional blood volume after termination of bypass. Administration of blood, colloids, and crystalloid is guided by observation of the left ventricle on TEE, filling pressures, and the postbypass hematocrit. A final hematocrit of 25% to 30% is desirable. Blood remaining in the CPB reservoir can be transfused via the aortic cannula, or it can be washed and processed by a cell-saver device and given intravenously. Frequent ventricular ectopy may reflect electrolyte disturbances or residual ischemia and usually should be treated with amiodarone; hypokalemia or hypomagnesemia should be corrected. Ventricular arrhythmias in this setting can rapidly deteriorate into ventricular tachycardia and fibrillation.

### Reversal of Anticoagulation

Once hemostasis is judged acceptable and the patient continues to remain stable,
heparin activity is reversed with protamine. **Protamine** is a highly positively charged protein that binds and effectively inactivates heparin (a highly negatively charged polysaccharide). Heparin–protamine complexes are then removed by the reticuloendothelial system. Protamine can be dosed in varying ways, but the results of all techniques should be checked for adequacy by repeating the ACT 3 to 5 min after completion of the protamine infusion. Additional incremental doses of protamine may be necessary.

One dosing technique bases the protamine dose on the amount of heparin initially required to produce the desired ACT; the protamine is then given in a ratio of 1 to 1.3 mg of protamine per 100 units of heparin. A still simpler approach is to give adult patients a defined dose (eg, 3–4 mg/kg) then check for adequacy of reversal. Another approach calculates the protamine dose based on the heparin dose–response curve (**Figure 22–14**). Automated heparin–protamine titration assays effectively measure residual heparin concentration and can also be used to calculate the protamine dose. The justification for using this methodology is the observation that when protamine is given in excess it may have anticoagulant activity, although this has never been demonstrated in humans. This approach also assumes that administered protamine remains in circulation for a prolonged time (which has been proven false in studies of patients undergoing cardiac surgery). To accomplish the heparin:protamine titration, premeasured amounts of protamine are added in varying quantities to several wells, each containing a blood sample. The well whose protamine concentration best matches the heparin concentration will clot first. Clotting will be prolonged in wells containing either too much or too little protamine. The protamine dose can then be estimated by multiplying the concentration in the tube that clots first by the patient’s calculated blood volume. Supplemental protamine (50–100 mg) may be considered after administration of unwashed blood remaining in the pump reservoir after CPB because that blood contains heparin.

Protamine administration can result in a number of adverse hemodynamic effects, some of which are immunological in origin. Protamine given slowly (5–10 min) usually has few effects; when given more rapidly it produces a fairly consistent vasodilation that is easily treated with blood from the pump oxygenator and small doses of phenylephrine. Catastrophic protamine reactions often include myocardial depression and marked pulmonary hypertension. Diabetic patients previously maintained on protamine-containing insulin (such as NPH) may be at increased risk for adverse reactions to protamine.
Persistent Bleeding

 Persistent bleeding often follows prolonged durations of bypass (>2 h) and in most instances has multiple causes. Inadequate surgical control of bleeding sites, incomplete reversal of heparin, thrombocytopenia, platelet dysfunction, hypothermia-induced coagulation defects, and undiagnosed preoperative hemostatic defects, or newly acquired factor deficiency or hypofibrinogenemia may be responsible. The absence (or loss) of clot formation may be noted in the surgical field. Normally, the ACT should return to baseline following administration of protamine; additional doses of protamine (25–50 mg) may be necessary. Reheparinization (heparin rebound) after apparent adequate reversal is poorly understood but often attributed to redistribution of peripherally bound heparin to the central compartment and to the exceedingly short persistence of protamine in blood. Hypothermia (<35°C) accentuates hemostatic defects and should be corrected. The administration of platelets and coagulation factors should be guided by additional coagulation studies, but empiric therapy may be necessary when such tests are not readily or promptly available as well as when treating massive transfusion. On the other hand, there can be abnormalities in multiple tests of coagulation whether or not there is bleeding, so the true diagnostic specificity and reliability of these tests is often overstated.

 If diffuse oozing continues despite adequate surgical hemostasis and the ACT is normal or the heparin–protamine titration assay shows no residual heparin, thrombocytopenia or platelet dysfunction is most likely. Comparison of a conventional ACT with an ACT measured in the presence of heparinase (an enzyme that cleaves and inactivates heparin) can confirm that no residual heparin requiring protamine reversal remains present when both tests provide the same result. Platelet defects are recognized complications of CPB, which may necessitate platelet transfusion. Significant depletion of coagulation factors, particularly factors V and VIII, during CPB is less commonly responsible for bleeding but should be treated with fresh frozen plasma; both the prothrombin time and partial thromboplastin time are usually prolonged in such instances. Hypofibrinogenemia (fibrinogen level <100 mg/dL or a prolonged thrombin time without residual heparin) should be treated with cryoprecipitate. Desmopressin (DDAVP), 0.3 mcg/kg (intravenously over 20 min), can increase the activity of factors VIII and XII and the von Willebrand factor by releasing them from the vascular endothelium. DDAVP may be effective in reversing qualitative platelet defects in some patients but is not recommended for routine use. Accelerated fibrinolysis may occasionally be encountered following CPB and should be treated with e-aminocaproic acid or tranexamic acid if one or the other of these
agents has not already being given; the diagnosis should be confirmed by elevated fibrin degradation products (≥32 mg/mL), or evidence of clot lysis on thromboelastography. Increasingly, factor VII concentrate or prothrombin complex concentrate are administered as a “last resort” in the setting of coagulopathic bleeding following cardiac surgery.

Anesthesia

Unless a continuous intravenous infusion technique is used, additional anesthetic agents are necessary following CPB; the choice may be determined by the hemodynamic response of the patient following CPB. We have found that most patients tolerate modest doses of volatile agents or propofol infusion. Patients with hypertension that is unresponsive to adequate anesthesia with opioids and either a volatile agent or propofol (or both) should receive a vasodilator such as nitroglycerin, nitroprusside, clevidipine, or nicardipine (Table 22–4). Fenoldopam may be used and has the added benefit of increasing renal blood flow, which might possibly improve kidney function in the early postoperative period.

It is common for an opioid (morphine or hydromorphone) and either propofol or dexmedetomidine to be given to provide analgesia and sedation during transfer to the ICU and analgesia (after discontinuation of the propofol or dexmedetomidine) during emergence.

Transportation

Transporting patients with critical illness from the operating room to the ICU is a consistently nerve-wracking and occasionally hazardous process that is complicated by the possibilities of monitor failure, overdosage, or interruption of drug infusions, and hemodynamic instability en route. Portable monitoring equipment, infusion pumps, and a full oxygen cylinder with a self-inflating bag for ventilation should be readied prior to the end of the operation. Minimum monitoring during transportation includes the ECG, arterial blood pressure, and pulse oximetry. A spare endotracheal tube, laryngoscope, succinylcholine, and emergency resuscitation drugs should also accompany the patient. Upon arrival in the ICU, the patient should be attached to the ventilator, breath sounds should be checked, and an orderly transfer of monitors and infusions (one at a time) should follow. The handoff to the ICU staff should include a brief summary of the procedure, intraoperative problems, current drug therapy, and any expected difficulties. Many centers insist on a standard protocol for the “handoff,” and we
strongly recommend this practice.

6. Postoperative Period

Depending on the patient, the type of surgery, and local practices, patients may be mechanically ventilated for 1 to 12 h postoperatively. Sedation may be maintained by a propofol or dexmedetomidine infusion. The emphasis in the first few postoperative hours should be on maintaining hemodynamic stability and monitoring for excessive postoperative bleeding. Chest tube drainage in the first 2 h of more than 250 to 300 mL/h (10 mL/kg/h)—in the absence of a hemostatic defect—is excessive and may require surgical reexploration. Subsequent drainage that exceeds 100 mL/h is also worrisome. Intrathoracic bleeding at a site not adequately drained may cause cardiac tamponade, requiring immediate reopening of the chest.

Hypertension despite analgesia and sedation is a common postoperative problem and should generally be treated promptly so as not to exacerbate bleeding or myocardial ischemia. Nitroprusside, nitroglycerin, clevidipine, nicardipine, or esmolol is generally used. Fluid replacement may be guided by filling pressures, echocardiography, or by responses to treatment. Most patients present with relative hypovolemia for several hours following operation. Hypokalemia (from intraoperative diuretics) often develops and requires replacement. Postoperative hypomagnesemia should be expected in patients who receive no magnesium supplementation intraoperatively.

Extubation should be considered only when muscle paralysis has worn off (or been reversed) and the patient is hemodynamically stable. Caution should be exercised in obese and elderly patients and those with underlying pulmonary disease. Cardiothoracic procedures are typically associated with marked decreases in functional residual capacity and postoperative diaphragmatic dysfunction.

Off-Pump Coronary Artery Bypass Surgery

The development of advanced epicardial stabilizing devices, such as the Octopus (Figure 22–16), facilitated coronary artery bypass grafting without the use of CPB, also known as off-pump coronary artery bypass (OPCAB). This type of retractor uses suction to stabilize and lift the anastomotic site rather than compress it down, which allows for greater hemodynamic stability. Full (CPB) dose heparinization is usually given and the CPB machine is usually immediately available if needed.
Intravenous fluid loading together with intermittent or continuous infusion of a vasopressor may be necessary while the distal anastomoses are sewn. In contrast, a vasodilator may be required to reduce the systolic pressure to 90 to 100 mm Hg during partial clamping of the aorta for the proximal anastomosis. Intravenous nitroglycerin is often used because of its ability to ameliorate myocardial ischemia.

Although OPCAB was initially proposed for “simple” one- or two-vessel bypass grafting in patients with good left ventricular function, it may be the sicker, older patients who benefit most from avoidance of CPB. The surgeon may use an intraluminal shunt to maintain coronary blood flow during sewing of distal anastomoses. Volatile anesthetic agents and morphine provide myocardial protection during prolonged periods of ischemia. Maintenance of anesthesia with a volatile agent may therefore be desirable. When the surgeon is skillful, long-term graft patency may be comparable to procedures done with CPB. Patients with extensive coronary disease, particularly those with poor target vessels, may not be good candidates. OPCAB may decrease the incidence of postoperative
neurological complications and the need for transfusion relative to conventional coronary bypass with CPB.

**PEDIATRIC PATIENTS**

Cardiovascular function in infants and young children differs from that in adults. Stroke volume is relatively fixed, so that cardiac output is primarily dependent on heart rate. The immature hearts of neonates and infants often are less forgiving of pressure or volume overload. Furthermore, the functions of both ventricles are more interdependent, so that failure of one ventricle often precipitates failure of the other (biventricular heart failure). Transition of the neonate from the fetal to the adult circulation is discussed in Chapter 40.

**Preoperative Evaluation**

The potentially complex nature of congenital heart defects and their operative repair demand close communication among the anesthesiologist, perfusionist, and surgeon. In children, the focus should include the exact anatomic abnormality and its physiological consequences, whether there has been any previous palliation or correction, and whether there are any other congenital malformations. The hemodynamic significance of the lesion and the planned surgical correction must be clearly understood. Congestive heart failure and pulmonary infections should be treated. Prostaglandin E$_1$ infusion (0.05–0.1 mcg/kg/min) is used preoperatively to prevent closure of the ductus arteriosus in infants dependent on ductal flow for survival. Congenital cardiac surgical emergencies are rare, chiefly correction of total anomalous pulmonary venous return or of excessive postoperative bleeding, or institution of extracorporeal membrane oxygenation (ECMO).

Assessment of disease severity relies on both clinical and laboratory evaluation. Deterioration in infants may be manifested by increasing tachypnea, cyanosis, or sweating, particularly during feeding. Older children may complain of easy fatigability. In infants body weight is generally a good indication of disease severity, with the sickest children showing failure to thrive and reduced weight relative to expectations for age. Signs of congestive heart failure include failure to thrive, tachycardia, an $S_3$ gallop, weak pulses, tachypnea, pulmonary rales, and hepatomegaly. Cyanosis may be noted, but hypoxemia is best assessed by measurements of arterial blood gases and the hematocrit. In the absence of iron deficiency, the degree of polycythemia is related to the severity and duration
of hypoxemia. Clubbing of the fingers is frequent in children with cyanotic defects. The evaluation should also search for other congenital abnormalities, which are present in up to 30% of patients with congenital heart disease.

The results of echocardiography, heart catheterization, electrocardiography, and chest radiography should be reviewed. Laboratory evaluation typically includes a complete blood count (with platelet count), coagulation studies, electrolytes, blood urea nitrogen, and serum creatinine. Measurements of ionized calcium and glucose are also useful in neonates and critically ill children.

**Preinduction Period**

**A. Fasting**

Fasting requirements vary according to the patient’s age and current guidelines. A preoperative intravenous infusion that provides maintenance fluid requirements should be used in patients susceptible to dehydration, in those with severe polycythemia, and when excessive delays occur prior to surgery.

**B. Premedication**

Premedication varies according to age and cardiac and pulmonary reserves. Atropine, 0.02 mg/kg intramuscularly (minimum dose, 0.15 mg), has by tradition been given to pediatric cardiac patients to counteract enhanced vagal tone. Neonates and infants younger than 6 months of age may receive no premedication or be given only atropine. Sedation is desirable in older patients, particularly those with cyanotic lesions (tetralogy of Fallot), as agitation and crying worsen right-to-left shunting. Patients older than 1 year may be given midazolam orally (0.5–0.6 mg/kg) or intramuscularly (0.08 mg/kg).

**Induction of Anesthesia**

**A. Hemodynamic Anesthetic Goals**

1. **Obstructive lesions**—Anesthetic management should strive to avoid hypovolemia, bradycardia, tachycardia, and myocardial depression. The optimal heart rate should be selected according to age; slow rates decrease cardiac output, whereas fast rates may impair ventricular filling. Mild cardiac depression may be desirable in some hyperdynamic patients, eg, those with coarctation of the aorta.

2. **Shunts**—A favorable ratio of pulmonary vascular resistance (PVR) to SVR
should be maintained in the presence of shunting. Factors known to increase PVR, such as acidosis, hypercapnia, hypoxia, enhanced sympathetic tone, and high mean airway pressures, are to be avoided in patients with right-to-left shunting; hyperventilation (hypocapnia) with 100% oxygen is usually effective in lowering PVR. Systemic vasodilation also worsens right-to-left shunting and should be avoided; phenylephrine may be used to raise SVR. Inhaled nitric oxide has no effect on systemic arterial pressure. Conversely, patients with left-to-right shunting may benefit from systemic vasodilation and increases in PVR.

B. Monitoring
Standard intraoperative monitors are generally used, but they may be first applied during the course of an inhaled induction in some patients. A large discrepancy between end-tidal and arterial CO\textsubscript{2} tensions should be anticipated in patients with large right-to-left shunts because of increased dead space. Following induction, intraarterial and central venous pressure monitoring are employed for thoracotomies and all procedures employing CPB. We recommend sonographic guidance for these cannulations. A 22- or 24-gauge catheter is used to enter the radial artery; 24-gauge catheters may be more appropriate for small neonates and premature infants. A cutdown may be necessary in some instances. The internal jugular or subclavian vein is generally used for central venous cannulation; if this approach is unsuccessful, a right atrial catheter may be placed intraoperatively by the surgeon. TEE is invaluable for assessing the surgical repair following CPB. Ever smaller probes are yielding better resolution as the technology advances. Probes are currently available for patients as small as 3 kg. Intraoperative epicardial echocardiography is commonly used either in addition to or instead of TEE.

C. Venous Access
Venous access is desirable but not always necessary for induction. Agitation and crying are particularly undesirable in patients with cyanotic lesions and can increase right-to-left shunting. Intravenous access can be established after induction but before intubation in most patients. Subsequently, at least two intravenous fluid infusion portals are required; one is typically via a central venous catheter. Caution is necessary to avoid even the smallest air bubbles. Shunting lesions allow the passage of venous air into the arterial circulation; paradoxical embolism can occur through the foramen ovale even in patients without obvious right-to-left shunting. Aspiration prior to each injection prevents dislodgment of any trapped air at stopcock injection ports.
D. Route of Induction
To a major extent, the effect of premedication and the presence of venous access determine the induction technique.

1. Intravenous—Propofol (2–3 mg/kg), ketamine (1–2 mg/kg), fentanyl (25–50 mcg/kg), or sufentanil (5–15 mcg/kg) can be used for intravenous induction. A pure opioid technique may be suitable for critically ill patients when postoperative ventilation is planned. Intravenous agents’ onset of action may be more rapid in patients with right-to-left shunting; drug boluses should be given slowly to avoid transiently high arterial blood levels. In contrast, recirculation in patients with large left-to-right shunts dilutes arterial blood concentration and can delay the appearance of intravenous agents’ clinical effects.

2. Intramuscular—Ketamine, 4 to 10 mg/kg, is most commonly used, and onset of anesthesia is within 5 min. Coadministration with atropine helps prevent excessive secretions. Ketamine is a good choice for agitated and uncooperative patients as well as patients with decreased cardiac reserve. Its safety with cyanotic lesions (particularly in patients with tetralogy of Fallot) is well established. Ketamine does not appear to increase PVR in children.

3. Inhalation—Sevoflurane is the most commonly used volatile agent. The technique is the same as for noncardiac surgery, except for greater concerns about avoiding excessive anesthetic doses. Sevoflurane is particularly suitable for patients with good cardiac reserve. Nitrous oxide is not often used other than to speed loss of consciousness with inhalation inductions. The uptake of inhalation agents may be slowed in patients with right-to-left shunts; in contrast, no significant effect on uptake is generally observed with left-to-right shunting. Intubation is facilitated by a nondepolarizing agent (rocuronium, 1.2 mg/kg, or vecuronium, 0.1 mg/kg) or, much less commonly, succinylcholine, 1.5 to 2 mg/kg.

Maintenance Anesthesia
Following induction, opioids or inhalation anesthetics are used for maintenance. Fentanyl and sufentanil are the most commonly used intravenous agents, and isoflurane and sevoflurane the most commonly used inhalation agents. Some clinicians choose the anesthetic according to the patient’s hemodynamic responses. Isoflurane and sevoflurane may be more suitable than halothane (the most commonly used inhaled agent in years past) for most patients; in equivalent anesthetic doses, halothane causes more myocardial depression, more slowing of
the heart rate, but less vasodilation than sevoflurane or isoflurane. However, one can make a sound theoretical argument in favor of halothane over sevoflurane for patients with tetralogy of Fallot (and similarly obstructive lesions such as hypertrophic subaortic stenosis), where myocardial depression is much preferred over vasodilation.

**Cardiopulmonary Bypass**

The circuit and technique used are similar to those used for adults. Because the smallest circuit volume used is still about three times an infant’s blood volume, blood is used to prime the circuit for neonates and infants to prevent excessive hemodilution. CPB may be complicated by intracardiac and extracardiac shunts and a very compliant arterial system (in very young patients); both tend to lower mean arterial pressure (20–50 mm Hg) and can impair systemic perfusion. High flow rates (up to 200 mL/kg/min) may be necessary to ensure adequate perfusion in very young patients. As noted previously, some evidence suggests that pH-stat management during CPB may be associated with better neurological outcome in children who will undergo circulatory arrest. Weaning from CPB is generally not a problem in pediatric patients if the surgical repair is adequate; primary pump failure is unusual. Difficulty in weaning should prompt the surgeon to check the repair and search for undiagnosed and uncorrected lesions. Intraoperative echocardiography, together with measurement of the pressure and oxygen saturation within the various chambers, may reveal the problem. Inotropic support may be provided by any of the agents used for adults. Calcium salts are more often useful in critically ill young patients than in adults as children more often have impaired calcium homeostasis; ionized calcium measurements are invaluable in such cases. Close monitoring of glucose is required because both hyperglycemia and hypoglycemia may be observed. Dopamine and epinephrine are the most commonly used inotropes in pediatric patients. Addition of a phosphodiesterase inhibitor is also useful when PVR or SVR is increased. Hypocapnia, systemic alkalosis, and a high inspired oxygen concentration should also be used to decrease PVR in patients with pulmonary hypertension; additional pharmacological adjuncts may include prostaglandin E\(_1\) (0.05–0.1 mcg/kg/min) or prostacyclin (1–40 mcg/kg/min). Inhalation nitric oxide may also be helpful for refractory pulmonary hypertension.

Children appear to have an intense inflammatory response during CPB that may be related to their blood being exposed to very large artificial surfaces relative to their size. Corticosteroids are often given to suppress this response.
Many centers use modified ultrafiltration after weaning from CPB to partially correct the hemodilution but remove inflammatory vasoactive substances (cytokines); the technique takes blood from the aortic cannula and venous reservoir, passes it through an ultrafilter, and returns it to the right atrium.

Surgical correction of complex congenital lesions often requires a period of complete circulatory arrest under deep hypothermia (deep hypothermic circulatory arrest; DHCA). Following institution of CPB, cooling is accomplished by a combination of surface cooling and a cold perfusate. At a core temperature of 15°C, up to 60 min of complete circulatory arrest may be safe. Ice packing around the head is used to delay rewarming and for surface cooling of the brain. Pharmacological brain protection is often attempted with methylprednisolone, 30 mg/kg, and mannitol, 0.5 g/kg. Following the repair, CPB flow is restarted and rewarming takes place.

**Postbypass Period**

Because of the large priming volumes used (often 200–300% of the patient’s blood volume), hemostatic defects from dilution of clotting factors and platelets are commonly seen after CPB in infants; in addition to heparin reversal, administration of fresh frozen plasma and platelets is often necessary.

Patients undergoing extensive or complicated procedures will generally remain intubated. Extubation may be considered for older, relatively healthy patients undergoing simple procedures such as closure of a patent ductus or atrial septal defect or repair of coarctation of the aorta.

---

**Cardiac Transplantation**

**Preoperative Considerations**

Cardiac transplantation is the treatment of choice for otherwise healthy patients with end-stage heart disease so severe that they are unlikely to survive the next 6 to 12 months. The procedure is generally associated with 80% to 90% postoperative survival at 1 year and 60% to 90% survival at 5 years. Transplantation improves quality of life, allowing most patients to resume a relatively normal lifestyle. Unfortunately, the number of cardiac transplants performed is limited by the supply of donor hearts, which are obtained from brain-dead patients, most commonly following intracranial hemorrhage or head trauma.
Patients with intractable heart failure have an ejection fraction of less than 20% and fall into New York Heart Association functional class IV (see Chapter 21) and heart failure class D. For most patients, the primary diagnosis is cardiomyopathy. Intractable heart failure may be the result of a severe congenital lesion, ischemic cardiomyopathy, viral cardiomyopathy, peripartum cardiomyopathy, a failed prior transplantation, or valvular heart disease. Medical therapy should include the standard drugs used for heart failure, including angiotensin-converting enzyme inhibitors (or angiotensin receptor blockers, or both) and β-blockade (usually with carvedilol). Many will receive electrical pacing with an automatic implanted defibrillator. Other drugs may include diuretics, vasodilators, and even oral inotropes; oral anticoagulation with warfarin may also be necessary. Patients may not be able to survive without intravenous inotropes while awaiting transplantation. Intraaortic balloon counterpulsation, an LVAD, or even a total mechanical heart may also be necessary while the patient awaits a transplant.

Transplant candidates must not have suffered extensive end-organ damage or have other major systemic illnesses. Reversible kidney and hepatic dysfunction are common because of chronic hypoperfusion and venous congestion. PVR must be normal or at least responsive to oxygen or vasodilators. Irreversible pulmonary vascular disease is usually associated with a PVR of more than 6 to 8 Wood units (1 Wood unit = 80 dyn·s·cm⁻⁵) and is a contraindication to orthotopic cardiac transplantation because right ventricular failure is a major cause of early postoperative mortality. Patients with long-standing pulmonary hypertension may, however, be candidates for combined heart–lung transplantation.

Tissue cross-matching is generally not performed. Donor–recipient compatibility is based on size, ABO blood-group typing, and cytomegalovirus serology. Donor organs from patients with hepatitis B or C or HIV infections are excluded.

ANESTHETIC MANAGEMENT

Proper timing and coordination are necessary between the donor organ retrieval team and the transplant center. Premature induction of anesthesia unnecessarily prolongs the time under anesthesia for the recipient, whereas delayed induction may jeopardize graft function by prolonging the period of ischemia.

Patients may receive little advance warning of the availability of a suitable organ. Many will have eaten a recent meal and should be considered to have a
full stomach. Oral cyclosporine must be given preoperatively. Administration of a clear antacid (sodium citrate), a histamine H₂-receptor blocker, and metoclopramide should be considered. Any sedating premedication may be administered intravenously just prior to induction.

Monitoring is similar to that used for other cardiac procedures. Strict asepsis should be observed during invasive procedures. Use of the right internal jugular vein for central access does not appear to compromise its future use for postoperative endomyocardial biopsies. A pulmonary artery catheter is used in many centers for postbypass management. It need not be placed in the pulmonary artery before CPB.

A rapid sequence induction may be performed. The principal objective of anesthetic management is to maintain organ perfusion until the patient is on CPB. Induction may be carried out with small doses of opioids (fentanyl, 5–10 mcg/kg) with or without etomidate (0.2–0.3 mg/kg). A low-dose ketamine–midazolam technique (as noted earlier) may also be suitable. Sufentanil, 5 mcg/kg, followed by succinylcholine, 1.5 mg/kg, can be used as a rapid-sequence technique. Anesthesia is maintained in a similar fashion as for other cardiac operations. A TEE probe is placed following induction, and antirejection drugs are given.

Sternotomy and cannulation for CPB may be complicated by scarring from prior cardiac operations. Aminocaproic acid or tranexamic acid can be used to decrease postoperative bleeding. CPB is initiated following cannulation of the aorta and both cavae. If a pulmonary artery catheter was placed, it must be completely withdrawn from the heart with its tip in the superior vena cava. It must remain within its sterile, protective sheath if it is to be safely refloated again into the pulmonary artery following CPB. The recipient’s heart is then excised, allowing the posterior wall of both atria (with the caval and pulmonary vein openings) to remain. The atria of the donor heart are anastomosed to the recipient’s atrial remnants (left side first). The aorta and then the pulmonary artery are anastomosed end to end. The donor heart is then flushed with saline and intracardiac air is evacuated. Methylprednisolone is given before the aortic cross-clamp is released.

Inotropic support is usually started prior to separation from CPB to counteract bradycardia from sympathetic denervation. Prolonged graft ischemia may result in transient myocardial depression. Slow junctional rhythms are common and may require epicardial pacing. Although the transplanted heart is totally denervated and direct autonomic influences are absent, its response to circulating catecholamines is usually normal. The pulmonary artery catheter can be
refloated into position after CPB and is used in conjunction with TEE to evaluate the patient. Right ventricular failure from pulmonary hypertension, a common post-CPB problem, can be treated with hyperventilation, prostaglandin E₁ (0.025–0.2 mcg/kg/min), inhaled nitric oxide (10–60 ppm), milrinone, or an RVAD, if necessary. Bleeding is also a common problem.

Patients will be extubated when they meet criteria, as with other major cardiac operations. The postoperative course may be complicated by acute rejection, renal and hepatic dysfunction, and infections.

Many heart failure patients are treated with long-term LVADs, as they do not qualify for heart transplantation. Moreover, there are insufficient hearts available to meet the needs of the heart failure population. Perioperative management concerns of the LVAD patient are similar to those of the heart failure patient as both procedures are surgical interventions to treat heart failure. Patients are routinely scheduled for LVAD placement as elective procedures. Such patients are frequently managed with home milrinone inotropic therapy and often are treated with furosemide infusions to promote diuresis while awaiting surgical intervention. Ideally, LVAD placement and heart transplantation occur before deterioration in hepatic and kidney function.

TEE examination is required perioperatively to rule out the presence of a patent foramen ovale or other conditions that could lead to a right-to-left shunt (eg, atrial septal defects) following LVAD placement. When activated, the LVAD drains blood from the left ventricle and in a nonpulsatile manner pumps it into the aorta (Figure 22–17). Left-sided heart pressures decrease. If right-sided pressures are greater than those of the left heart, venous blood will flow across an atrial septal defect or patent foramen ovale into the left atrium, decreasing arterial oxygen saturation.
Additionally, TEE examination is necessary to assess right heart function perioperatively. The right ventricle must sufficiently overcome any pulmonary hypertension to deliver an adequate blood volume to the left heart for the LVAD to pump into the aorta. Should the left heart be inadequately filled, the LVAD device will “suck down” the walls of the left ventricle, resulting in dramatically reduced LVAD pump flow.

A temporary RVAD may be needed perioperatively if right ventricular failure ensues. Pulmonary arterial vasodilators (eg, nitric oxide) are used to reduce pulmonary artery pressure and thus decrease the resistance against which the right ventricle must pump.

Various temporary assist devices are available to transiently support ventricular function. Percutaneous devices can be placed in the cardiac catheterization laboratory to support left ventricular function by pumping blood from the left ventricle and ejecting it past the aortic valve into the aorta. Often these devices are employed during percutaneous coronary artery interventions to
support ventricular function. Patients in need of emergency coronary artery bypass surgery following failed percutaneous interventions will routinely present to the operating room supported with a percutaneous ventricular assist device (**Figure 22–18**).

**PERICARDIAL DISEASE**

The parietal pericardium is a fibrous membrane surrounding the heart, to which it normally is not adherent. The pericardium encompasses a relatively fixed intrapericardiac volume that includes a small volume of pericardial fluid (20–50 mL in adults), in addition to the heart and blood. As a result, the pericardium normally limits acute dilation of the ventricles and promotes diastolic coupling of the two ventricles (distention of one ventricle interferes with filling of the other). The latter effect is also due to the interventricular septal wall they share. Moreover, diseases of the pericardium or larger pericardial fluid collections can seriously impair cardiac output.

Pericardial effusions may be due to viral, bacterial, or fungal infections;
malignancies; bleeding after cardiac surgery; trauma; uremia; myocardial infarction; aortic dissection; hypersensitivity or autoimmune disorders; drugs; or myxedema.

1. Cardiac Tamponade

Preoperative Considerations

Cardiac tamponade exists when increased pericardial pressure impairs diastolic filling of the heart. Cardiac filling is ultimately related to the diastolic transmural (distending) pressure across each chamber, and any increase in pericardial pressure relative to the pressure within the chamber reduces filling. Pressure is applied equally to each cardiac chamber when the problem is a pericardial fluid collection; or, it can be applied “selectively,” as for example when an isolated pericardial blood clot compresses the left atrium. In general, the thin-walled atria and the right ventricle are more susceptible to pressure-induced abnormalities of filling than the left ventricle.

Pericardial pressure is normally similar to pleural pressure, varying with respiration between −4 and +4 mm Hg. Elevations in pericardial pressure are most commonly due to increases in pericardial fluid volume (as a consequence of effusions or bleeding). The magnitude of the increased pressure depends on both the volume of fluid and the rate of fluid accumulation; sudden increases exceeding 100 to 200 mL precipitously increase pericardial pressure, whereas very slow accumulations up to 1000 mL allow the pericardium to stretch with minimal increases in pericardial pressure.

The principal hemodynamic features of cardiac tamponade include decreased cardiac output from reduced stroke volume with an increase in central venous pressure. In the absence of severe left ventricular dysfunction, equalization of diastolic pressure occurs throughout the heart (right atrial pressure [RAP] = right ventricular end-diastolic pressure [RVEDP] = left atrial pressure [LAP] = left ventricular end-diastolic pressure [LVEDP]).

The central venous pressure waveform is characteristic in cardiac tamponade. Impairment of both diastolic filling and atrial emptying abolishes the y descent; the x descent (systolic atrial filling) is normal or even accentuated. Reflex sympathetic activation is a prominent compensatory response in cardiac tamponade. The resulting increases in heart rate and contractility help maintain cardiac output. Arterial vasoconstriction (increased SVR) supports systemic blood pressure, whereas sympathetic activation reduces vascular capacitance,
having the effect of an autotransfusion. Because stroke volume remains relatively fixed, cardiac output becomes primarily dependent on heart rate.

Acute cardiac tamponade usually presents as sudden hypotension, tachycardia, and tachypnea. Physical signs include jugular venous distention, a narrowed arterial pulse pressure, and muffled heart sounds. The patient may complain of an inability to lie flat. A prominent pulsus paradoxus (a cyclic inspiratory decrease in systolic blood pressure of more than 10 mm Hg) is typically present. The latter actually represents an exaggeration of a normal phenomenon related to inspiratory decreases in intrathoracic pressure. (A marked pulsus paradoxus may also be seen with severe airway obstruction or right ventricular infarction.) The heart may appear normal or enlarged on a chest radiograph. Electrocardiographic signs are generally nonspecific and are often limited to decreased voltage in all leads and nonspecific ST-segment and T-wave abnormalities. Electrical alternans (a cyclic alteration in magnitude of the P waves, QRS complex, and T waves) may be seen with large pericardial effusions and is thought to be due to pendular swinging of the heart within the pericardium. Generalized ST-segment elevation may also be seen in two or three limb leads as well as V₂ to V₆ in the early phase of pericarditis. A friction rub may be heard by auscultation. Echocardiography is invaluable in diagnosing and measuring pericardial effusions and cardiac tamponade, and as a guide for accurate needle insertion for pericardiocentesis. Signs of tamponade include diastolic compression or collapse of the right atrium and right ventricle, leftward displacement of the ventricular septum, and an exaggerated increase in right ventricular size with a reciprocal decrease in left ventricular size during inspiration.

Anesthetic Considerations

Symptomatic cardiac tamponade requires evacuation of the pericardial fluid, either surgically or by pericardiocentesis. The latter is associated with a risk of lacerating the heart or coronary arteries and of pneumothorax. Traumatic postoperative (following thoracotomy) cardiac tamponade is nearly always treated surgically, whereas tamponade from other causes may more often be amenable to pericardiocentesis. Surgical treatment is also often undertaken for large recurrent pericardial effusions (infectious, malignant, autoimmune, uremic, or radiation induced) to prevent tamponade. Simple needle drainage of pericardial fluid may be achieved through a subxiphoid approach, whereas drainage combined with pericardial biopsy or pericardiectomy may be
performed via a left anterior thoracotomy or median sternotomy. Drainage and biopsies can also be accomplished through left-sided thoracoscopy.

The anesthetic approach must be tailored to the patient. For the intubated postoperative cardiac patient in extremis, the chest may be reopened immediately in the ICU. For awake conscious patients who will undergo left thoracotomy or median sternotomy, general anesthesia and endotracheal intubation are necessary. Local anesthesia may be used for patients undergoing simple drainage through a subxiphoid approach or pericardiocentesis. Removal of even a small volume of fluid may be sufficient to greatly improve cardiac output and allow safe induction of general anesthesia. Small doses (10 mg intravenously at a time) of ketamine also provide excellent supplemental analgesia.

Induction of general anesthesia in patients with cardiac tamponade can precipitate severe hypotension and cardiac arrest. We find it useful to have an epinephrine infusion available and we sometimes initiate it before induction.

Large-bore intravenous access is mandatory. Monitoring of intraarterial pressure is useful, but placement of monitors should not delay pericardial drainage if the patient is unstable. The anesthetic technique should maintain a high sympathetic tone until the tamponade is relieved; in other words, “deep” anesthesia is not the object. Cardiac depression, vasodilation, and slowing of the heart rates should be avoided. Similarly, increases in mean airway pressures can seriously jeopardize venous return. Awake intubation with maintenance of spontaneous ventilation is theoretically desirable but rarely done because coughing, straining, hypoxemia, and respiratory acidosis are detrimental and should be avoided. Thoracoscopy requires one-lung anesthesia.

Ketamine is the agent of choice for induction and maintenance until the tamponade is relieved. Small doses of epinephrine (5–10 mcg) may be useful as a temporary inotrope and chronotrope. Generous intravenous fluid administration is useful in maintaining cardiac output.

2. Constrictive Pericarditis

Preoperative Considerations

Constrictive pericarditis may develop as a sequel of acute or recurrent pericarditis. Pathologically, the pericardium is thickened, fibrotic, and often calcified. The parietal pericardium is typically adherent to the visceral pericardium on the heart, often obliterating the pericardial space. The stiffened
parietal pericardium limits diastolic filling of the heart to a fixed and reduced volume. In contrast to acute cardiac tamponade, filling during early diastole is typically accentuated and manifested by a prominent y descent on the central venous pressure waveform.

Patients with constrictive pericarditis display jugular venous distention, hepatomegaly, and often ascites. Liver function may be abnormal. In contrast to acute tamponade, constrictive pericarditis prevents respiratory fluctuations in pericardial pressure; because venous return to the heart does not increase during inspiration, a pulsus paradoxus is uncommon. In fact, venous pressure does not fall or may paradoxically rise during inspiration (Kussmaul sign). The chest radiograph will often reveal pericardial calcification. Low QRS voltage and diffuse T-wave abnormalities are usually present on the ECG. Atrial fibrillation and conduction blocks may be present. Echocardiography may be helpful in making the diagnosis.

**Anesthetic Considerations**

Pericardiectomy is usually reserved for patients with moderate to severe disease. The procedure is usually performed through a median sternotomy. It is complicated by the necessity for extensive manipulations of the heart that interfere with cardiac filling and ejection, induce frequent arrhythmias, and risk cardiac perforation. CPB may be required. Selection of specific anesthetic agents is less important than avoiding excessive cardiac depression, vasodilation, and bradycardia. Cardiac output is generally rate dependent. Adequate large-bore intravenous access and direct arterial and central venous pressure monitoring are usually employed. Although cardiac function usually improves immediately following pericardiectomy, some patients display a persistently low cardiac output and require temporary postoperative inotropic support.

**Anesthetic Management of Vascular Surgery**

**ANESTHESIA FOR SURGERY ON THE AORTA**

**Preoperative Considerations**

Open surgery on the aorta represents a great challenge for anesthesiologists. Regardless of which part of the vessel is involved, the procedure is complicated
by the need to cross-clamp the aorta and by the potential for large intraoperative blood losses. Aortic cross-clamping without CPB acutely increases left ventricular afterload and severely compromises organ perfusion distal to the point of occlusion. Severe hypertension, myocardial ischemia, left ventricular failure, or aortic valve regurgitation may be precipitated. Interruption of blood flow to the spinal cord, kidneys, and intestines can produce paraplegia, kidney failure, or intestinal infarction, respectively. Moreover, emergency aortic surgery is frequently necessary in critically ill patients who are acutely hypovolemic and have a high incidence of coexistent cardiac, renal, and pulmonary disease; hypertension; and diabetes. Advances in surgical techniques now permit many aortic lesions to be managed using stents, thereby avoiding many of the challenges presented by open surgery.

Indications for aortic surgery include aortic dissections, aneurysms, occlusive disease, trauma, and coarctation. Lesions of the ascending aorta lie between the aortic valve and the innominate artery, whereas lesions of the aortic arch lie between the innominate and left subclavian arteries. Disease distal to the left subclavian artery but above the diaphragm involves the descending thoracic aorta; lesions below the diaphragm involve the abdominal aorta.

**SPECIFIC LESIONS OF THE AORTA**

**Aortic Dissection**

In an aortic dissection an intimal tear allows blood to track into the aortic wall (the media), creating a new pathway for blood flow. In many cases, a primary degenerative process called cystic medial necrosis predisposes for dissection to occur. Patients with hereditary connective tissue defects such as Marfan syndrome and Ehlers–Danlos syndrome eventually develop cystic medial necrosis and are at risk for aortic dissection. Propagation of the dissection is thought to occur as a result of hemodynamic shear forces acting on the intimal tear; indeed, hypertension is a common finding in patients with aortic dissection. Dissection can also occur from hemorrhage into an atheromatous plaque or at the aortic cannulation site following cardiac surgery.

Dissections may occlude the orifice of any artery arising directly from the aorta; they may extend into the aortic root, producing incompetence of the aortic valve; or may rupture into the pericardium or pleura, producing cardiac tamponade or hemothorax, respectively. TEE plays an important role in diagnosing and characterizing aortic dissections. Dissections are most commonly
of the proximal type (Stanford type A, De Bakey types I and II) involving the ascending aorta. Type II dissections do not extend beyond the innominate artery. Distal dissections (Stanford type B, De Bakey type III) originate beyond the left subclavian artery and propagate only distally. Proximal dissections are nearly always treated surgically, whereas distal dissections may be treated medically. In either case, from the time the diagnosis is suspected, measures to reduce systolic blood pressure (usually to 90–120 mm Hg) and aortic wall stress are initiated. These measures usually include intravenous vasodilators (nicardipine or nitroprusside) and β-adrenergic blockade (esmolol or a longer acting agent). The latter is important in reducing the shear forces related to the rate of rise of aortic pressure \( (dP/dt) \), which may actually increase with nitroprusside alone.

Aortic Aneurysms

Aneurysms more commonly occur in the abdominal than in the thoracic aorta. The vast majority of aortic aneurysms are due to atherosclerosis; cystic medial necrosis is also an important cause of thoracic aortic aneurysms. Syphilitic aneurysms characteristically involve the ascending aorta. Other etiologies include various connective tissue diseases and trauma. Dilation of the aortic root often produces aortic regurgitation. Expanding aneurysms of the upper thoracic aorta can also cause tracheal or bronchial compression or deviation, hemoptysis, and superior vena cava syndrome. Compression of the left recurrent laryngeal nerve produces hoarseness and left vocal cord paralysis. Distortion of the normal anatomy may also complicate endotracheal or endobronchial intubation or cannulation of the internal jugular and subclavian veins.

The greatest danger from untreated aortic aneurysms is rupture and exsanguination. A pseudoaneurysm forms when the intima and media are ruptured and only adventitia or blood clot forms the outer layer. Acute expansion (from leaking), manifested as sudden severe pain, may herald rupture. The likelihood of catastrophic rupture is related to size. The normal aorta in adults varies from 2 to 3 cm in width (it is wider cephalad). The data are clear for abdominal aortic aneurysms; rupture occurs in 50% of patients within 1 year when an aneurysm is 6 cm or greater in diameter. Elective treatment is generally performed in most patients with aneurysms 5 cm or greater. Most often this is accomplished with an intravascular stent; less often, open surgery and a prosthetic graft is used. The operative mortality rate is about 2% to 5% in good-risk patients and exceeds 50% if leaking or rupture has already occurred. The risks are much less with intravascular stenting, which has become the preferred procedure whenever the anatomy permits.
Occlusive Disease of the Aorta

Atherosclerotic obliteration of the aorta most commonly occurs near the aortic bifurcation (Leriche syndrome). Occlusion results from a combination of atherosclerotic plaque and thrombosis. Atherosclerosis is usually generalized and affects other parts of the arterial system, including the cerebral, coronary, and renal arteries. Treatment may be accomplished by intravascular stenting or by open surgery with an aortobifemoral bypass graft; proximal thromboendarterectomy may also be necessary.

Aortic Trauma

Aortic trauma may be penetrating or nonpenetrating. Both types of injuries can result in massive hemorrhage and require immediate operation. Whereas penetrating injuries are usually obvious, blunt aortic trauma may be easily overlooked if not suspected and the appropriate diagnostic testing performed. Nonpenetrating aortic trauma typically results from sudden high-speed decelerations such as those caused by automobile accidents (eg, in which the driver’s chest impacts the steering wheel) and falls. The injury can vary from a partial tear to a complete aortic transection. Because the aortic arch is relatively fixed whereas the descending aorta is relatively mobile, the shear forces are greatest and the site of injury most common just distal to the subclavian artery. The most consistent initial finding is a widened mediastinum on a chest radiograph. Definitive diagnosis can be accomplished with magnetic resonance or computed tomographic imaging or TEE.

Coarctation of the Aorta

This congenital heart defect may be classified according to the position of the narrowed segment relative to the position of the ductus arteriosus. In the preductal (infantile) type, the narrowing occurs proximal to the opening of the ductus. This lesion, which is often associated with other congenital heart defects, is recognized in infancy because of a marked difference in perfusion between the upper and lower halves of the body; the lower half is cyanotic. Perfusion to the upper body is derived from the aorta, whereas perfusion to the lower body is primarily from the pulmonary artery. Postductal coarctation of the aorta may not be recognized until adulthood. The symptoms and hemodynamic significance of this lesion depend on the severity of the narrowing and the extent of collateral circulation that develops to the lower body (internal mammary, subscapular, and
lateral thoracic to intercostal arteries). Hypertension in the upper body, with or without left ventricular failure, is usually present. So-called “rib notching” may be present on the chest radiograph as a result of dilated collateral intercostal arteries.

ANESTHETIC MANAGEMENT

Surgery on the Ascending Aorta

Surgery on the ascending aorta routinely uses median sternotomy and CPB, and may also include DHCA. The conduct of anesthesia is similar to that for cardiac operations involving CPB, but the intraoperative course may be complicated by long aortic cross-clamp times and large intraoperative blood losses. TEE is especially useful. Blood loss can be reduced by administration of ε-aminocaproic acid or tranexamic acid. Concomitant aortic valve replacement and coronary reimplantation are often necessary (Bentall procedure). The radial artery cannulation site should be guided by the possible need for clamping of either the subclavian or innominate arteries during the procedure. Nicardipine or nitroprusside may be used for precise blood pressure control. β-Adrenergic blockade should also be employed in the presence of an aortic dissection. On the other hand, bradycardia worsens aortic regurgitation and should be avoided. The arterial inflow cannula for CPB is placed in a femoral artery for patients with dissections. In the event that sternotomy may rupture an aneurysm, prior establishment of partial CPB (using the femoral artery and femoral vein) should be considered.

Surgery Involving the Aortic Arch

These procedures are usually performed through a median sternotomy with DHCA (following institution of CPB). Additional considerations focus on achieving optimal cerebral protection with systemic and topical hypothermia (as noted earlier). Hypothermia to 15°C, drug infusion to maintain a flat EEG, methylprednisolone or dexamethasone, mannitol, and phenytoin are also commonly administered (but there is vanishingly small evidence for efficacy of these drug treatments). The necessarily long rewarming periods probably contribute to the larger intraoperative blood losses commonly observed after CPB.
Surgery Involving the Descending Thoracic Aorta

Surgery limited to the descending thoracic aorta may be performed through a left thoracotomy without CPB, with or without (so-called “clamp-and–run” technique) a heparin-impregnated left ventricular apex to femoral artery shunt; or using partial right atrium to femoral artery bypass. Alternatively, stenting may obviate the need for complex open surgery. A thoracoabdominal incision is necessary for lesions that also involve the abdominal aorta. One-lung anesthesia greatly facilitates surgical exposure. Correct positioning of the endobronchial tube (even with fiberoptic bronchoscopy) may be difficult because of distortion of the anatomy. A double-lumen tube or a regular endotracheal tube with a bronchial blocker may be necessary.

The aorta must be cross-clamped above and below the lesion. Acute hypertension develops above the clamp, with hypotension below when there is no shunt or partial bypass. Arterial blood pressure should be monitored from the right radial artery, as clamping of the left subclavian artery may be necessary. The sudden increase in left ventricular afterload after application of the aortic cross-clamp during aortic surgery may precipitate acute left ventricular failure and myocardial ischemia, particularly in patients with underlying ventricular dysfunction or coronary disease; it can also exacerbate preexisting aortic regurgitation. Cardiac output falls and left ventricular end-diastolic pressure and volume rise. The magnitude of these changes is inversely related to ventricular function. These effects can be ameliorated by the use of shunting or partial bypass. Moreover, the adverse effects of aortic clamping become less pronounced the more distal on the aorta that the clamp is applied. A vasodilator infusion is often needed to prevent excessive increases in blood pressure. In patients with good ventricular function, increasing anesthetic depth just prior to cross-clamping may also be helpful.

Excessive intraoperative bleeding may occur during these procedures. Prophylaxis with antifibrinolytic agents may be helpful. A blood scavenging device (cell saver) for autotransfusion is routinely used. Adequate venous access and intraoperative monitoring are critical. Multiple large-bore (14-gauge) intravenous catheters (preferably with blood warmers) are useful. Intraoperative TEE is often used. The period of greatest hemodynamic instability follows the release of the aortic cross-clamp; the abrupt decrease in afterload together with bleeding and the release of vasodilating acid metabolites from the ischemic lower body can precipitate severe systemic hypotension and less commonly hyperkalemia. Decreasing anesthetic depth, volume loading, and partial or slow release of the cross-clamp are helpful in avoiding severe hypotension. A bolus
dose of a vasopressor may be necessary. Sodium bicarbonate is often used, particularly for persistent severe metabolic acidosis (pH <7.20) in association with hypotension. Calcium chloride may be necessary when symptomatic hypocalcemia follows massive transfusion of citrated blood products.

**A. Paraplegia**

Spinal cord ischemia can complicate thoracic aortic cross-clamping. The incidence of transient postoperative deficits and postoperative paraplegia are 11% and 6%, respectively. Increased rates are associated with cross-clamping periods longer than 30 min, extensive surgical dissections, and emergency procedures. The classic deficit is an anterior spinal artery syndrome with loss of motor function and pinprick sensation but preservation of vibration and proprioception. Anatomic variations in spinal cord blood supply are responsible for the unpredictable occurrence and variable nature of deficits. The spinal cord receives its blood supply from the vertebral arteries and from the thoracic and abdominal aorta. One anterior and two posterior arteries descend along the cord. Intercostal arteries feed the anterior and posterior arteries in the upper thoracic aorta. Textbook descriptions suggest that in the lower thoracic and lumbar cord, the anterior spinal artery is supplied by the thoracolumbar artery of Adamkiewicz. The truth is that a single large feeding artery cannot always be identified. When present, this artery has a variable origin from the aorta, arising between T5 and T8 in 15%, between T9 and T12 in 60%, and between L1 and L2 in 25% of individuals; it nearly always arises on the left side. It may be damaged during surgical dissection or occluded by the aortic cross-clamping. Monitoring motor and somatosensory evoked potentials may be useful in preventing paraplegia, but clearly surgical technique and speed are most important.

As noted earlier, use of a temporary heparin-coated shunt or partial CPB with hypothermia maintains distal perfusion and decreases the incidence of paraplegia, hypertension, and ventricular failure. Partial CPB has the disadvantage of requiring heparinization, which increases blood loss. Using a heparin-coated shunt precludes the need for heparinization. It is usually positioned proximally in the left ventricular apex and distally in a femoral artery. Other therapeutic measures that may be protective of the spinal cord include methylprednisolone, mild hypothermia, mannitol, and drainage of cerebrospinal fluid (CSF) to reduce the CSF pressure in the spine; magnesium is also protective in some animal models. The efficacy of mannitol appears to be related to its ability to lower CSF pressure by decreasing its production. Spinal cord
Perfusion pressure is mean arterial blood pressure minus CSF pressure; the rise in CSF pressure following experimental cross-clamping of the aorta may explain how a mannitol-induced decrease in CSF pressure could improve spinal cord perfusion pressure during cross-clamping. Any protective effect of drainage of CSF via a lumbar catheter may have a similar mechanism.

The excessive use of vasodilators to control the hypertensive response to cross-clamping may be a contributing factor in spinal cord ischemia, as drug actions also occur distal to the cross-clamp. Excessive reduction in blood pressure above the cross-clamp should therefore be avoided to prevent inadequate blood flow and excessive hypotension below it.

**B. Kidney Failure**

An increased incidence of acute kidney failure following aortic surgery is reported after emergency procedures, prolonged cross-clamping periods, and prolonged hypotension, particularly in patients with preexisting kidney disease. A variety of “cocktails” have been employed in the hope of reducing the risk of kidney failure, including infusion of mannitol (0.5 g/kg) prior to cross-clamping, furosemide, and fenoldopam (or low-dose dopamine); however, there is no convincing evidence that these treatments alter renal outcomes.

**Surgery on the Abdominal Aorta**

Stents are most often placed via catheters inserted in a femoral artery. When an open technique is chosen, either an anterior transperitoneal or an anterolateral retroperitoneal approach can be used to access the abdominal aorta. Depending on the location of the lesion, the cross-clamp can be applied to the supraceliac, suprarenal, or infrarenal aorta. Heparin is usually administered prior to aortic clamping. Intraarterial blood pressure can be monitored from either upper extremity. In general, the more distally the clamp is applied to the aorta, the less the effect on left ventricular afterload. In fact, occlusion of the infrarenal aorta frequently results in minimal hemodynamic changes. In contrast, release of the clamp usually produces hypotension; the same techniques that were described earlier may be used to counteract the effects of unclamping. The large incision and extensive retroperitoneal surgical dissection increase fluid requirements beyond intraoperative blood loss. We recommend colloid to maintain intravascular volume and crystalloid for maintenance fluids. Fluid replacement may be guided by monitoring central venous pressure, or better, noninvasive monitors of stroke volume or TEE.
Clamping of the infrarenal aorta decreases renal blood flow, which may contribute to postoperative kidney failure. The decrease in renal blood flow is not prevented by epidural anesthesia or blockade of the renin–angiotensin system. Some centers use continuous epidural anesthesia combined with general anesthesia for abdominal aortic surgery. This combined technique decreases the general anesthetic requirement and appears to suppress the release of stress hormones. It also provides an excellent route for administering postoperative epidural analgesia. Systemic heparinization during surgery introduces concern regarding the risk of paraplegia secondary to an epidural hematoma; however, all credible studies suggest that when the catheter is placed atraumatically well in advance of heparinization and removed after reversal of anticoagulation there is no increased risk of neuraxial hematoma.

Postoperative Considerations

Those undergoing stenting may not require intubation either during or after the procedure. Most patients undergoing open surgery on the ascending aorta, the arch, or the thoracic aorta will remain intubated and ventilated for 1 to 24 h postoperatively. As with cardiac surgery, the initial emphasis in their postoperative care should be on hemodynamic stability and monitoring for postoperative bleeding. Patients undergoing open abdominal aortic surgery may be extubated at the end of the procedure.

ANESTHESIA FOR CAROTID ARTERY SURGERY

Preoperative Considerations

Ischemic cerebrovascular disease accounts for 80% of strokes; the remaining 20% are due to hemorrhage. Ischemic strokes are usually the result of embolism or (less commonly) thrombosis in one of the blood vessels supplying the brain. Ischemic stroke may follow severe vasospasm after subarachnoid hemorrhage. By convention, a stroke is defined as a neurological deficit that lasts more than 24 h; its pathological correlate is typically focal infarction of brain. Transient ischemic attacks (TIAs), on the other hand, are neurological deficits that resolve within 24 h; they may be due to a low-flow state at a tightly stenotic lesion or to emboli that arise from an extracranial vessel or the heart. When a stroke is associated with progressive worsening of signs and symptoms, it is frequently termed a stroke in evolution. A second distinction is also often made between complete and incomplete strokes, based on whether the territory involved is
completely affected or additional brain remains at risk for focal ischemia (eg, hemiplegia versus hemiparesis). The bifurcation of the common carotid artery (the origin of the internal carotid artery) is the most common site of atherosclerotic plaques that may lead to TIA or stroke. The mechanism may be embolization of platelet-fibrin or plaque material, stenosis, or complete occlusion. The last may be the result of thrombosis or hemorrhage into a plaque. Symptoms depend on the adequacy of collateral circulation. Emboli distal to regions lacking collateral blood flow are more likely to produce symptoms. Small emboli in the ophthalmic branches can cause transient monocular blindness (amaurosis fugax). Larger emboli usually enter the middle cerebral artery, producing contralateral motor and sensory deficits that primarily affect the arm and face. Aphasia also develops if the dominant hemisphere is affected. Emboli in the anterior cerebral artery territory typically result in contralateral motor and sensory deficits that are worse in the leg. It is common for TIAs or minor strokes to precede a major stroke.

Indications for surgical interventions include TIAs associated with ipsilateral severe carotid stenosis (>70% occlusion), severe ipsilateral stenosis in a patient with a minor (incomplete) stroke, and 30% to 70% occlusion in a patient with ipsilateral symptoms (usually an ulcerated plaque). In the past, carotid endarterectomy was recommended for asymptomatic but significantly stenotic lesions (>60%). Currently, stenting would be the recommendation. Operative mortality for open surgery is 1% to 4% and is primarily due to cardiac complications (myocardial infarction). Perioperative morbidity is 4% to 10% and is principally neurological; patients with preexisting neurological deficits have the greatest risk of perioperative neurological events. **Studies suggest that age greater than 75 years, symptomatic lesions, uncontrolled hypertension, angina, carotid thrombus, and occlusions near the carotid siphon increase operative risk.**

**Preoperative Anesthetic Evaluation & Management**

Most patients undergoing carotid endarterectomy are elderly and hypertensive, with generalized arteriosclerosis. Many are also diabetic. Preoperative evaluation and management should focus on defining preexisting neurological deficits as well as optimizing the patient’s clinical status in terms of coexisting diseases. Most postoperative neurological deficits appear to be related to surgical technique. Uncontrolled perioperative hyperglycemia can increase morbidity by enhancing ischemic cerebral injury.

Patients should receive their usual cardiac medications on schedule until the
time of surgery. Blood pressure and the blood glucose concentration should be controlled. Angina should be stable and controlled, and signs of overt congestive heart failure should be absent. Because most patients are elderly, enhanced sensitivity to premedication should be expected.

**General Anesthesia**

The emphasis of anesthetic management during carotid surgery is on maintaining adequate perfusion to the brain and heart. Traditionally, this is accomplished by close regulation of arterial blood pressure and avoidance of tachycardia. Monitoring of intraarterial pressure is therefore nearly always done. Electrocardiographic monitoring should include the V₅ lead to detect ischemia. Continuous computerized ST-segment analysis is desirable. Carotid endarterectomy is not usually associated with significant blood loss or fluid shifts.

Regardless of the anesthetic agents selected, mean arterial blood pressure should be maintained at—or slightly above—the patient’s usual range. Propofol and etomidate are popular choices for induction because they reduce cerebral metabolic rate proportionately more than cerebral blood flow. Small doses of an opioid or β-adrenergic blocker can be used to blunt the hypertensive response to endotracheal intubation. In theory, isoflurane may be the volatile agent of choice because it appears to provide the greatest protection against cerebral ischemia. However, we do not regard the differences in neuroprotection among inhaled agents as clinically important. Some clinicians also prefer remifentanil as the opioid for rapid emergence.

Intraoperative hypertension is common and generally necessitates the use of an intravenous vasodilator. Nitroglycerin is usually a good choice for mild to moderate hypertension because of its beneficial effects on the coronary circulation. Marked hypertension requires a more potent agent, such as nicardipine, nitroprusside, or clevidipine. β-Adrenergic blockade facilitates management of the hypertension and prevents reflex tachycardia from vasodilators, but should be used cautiously. Hypotension should be treated with vasopressors. Many clinicians consider phenylephrine the vasopressor of choice; if selected, it should be administered in small increments to prevent excessive hypertension.

Pronounced or sustained reflex bradycardia or heart block caused by manipulation of the carotid baroreceptor can be treated with atropine. To prevent this response, some surgeons infiltrate the area of the carotid sinus with
lidocaine, but the infiltration itself can induce bradycardia. Arterial CO₂ tension should be maintained in the normal range because hypercapnia can induce intracerebral steal, whereas extreme hypocapnia decreases cerebral perfusion. Ventilation should be adjusted to maintain normocapnia. Maintenance intravenous fluids should consist of glucose-free solutions because of the potentially adverse effects of hyperglycemia. Heparin (5000–7500 units intravenously) is usually administered prior to occlusion of the carotid artery. Some clinicians routinely use a shunt (as noted below). Protamine is usually given to reverse heparin prior to skin closure.

Rapid emergence from anesthesia is desirable because it allows immediate neurological assessment, but the clinician must be prepared to treat hypertension and tachycardia. Postoperative hypertension may be related to surgical denervation of the ipsilateral carotid baroreceptor. Denervation of the carotid body blunts the ventilatory response to hypoxemia. Following extubation, patients should be observed closely for the development of a wound hematoma. When an expanding wound hematoma compromises the airway, the initial treatment maneuver may require opening the wound to release the hematoma. Transient postoperative hoarseness and ipsilateral deviation of the tongue may be noted; they are due to intraoperative retraction of the recurrent laryngeal or hypoglossal nerves, respectively.

**Monitoring Cerebral Function**

Unless regional anesthesia is used, indirect methods must be relied upon to assess the adequacy of cerebral perfusion during carotid cross-clamping. Some surgeons routinely use a shunt, but this practice may increase the incidence of postoperative neurological deficits; shunt insertion can dislodge emboli. Carotid stump pressure distal to the cross-clamp, EEG, somatosensory evoked potentials (SSEPs), and cerebral oximetry have been used in some centers to determine whether a shunt is needed. A distal stump pressure of less than 50 mm Hg has traditionally been used as an indication for a shunt. Electrophysiological signs of ischemia (or a marked decline in cerebral oxygen saturation) after cross-clamping dictate the use of a shunt; changes lasting more than 10 min may be associated with a new postoperative neurological deficit. Although multichannel recordings and computer processing can enhance the sensitivity of the EEG, neither EEG nor SSEP monitoring is sufficiently sensitive or specific to reliably predict the need for shunting or the occurrence of postoperative deficits (see case discussion in Chapter 26). Other techniques, including measurements of regional
cerebral blood flow with radioactive xenon-133, transcranial Doppler measurement of middle cerebral artery flow velocity, cerebral oximetry, jugular venous oxygen saturation, and transconjunctival oxygen tension, are also not sufficiently reliable.

**Regional Anesthesia**

Carotid surgery may be performed under regional anesthesia. Blockade of the superficial cervical plexus effectively blocks the C2–C4 nerves and allows the patient to remain comfortably awake during surgery. Deep cervical plexus block is not required. A substantial fraction of patients will require administration of local anesthetic by the surgeon into the carotid sheath (whether or not a deep cervical block is performed). The principal advantage of regional anesthesia (and it is a tremendous advantage) is that the patient can be examined intraoperatively; thus, the need for a temporary shunt can be assessed and any new neurological deficits diagnosed immediately during surgery. In fact, intraoperative neurological examination may be the most reliable method for assessing the adequacy of cerebral perfusion during carotid cross-clamping. The examination minimally consists of level of consciousness, speech, and contralateral hand grip. Experienced clinicians use minimal sedation and “cocktail conversation” with the patient to monitor the neurological status. Some studies also suggest that when compared with general anesthesia, regional anesthesia results in more stable hemodynamics but outcomes appear similar. Regional anesthesia for carotid surgery requires the cooperation of the surgeon and patient.

**CASE DISCUSSION**

**A Patient for Cardioversion**

A 55-year-old man with new-onset atrial fibrillation is scheduled for elective cardioversion.

*What are the indications for an elective cardioversion?*

Direct current (DC) cardioversion may be used to terminate supraventricular and ventricular tachyarrhythmias caused by reentry. It is not effective for arrhythmias from enhanced automaticity (multifocal atrial
tachycardia) or triggered activity (digitalis toxicity). By simultaneously depolarizing the entire myocardium and possibly prolonging the refractory period, DC cardioversion can terminate atrial fibrillation and flutter, atrioventricular nodal reentry, reciprocating tachycardias from preexcitation syndromes, and ventricular tachycardia or fibrillation.

Specific indications for cardioversion of patients with atrial fibrillation include symptomatic fibrillation, recent onset, and no response to medications. Patients with long-standing fibrillation, a large atrium, chronic obstructive lung disease, congestive heart failure, or mitral regurgitation have a high recurrence rate. A TEE is usually performed shortly before cardioversion to rule out left atrial blood clots. Such clots are typically located in the left atrial appendage and can be embolized by the cardioversion procedure or by sinus rhythm.

Emergency cardioversion is indicated for any tachyarrhythmia associated with hypotension, congestive heart failure, or angina.

**How is cardioversion performed?**

Although the procedure is usually performed by cardiologists, the need for immediate cardioversion may arise in the operating room, ICU, or during cardiopulmonary resuscitation. Anesthesiologists must therefore be familiar with the technique. Following deep sedation or light general anesthesia, DC shock is applied by either self-adhesive pads or 8- to 13-cm paddles. Larger paddles help reduce any shock-induced myocardial necrosis by distributing the current over a wider area. The energy output should be kept at the minimally effective level to prevent myocardial damage. Placement of the electrodes can be anterolateral or anteroposterior. In the first position, one electrode is placed on the right second intercostal space next to the sternum and the other is placed on the left fifth intercostal space in the midclavicular line. When pads are used for the anteroposterior technique, one is placed anteriorly over the ventricular apex in the fifth intercostal space and the other underneath the patient in the left infrascapular region.

For supraventricular tachycardias, with the notable exception of atrial fibrillation, energy levels of 25 to 50 J can successfully reestablish normal sinus rhythm. Synchronized shocks should be used for all tachyarrhythmias except ventricular fibrillation. Synchronization times the delivery so that it is given during the QRS complex. If the shock occurs in the ST segment or the T wave (unsynchronized), it can precipitate a more serious arrhythmia,
including ventricular fibrillation. All medical personnel should stand clear of the patient and the bed during the shock.

Atrial fibrillation usually requires a minimum of 50 to 100 J, and larger energy levels are often used. Hemodynamically stable ventricular tachycardia can often be terminated with 25 to 50 J, but ventricular fibrillation and unstable ventricular tachycardia require 200 to 360 J. Regardless of the arrhythmia, a higher energy level is necessary when the first shock is ineffective.

_The cardiologist wants to do the cardioversion in the postanesthesia care unit (PACU). Is this an appropriate place for cardioversion?_

Elective cardioversion can be performed in any setting in which full provisions for cardiopulmonary resuscitation, including cardiac pacing capabilities, are immediately available. A physician skilled in airway management should be in attendance. Cardioversions are commonly performed in an ICU, emergency department, PACU, procedure room, or cardiac catheterization suite.

_How would you evaluate this patient?_

The patient should be fasted, evaluated, and treated as though he were receiving a general anesthetic in the operating room. An ECG is performed immediately before the procedure to confirm that the arrhythmia is still present; another is performed immediately afterward to confirm the new rhythm. Preoperative laboratory values should be within normal limits because metabolic disorders, particularly electrolyte and acid–base abnormalities, may contribute to the arrhythmia. If not corrected preoperatively, they can reinitiate the tachycardia following cardioversion. An antiarrhythmic agent is often started in patients with atrial fibrillation 1 to 2 days prior to the procedure to help maintain normal sinus rhythm. Patients with atrial fibrillation of longer than a few hours duration likely will have been anticoagulated for a sufficient time prior to cardioversion to reduce the likelihood of a left atrial thrombus. Such clots may embolize upon restoration of a sinus rhythm.

_What are the minimum monitors and anesthetic equipment required?_

Minimum monitoring consists of the ECG, blood pressure, and pulse
oximetry. A precordial stethoscope is useful for monitoring breath sounds. Maintaining continuous verbal contact with the patient may the best method for assessing whether a sufficient amnestic dose of (usually) propofol has been given.

In addition to a DC defibrillator capable of delivering up to 400 J (synchronized or unsynchronized) and transcutaneous pacing, the minimum equipment should include the following:
• Reliable intravenous access.
• A functional bag-mask device capable of delivering 100% oxygen (see Chapter 3).
• An oxygen source from a wall outlet or a full tank.
• An airway kit with oral and nasal airways and appropriate laryngoscopes and endotracheal tubes.
• A functional suction apparatus.
• An anesthetic drug kit that includes at least one sedative-hypnotic as well as succinylcholine.
• A cart that includes all necessary drugs and equipment for cardiopulmonary resuscitation (see Chapter 55).

What anesthetic techniques would be appropriate?

Premedication is not necessary. Only very brief (1–2 min) light general anesthesia is required. A short-acting agent such as propofol or methohexital is customarily used. Etomidate may be used but may be associated with phonation. Following preoxygenation with 60% to 100% oxygen for 3 to 5 min, the sedative-hypnotic is given in small increments) every 30 to 60 s while maintaining verbal contact with the patient. The shock is delivered when the patient is no longer able to respond verbally; some clinicians use loss of the eyelid reflex as an end point. The shock usually arouses the patient. Transient airway obstruction or apnea may be observed, particularly if more than one shock is necessary.

What are the complications of cardioversion?

Complications include transient myocardial depression, postshock arrhythmias, and arterial embolism. Arrhythmias are usually due to inadequate synchronization, but even a properly timed cardioversion can occasionally result in ventricular fibrillation. Most arrhythmias are transient and resolve spontaneously. Although patients may develop ST-segment elevation, serum creatine phosphokinase levels (MB fraction) are usually
normal. Embolism of a left-sided clot may be responsible for delayed awakening.

**How should the patient be cared for following cardioversion?**

Although recovery of consciousness is usually very rapid, patients should be treated like others receiving general anesthesia (see Chapter 56). Recovery also specifically includes monitoring for both recurrence of the arrhythmia and signs of cerebral embolism.

**GUIDELINES**

Hiratzka LF, Bakris GL, Beckman JA, et al. 2010

See [www.guidelines.gov](http://www.guidelines.gov) for additional guidelines from multiple organizations related to these topics.

**SUGGESTED READINGS**

The trachea serves as a conduit for ventilation and for clearance of tracheal and bronchial secretions and has an average length of 10 to 13 cm. The trachea bifurcates at the carina into the right and left mainstem bronchi. The right mainstem bronchus lies in a more linear arrangement with the trachea, whereas the left mainstem bronchus lies in a more angular orientation with the trachea.

The periodic exchange of alveolar gas with the fresh gas from the upper airway reoxygenates desaturated blood and eliminates CO$_2$. This exchange is normally brought about by small cyclic pressure gradients established within the airways. During spontaneous ventilation, these gradients are secondary to variations in intrathoracic pressure; during mechanical ventilation, they are produced by intermittent positive pressure in the upper airway.

The lung volume at the end of a normal exhalation is called functional residual capacity (FRC). At this volume, the inward elastic recoil of the lung approximates the outward elastic recoil of the chest (including resting diaphragmatic tone).

Closing capacity is normally well below FRC, but it rises steadily with age. This increase is probably responsible for the normal age-related decline in arterial O$_2$ tension.

Whereas both forced expiratory volume in the first second of exhalation (FEV$_1$) and forced vital capacity (FVC) are effort dependent, forced midexpiratory flow (FEF$_{25–75%}$) is more effort independent and may be a more reliable measure of obstruction.

Changes in lung mechanics due to general anesthesia occur shortly after induction. The supine position reduces the FRC by 0.8 to 1.0 L, and
induction of general anesthesia further reduces the FRC by 0.4 to 0.5 L. FRC reduction is a consequence of alveolar collapse and compression atelectasis due to loss of inspiratory muscle tone, change in chest wall rigidity, and upward shift of the diaphragm.

Local factors are more important than the autonomic system in influencing pulmonary vascular tone. Hypoxia is a powerful stimulus for pulmonary vasoconstriction (the opposite of its systemic effect).

Because alveolar ventilation ($V_A$) is normally about 4 L/min and pulmonary capillary perfusion ($Q$) is 5 L/min, the overall ratio is about 0.8.

Shunting denotes the process whereby desaturated, mixed venous blood from the right heart returns to the left heart without being oxygenated in the lungs. The overall effect of shunting is to decrease (dilute) arterial $O_2$ content; this type of shunt is referred to as right-to-left.

General anesthesia commonly increases venous admixture to 5% to 10%, probably as a result of atelectasis and airway collapse in dependent areas of the lung.

Note that large increases in $P_{aco_2}$ (>75 mm Hg) readily produce hypoxia ($P_{a_o_2}$ <60 mm Hg) at room air, but not at high inspired $O_2$ concentrations.

The binding of $O_2$ to hemoglobin seems to be the principal rate-limiting factor in the transfer of $O_2$ from alveolar gas to blood.

The greater the shunt, the less likely the possibility that an increase in the fraction of inspired oxygen ($F_{io_2}$) will correct hypoxemia.

A rightward shift in the oxygen–hemoglobin dissociation curve lowers $O_2$ affinity, displaces $O_2$ from hemoglobin, and makes more $O_2$ available to tissues; a leftward shift increases hemoglobin’s affinity for $O_2$, reducing its availability to tissues.

Bicarbonate represents the largest fraction of $CO_2$ in blood.

Central chemoreceptors are thought to lie on the anterolateral surface of the medulla and respond primarily to changes in cerebrospinal fluid [H$^+$]. This mechanism is effective in regulating $P_{aco_2}$, because the blood–brain barrier is permeable to dissolved $CO_2$ but not to bicarbonate ions.

With increasing depth of anesthesia, the slope of the $P_{aco_2}$/min
The importance of pulmonary physiology to anesthetic practice is obvious. The commonly used inhalation anesthetics depend on the lungs for uptake and elimination. Both inhalation and intravenously administered anesthetics produce prominent respiratory side effects. Moreover, muscle paralysis, unusual positioning during surgery, and techniques such as one-lung anesthesia and cardiopulmonary bypass profoundly alter normal pulmonary physiology.

This chapter reviews the basic pulmonary concepts necessary for understanding and applying anesthetic techniques. Although the pulmonary effects of each of the various anesthetic agents are discussed elsewhere in the book, this chapter also reviews the overall effects of general anesthesia on lung function.

**FUNCTIONAL RESPIRATORY ANATOMY**

1. **Rib Cage & Muscles of Respiration**

The rib cage contains the two lungs, each surrounded by its own pleura. The apex of the chest is small, allowing only for entry of the trachea, esophagus, and blood vessels, whereas the base is formed by the diaphragm. Contraction of the diaphragm—the principal pulmonary muscle—causes the base of the thoracic cavity to descend 1.5 to 7 cm and its contents (the lungs) to expand. Diaphragmatic movement normally accounts for 75% of the change in chest volume. Accessory respiratory muscles also increase chest volume (and lung expansion) by their action on the ribs. Each rib (except for the last two) articulates posteriorly with a vertebra and is angulated downward as it attaches anteriorly to the sternum. Upward and outward rib movement expands the chest.

During normal breathing, the diaphragm, and, to a lesser extent, the external intercostal muscles, are responsible for inspiration; expiration is generally passive. With increasing effort, the sternocleidomastoid, scalene, and pectoralis muscles can be recruited during inspiration. The sternocleidomastoid muscles assist in elevating the rib cage, whereas the scalene muscles prevent inward displacement of the upper ribs during inspiration. The pectoralis muscles can assist chest expansion when the arms are placed on a fixed support. Exhalation is normally passive in the supine position, but becomes active in the upright position and with increased effort. Exhalation may be facilitated by the abdominal muscles (rectus abdominis, external and internal oblique, and
transversus) and perhaps the internal intercostal muscles—aiding the downward movement of the ribs.

Although not usually considered respiratory muscles, some pharyngeal muscles are important in maintaining the patency of the airway. Tonic and reflex inspiratory activity in the genioglossus keeps the tongue away from the posterior pharyngeal wall. Tonic activity in the levator palati, tensor palati, palatopharyngeus, and palatoglossus prevents the soft palate from falling back against the posterior pharynx, particularly in the supine position.

2. Tracheobronchial Tree

The trachea serves as a conduit for ventilation and for clearance of tracheal and bronchial secretions. The trachea begins at the lower border of the cricoid cartilage, extends to the carina, and has an average length of 10 to 13 cm. It is composed of C-shaped cartilaginous rings, which form the anterior and lateral walls of the trachea and are connected posteriorly by the membranous wall of the trachea. The cricoid cartilage is the narrowest part of the trachea, with an average diameter of 17 mm in men and 13 mm in women.

The tracheal lumen narrows slightly as it progresses toward the carina, where it bifurcates into the right and left mainstem bronchi at the level of the sternal angle. The right mainstem bronchus lies in a more linear arrangement with the trachea, whereas the left mainstem bronchus lies in a more angular orientation with the trachea. The right mainstem bronchus continues as the bronchus intermedius after the take-off of the right upper lobe bronchus. The distance from the tracheal carina to the take-off of the right upper lobe bronchus is an average of 2.0 cm in men and approximately 1.5 cm in women. One in every 250 individuals in the general population may have an abnormal take-off of the right upper lobe bronchus emerging from above the tracheal carina on the right side. The left mainstem bronchus is longer than the right mainstem bronchus and measures an average of 5.0 cm in men and 4.5 cm in women. The left mainstem bronchus divides into the left upper lobe bronchus and the left lower lobe bronchus.

Humidification and filtering of inspired air are functions of the upper airway (nose, mouth, and pharynx). The tracheobronchial tree serves to conduct gas flow to and from the alveoli. Dichotomous division (each branch dividing into two smaller branches), starting with the trachea and ending in alveolar sacs, is estimated to involve 23 divisions, or generations (Figure 23–1). With each generation, the number of airways is approximately doubled. Each alveolar sac contains, on average, 17 alveoli. An estimated 300 to 500 million alveoli provide
an enormous membrane surface area (50–100 m²) for gas exchange in the average adult.

With each successive division, the mucosa makes a gradual transition from ciliated columnar to cuboidal and finally to flat alveolar epithelium. Gas exchange can occur only across the flat epithelium, which begins to appear on respiratory bronchioles (generations 17–19). The wall of the airway gradually loses its cartilaginous support (at the bronchioles) and then its smooth muscle. Loss of cartilaginous support causes the patency of smaller airways to become dependent on radial traction by the elastic recoil of the surrounding tissue; as a corollary, airway diameter becomes dependent on total lung volume.

Cilia on the columnar and cuboidal epithelium normally beat in a synchronized fashion, such that mucus produced by the secretory glands lining the airway (and any associated bacteria or debris) moves toward the mouth.

**Alveoli**

Alveolar size is a function of both gravity and lung volume. In the upright position, the largest alveoli are at the pulmonary apex, whereas the smallest tend to be at the base. With inspiration, discrepancies in alveolar size diminish.

Each alveolus is in close contact with a network of pulmonary capillaries. The
walls of each alveolus are asymmetrically arranged (Figure 23–2). Gas exchange occurs primarily on the thin side of the alveolocapillary membrane, which is less than 0.4 μm thick. The thick side (1–2 μm) provides structural support for the alveolus. On the thin side, the alveolar epithelium and capillary endothelium are separated by their respective cellular and basement membranes; on the thick side, where fluid and solute exchange occurs, the pulmonary interstitial space separates alveolar epithelium from capillary endothelium. The pulmonary interstitial space contains mainly elastin, collagen, and nerve fibers.

**FIGURE 23–2** The pulmonary interstitial space, with a capillary passing between the two alveoli. The capillary is incorporated into the thin (gas-exchanging) side of the alveolus on the right. The interstitial space is incorporated into the thick side of the alveolus on the left. (Reproduced with permission from Nunn JF. Nunn’s Applied Physiology. 4th ed. Oxford, UK: Butterworth; 2000.)

The pulmonary epithelium contains at least two cell types. Type I pneumocytes are flat and form tight (1-nm) junctions with one another. These
tight junctions are important in preventing the passage of large oncotically active molecules such as albumin into the alveolus. Type II pneumocytes, which are more numerous than type I pneumocytes (but because of their shape occupy <10% of the alveolar space), are round cells that contain prominent cytoplasmic inclusions (lamellar bodies). These inclusions contain surfactant, an important substance necessary for normal pulmonary mechanics. Unlike type I cells, type II pneumocytes are capable of cell division and can produce type I pneumocytes if the latter are destroyed. Other cell types present in the lower airways include pulmonary alveolar macrophages, mast cells, lymphocytes, and amino precursor uptake and decarboxylation (APUD) cells. Neutrophils are also typically present in smokers and patients with pneumonia or acute lung injury.

3. **Pulmonary Circulation & Lymphatics**

The lungs are supplied by two circulations, pulmonary and bronchial. The bronchial circulation arises from the left heart and sustains the metabolic needs of the tracheobronchial tree. The bronchial circulation provides a small amount of blood flow (ie, <4% of the cardiac output). Branches of the bronchial artery supply the wall of the bronchi and follow the airways as far as the terminal bronchioles. Along their courses, the bronchial vessels anastomose with the pulmonary arterial circulation and continue as far as the alveolar duct. Below that level, lung tissue is supported by a combination of the alveolar gas and pulmonary circulation.

The pulmonary circulation normally receives the total output of the right heart via the pulmonary artery, which divides into right and left branches to supply each lung. Deoxygenated blood passes through the pulmonary capillaries, where $O_2$ is taken up and $CO_2$ is eliminated. The oxygenated blood is then returned to the left heart by four main pulmonary veins (two from each lung). Although flows through the systemic and pulmonary circulations are equal, the lower pulmonary vascular resistance results in pulmonary pressures that are less than those in the systemic vessels; as a result, both pulmonary arteries and veins normally have thinner walls than systemic vessels with less smooth muscle.

There are connections between the bronchial and the pulmonary circulations. Direct pulmonary arteriovenous communications, bypassing the pulmonary capillaries, are normally insignificant but may become important in certain pathological states. The importance of the bronchial circulation in contributing to the normal venous admixture is discussed below.
Pulmonary Capillaries

Pulmonary capillaries are incorporated into the walls of alveoli. The average diameter of these capillaries (about 10 μm) is barely enough to allow passage of a single red cell. Because each capillary network supplies more than one alveolus, blood may pass through several alveoli before reaching the pulmonary veins. Because of the relatively low pressure in the pulmonary circulation, the amount of blood flowing through a given capillary network is affected by both gravity and alveolar size. Large alveoli have a smaller capillary cross-sectional area and consequently increased resistance to blood flow. In the upright position, apical capillaries tend to have reduced flows, whereas basal capillaries have higher flows.

The pulmonary capillary endothelium has relatively large junctions (5 nm wide), allowing the passage of large molecules such as albumin. As a result, pulmonary interstitial fluid is relatively rich in albumin. Circulating macrophages and neutrophils are able to pass through the endothelium, as well as the smaller alveolar epithelial junctions, with relative ease. Pulmonary macrophages are commonly seen in the interstitial space and inside alveoli; they serve to scavenge bacteria and debris.

Pulmonary Lymphatics

Lymphatic channels in the lung originate in the interstitial spaces of large septa and are close to the bronchial arteries. Bronchial lymphatics return fluids, proteins, and various cells that have entered the peribronchovascular interstitium back to the blood circulation. Because of the large endothelial junctions, pulmonary lymph has a relatively high protein content, and total pulmonary lymph flow may be as much as 20 mL/h. Large lymphatic vessels travel upward alongside the airways, forming the tracheobronchial chain of lymph nodes. Lymphatic drainage channels from both lungs communicate along the trachea.

4. Innervation

The diaphragm is innervated by the phrenic nerves, which arise from the C3–C5 nerve roots. Unilateral phrenic nerve block or palsy only modestly reduces most indices of pulmonary function (about 25%) in normal subjects. Although bilateral phrenic nerve palsies produce more severe impairment, accessory muscle activity may maintain adequate ventilation in some patients. Intercostal muscles are innervated by their respective thoracic nerve roots. Cervical cord injuries above C5 are incompatible with spontaneous ventilation because both
phrenic and intercostal nerves are affected.

The vagus nerves provide sensory innervation to the tracheobronchial tree. Both sympathetic and parasympathetic autonomic innervation of bronchial smooth muscle and secretory glands is present. Vagal activity mediates bronchoconstriction and increases bronchial secretions via muscarinic receptors. Sympathetic activity (T1–T4) mediates bronchodilation and also decreases secretions via β₂-receptors. The nerve supply of the larynx is reviewed in Chapter 19.

Both α- and β-adrenergic receptors are present in the pulmonary vasculature, but the sympathetic system normally has little effect on pulmonary vascular tone. α₁ Activity causes vasoconstriction; β₂ activity mediates vasodilation. Parasympathetic vasodilatory activity seems to be mediated via the release of nitric oxide.

**MECHANISMS OF BREATHING**

The periodic exchange of alveolar gas with the fresh gas from the upper airway reoxygenates desaturated blood and eliminates CO₂. This exchange is normally brought about by small cyclic pressure gradients established within the airways. During spontaneous ventilation, these gradients are secondary to variations in intrathoracic pressure; during mechanical ventilation, they are produced by intermittent positive pressure in the upper airway. During apneic oxygenation gas exchange depends on mass movement of gases along concentration gradients.

**Spontaneous Ventilation**

Normal pressure variations during spontaneous breathing are shown in Figure 23–3. The pressure within alveoli is always greater than the surrounding (intrathoracic) pressure unless the alveoli are collapsed. Alveolar pressure is normally atmospheric (zero for reference) at end-inspiration and end-expiration. By convention, in pulmonary physiology, pleural pressure is used as a measure of intrathoracic pressure. Although it may not be entirely correct to refer to the pressure in a potential space, the concept allows the calculation of transpulmonary pressure. Transpulmonary pressure, or \( P_{\text{transpulmonary}} \), is then defined as follows:
FIGURE 23–3 Changes in intrapleural and alveolar pressures during normal breathing. Note that at end inspiration, volume is maximal; flow is zero; and alveolar pressure is atmospheric. (Adapted with permission from West JB. Respiratory Physiology—The Essentials, 6th ed. Philadelphia, PA: Williams & Wilkins; 2000.)

\[ P_{\text{transpulmonary}} = P_{\text{alveolar}} - P_{\text{intrapleural}} \]

At end-expiration, intrapleural pressure normally averages about –5 cm H₂O,
and because alveolar pressure is 0 (no flow), transpulmonary pressure is +5 cm H$_2$O.

Diaphragmatic and intercostal muscle activation during inspiration expands the chest and decreases intrapleural pressure from –5 cm H$_2$O to –8 or –9 cm H$_2$O. As a result, alveolar pressure also decreases and an alveolar–upper airway gradient is established; gas flows from the upper airway into alveoli (Figure 23–4).

**FIGURE 23–4** Representation of the interaction of the lung and chest wall. **A:** At end-expiration, the muscles of respiration are relaxed. The inward elastic recoil of the lung is balanced by the outward elastic recoil of the chest wall. Intrapleural pressure is –5 cm H$_2$O; alveolar pressure is 0. The transmural pressure difference across the alveolus is therefore 0 cm H$_2$O – (–5 cm H$_2$O), or 5 cm H$_2$O. Since alveolar pressure is equal to atmospheric pressure, no airflow occurs. **B:** During inspiration, contraction of the muscles of inspiration causes intrapleural pressure to become more negative. The transmural pressure difference increases and the alveoli are distended, decreasing alveolar pressure below atmospheric pressure, which causes air to flow into the alveoli. (Reproduced with permission from Levitzky MG. *Pulmonary Physiology*. 8th ed. New York, NY: McGraw-Hill Education; 2013.)

During expiration, diaphragmatic relaxation returns intrapleural pressure to –5 cm H$_2$O. Now the transpulmonary pressure does not support the new lung volume, and the elastic recoil of the lung causes a reversal of the previous alveolar–upper airway gradient; gas flows out of alveoli, and original lung volume is restored.
Mechanical Ventilation

Most forms of mechanical ventilation intermittently apply positive airway pressure at the upper airway. During inspiration, gas flows into alveoli until pressure in the alveoli reaches that in the upper airway. During the expiratory phase of the ventilator, the positive airway pressure is decreased; the gradient reverses, allowing gas flow out of alveoli.

LUNG MECHANICS

The movement of the lungs is passive and determined by the impedance of the respiratory system, which can be divided into the elastic resistance of tissues and the gas–liquid interface and the nonelastic resistance to gas flow. Elastic resistance governs lung volume and the associated pressures under static conditions (no gas flow). Resistance to gas flow relates to frictional resistance to airflow and tissue deformation.

1. Elastic Resistance

Both the lungs and the chest have elastic properties. The chest has a tendency to expand outward, whereas the lungs have a tendency to collapse. When the pleural space is exposed to atmospheric pressure (open pneumothorax), the chest usually expands about 1 L in adults. In contrast, when the pleural space is exposed to atmospheric pressure, the lung collapses completely and all the gas within it is expelled. The recoil properties of the chest are due to structural components that resist deformation and chest wall muscle tone. The elastic recoil of the lungs is due to their high content of elastin fibers, and, even more important, the surface tension forces acting at the air–fluid interface in alveoli.

Surface Tension Forces

The gas–fluid interface lining the alveoli causes them to behave as bubbles. Surface tension forces tend to reduce the area of the interface and favor alveolar collapse. Laplace’s law can be used to quantify these forces:

\[ \text{Pressure} = \frac{2 \times \text{Surface tension}}{\text{Radius}} \]

The pressure derived from the equation is that within the alveolus and it is
directly proportional to surface tension. **Fortunately, pulmonary surfactant decreases alveolar surface tension in proportion to its concentration within the alveolus.** As alveoli become smaller, the surfactant within becomes more concentrated, and surface tension is more effectively reduced. Conversely, when alveoli are overdistended, surfactant becomes less concentrated, and surface tension increases. The net effect is to stabilize alveolar size: small alveoli are prevented from getting smaller, whereas large alveoli are prevented from getting larger.

**Compliance**

Elastic recoil is usually measured in terms of compliance (C), which is defined as the change in volume divided by the change in distending pressure. Compliance measurements can be obtained for either the chest, the lung, or both together. In the supine position, chest wall compliance (Cw) is reduced because of the weight of the abdominal contents against the diaphragm. Measurements are usually obtained under static conditions, (ie, at equilibrium). (Dynamic lung compliance [Cdyn,L], which is measured during rhythmic breathing, is also dependent on airway resistance.) **Lung compliance (Cl)** is defined as:

\[
Cl = \frac{\text{Change in lung volume}}{\text{Change in transpulmonary pressure}}
\]

Cl is normally 150 to 200 mL/cm H₂O. A variety of factors, including lung volume, pulmonary blood volume, extravascular lung water, and pathological processes (eg, inflammation and fibrosis) affect Cl,

\[
CW = \frac{\text{Change in chest volume}}{\text{Change in transthoracic pressure}}
\]

where transthoracic pressure equals atmospheric pressure minus intrapleural pressure.

Normal chest wall compliance is 200 mL/cm H₂O. Total compliance (lung and chest wall together) is 100 mL/cm H₂O and is expressed by the following equation:
2. Lung Volumes

Lung volumes are important parameters in respiratory physiology and clinical practice (Table 23–1 and Figure 23–5). The sum of all of the named lung volumes equals the maximum to which the lung can be inflated. Lung capacities are clinically useful measurements that represent a combination of two or more volumes.

**TABLE 23–1 Lung volumes and capacities.**

Functional Residual Capacity

The lung volume at the end of a normal exhalation is called functional residual capacity (FRC). At this volume, the inward elastic recoil of the lung approximates the outward elastic recoil of the chest (including resting diaphragmatic tone). Thus, the elastic properties of both chest and lung define the point from which normal breathing takes place. FRC can be measured by nitrogen washout, helium washin technique, or body plethysmography. Factors known to alter the FRC include the following:

- **Body habitus:** FRC is directly proportional to height. Obesity, however, can markedly decrease FRC (primarily as a result of reduced chest compliance).
- **Sex:** FRC is reduced by about 10% in females compared with males. Pregnancy is also associated with a reduction in FRC.
- **Posture:** FRC decreases as a patient is moved from an upright to a supine or prone position. This is the result of reduced chest compliance as the abdominal contents push up against the diaphragm. The greatest change occurs between 0° and 60° of inclination. No further decrease is observed with a head-down position of up to 30°.
- **Lung disease:** Decreased compliance of the lung, chest, or both is characteristic of restrictive pulmonary disorders all of which are associated with a low FRC.
- **Diaphragmatic tone:** This normally contributes to FRC, and its contribution is evident with phrenic nerve paralysis.
Closing Capacity

As described earlier, small airways lacking cartilaginous support depend on radial traction caused by the elastic recoil of surrounding tissue to keep them open; patency of these airways, particularly in basal areas of the lung, is highly dependent on lung volume. The volume at which these airways begin to close in dependent areas of the lung is called the **closing capacity**. At lower lung volumes, alveoli in dependent areas continue to be perfused but are no longer ventilated; the resulting **intrapulmonary shunting** of deoxygenated blood (venous admixture) promotes hypoxemia.

Closing capacity is usually measured with 100% oxygen, which is inhaled near residual volume and then exhaled from total lung capacity. Changes in the nitrogen concentration of the exhaled gas following oxygen inhalation are measured. The nitrogen concentration from alveoli at the base of the lungs is lower than that at the apex because any air remaining in the lungs at the residual volume is in the nondependent alveoli. Closing volume is discerned when the concentration of expired nitrogen rises, indicating that the alveoli from the dependent regions of the lung are no longer contributing to the exhaled gas because their airways have closed (Figure 23–6).

**FIGURE 23–6** Expired nitrogen concentration after inhalation of a single

Closing capacity is normally well below FRC (Figure 23–7), but rises steadily with age (Figure 23–8). This increase is probably responsible for the normal age-related decline in arterial O₂ tension. At an average age of 44 years, closing capacity equals FRC in the supine position; by age 66, closing capacity equals or exceeds FRC in the upright position in most individuals. Unlike FRC, closing capacity is unaffected by posture. Closing capacity also approaches or exceeds FRC in morbid obesity.

Vital Capacity

Vital capacity (VC) is the maximum volume of gas that can be exhaled following maximal inspiration. In addition to body habitus, VC is also dependent on respiratory muscle strength and chest–lung compliance. Normal VC is about 60 to 70 mL/kg.

3. Nonelastic Resistances

Airway Resistance to Gas Flow

Gas flow in the lung is a mixture of laminar and turbulent flow. Laminar flow can be thought of as consisting of concentric cylinders of gas flowing at different velocities; velocity is greatest in the center and decreases toward the periphery. During laminar flow,

\[
\text{Flow} = \frac{\text{Pressure gradient}}{R_{aw}}
\]
where $R_{aw}$ is airway resistance.

$$R_{aw} = \frac{8 \times \text{Length} \times \text{Gas viscosity}}{\pi \times (\text{Radius})^4}$$

Turbulent flow is characterized by random movement of the gas molecules down the air passages. Mathematical description of turbulent flow is considerably more complex:

$$\text{Pressure gradient} \approx \text{Flow}^2 \times \frac{\text{Gas density}}{\text{Radius}^5}$$

Resistance is not constant but increases in proportion to gas flow. Moreover, resistance is directly proportional to gas density and inversely proportional to the fifth power of the radius. As a result, turbulent gas flow is extremely sensitive to airway caliber.

Turbulence generally occurs at high gas flows, at sharp angles or branching points, and in response to abrupt changes in airway diameter. Whether turbulent or laminar flow occurs can be predicted by the Reynolds number, which results from the following equation:

$$\text{Reynolds number} = \frac{\text{Linear velocity} \times \text{Diameter} \times \text{Gas density}}{\text{Gas viscosity}}$$

A low Reynolds number ($<1000$) is associated with laminar flow, whereas a high value ($>1500$) produces turbulent flow. Laminar flow normally occurs only distal to small bronchioles ($<1$ mm). Flow in larger airways is probably turbulent. Of the gases used clinically, only helium has a significantly lower density-to-viscosity ratio, making it useful clinically during severe turbulent flow (as caused by upper airway obstruction). A helium–O$_2$ mixture not only is less likely to cause turbulent flow but also reduces airway resistance when turbulent flow is present.

Normal total airway resistance is about 0.5 to 2 cm H$_2$O/L/s, with the largest contribution coming from medium-sized bronchi (before the seventh generation). Resistance in large bronchi is low because of their large diameters, whereas resistance in small bronchi is low because of their large total cross-
sectional area. The most important causes of increased airway resistance include bronchospasm, secretions, and mucosal edema as well as volume-related and flow-related airway collapse.

**A. Volume-Related Airway Collapse**

At low lung volumes, loss of radial traction increases the contribution of small airways to total resistance; airway resistance becomes inversely proportional to lung volume (**Figure 23–9**). Increasing lung volume up to normal with positive end-expiratory pressure (PEEP) can reduce airway resistance.

![Figure 23–9](image)

**B. Flow-Related Airway Collapse**

During forced exhalation, reversal of the normal transmural airway pressure can cause collapse of these airways (dynamic airway compression). Two contributing factors are responsible: generation of a positive pleural pressure and a large pressure drop across intrathoracic airways as a result of increased airway...
resistance. The latter is in turn due to high (turbulent) gas flow and the reduced lung volume. The terminal portion of the flow/volume curve is therefore considered to be effort independent (Figure 23–10).

**FIGURE 23–10** Gas flow (A) during forced exhalation from total lung capacity
with varying effort and (B) with maximal effort from different lung volumes. Note that regardless of initial lung volume or effort, terminal expiratory flows are effort independent. (Reproduced with permission from Lumb A. Nunn's Applied Respiratory Physiology. 8th ed. St. Louis, MO: Elsevier; 2017.)

The point along the airways where dynamic compression occurs is called the equal pressure point. It is normally beyond the 11th to 13th generation of bronchioles where cartilaginous support is absent (see earlier discussion). The equal pressure point moves toward smaller airways as lung volume decreases. Emphysema or asthma predisposes patients to dynamic airway compression. Emphysema destroys the elastic tissues that normally support smaller airways. In patients with asthma, bronchoconstriction and mucosal edema intensify airway collapse and promote reversal of transmural pressure gradients across airways. Patients may terminate exhalation prematurely or purse their lips to increase expiratory resistance at the mouth. Premature termination of exhalation may increase FRC above normal, resulting in air trapping and auto-PEEP.

C. Forced Vital Capacity
Measuring vital capacity as an exhalation that is as forceful and rapid as possible (Figure 23–11) provides important information about airway resistance. The ratio of the forced expiratory volume in the first second of exhalation (FEV₁) to the total forced vital capacity (FVC) is proportional to the degree of airway obstruction. Normally, FEV₁/FVC is 80% or greater. Whereas both FEV₁ and FVC are effort dependent, forced midexpiratory flow (FEF₂₅–₇₅%) is more effort independent and may be a more reliable measurement of obstruction.
**FIGURE 23–11** The normal forced exhalation curve. FEF<sub>25–75%</sub> is also called the maximum midexpiratory flow rate (MMF<sub>25–75%</sub>). FRC, functional residual capacity; FEV<sub>1</sub>, forced expiratory volume in 1 s; FVC, forced vital capacity; RV, residual volume; TLC, total lung capacity.

**Tissue Resistance**

This component of nonelastic resistance is generally underestimated and often overlooked, but may account for up to half of total airway resistance. It seems to be primarily due to viscoelastic (frictional) resistance of tissues to gas flow.

**4. Work of Breathing**

Because expiration is normally entirely passive, both the inspiratory and the expiratory work of breathing is performed by the inspiratory muscles (primarily the diaphragm). Three factors must be overcome during ventilation: the elastic recoil of the chest and lung, frictional resistance to gas flow in the airways, and tissue frictional resistance.

Respiratory work can be expressed as the product of volume and pressure. During inhalation, both inspiratory airway resistance and pulmonary elastic recoil must be overcome; nearly 50% of the energy expended is stored pulmonary elastic recoil. During exhalation, the stored potential energy is
released and overcomes expiratory airway resistance. Increases in either inspiratory or expiratory resistance are compensated by increased inspiratory muscle effort. When expiratory resistance increases, the normal compensatory response is to increase lung volume such that VT breathing occurs at an abnormally high FRC. The greater elastic recoil energy stored at a higher lung volume overcomes the added expiratory resistance. Excessive amounts of expiratory resistance also activate expiratory muscles.

Respiratory muscles normally account for only 2% to 3% of O₂ consumption but operate at about 10% efficiency. Ninety percent of the work is dissipated as heat (due to elastic and airflow resistance). In pathological conditions that increase the load on the diaphragm, muscle efficiency usually progressively decreases, and contraction may become uncoordinated with increasing ventilatory effort; moreover, a point may be reached whereby any increase in O₂ uptake (because of augmented ventilation) is consumed by the respiratory muscles themselves.

The work required to overcome elastic resistance increases as VT increases, whereas the work required to overcome airflow resistance increases as respiratory rate (and, necessarily, expiratory flow) increases. Faced with either condition, patients minimize the work of breathing by altering the respiratory rate and VT (Figure 23–12). Patients with reduced compliance tend to have rapid, shallow breaths, whereas those with increased airflow resistance have a slow, deep breathing pattern.

**FIGURE 23–12** The work of breathing in relation to respiratory rate for normal...
individuals, patients with increased elastic resistance, and patients with increased airway resistance. (Reproduced with permission from Lumb A. *Nunn's Applied Respiratory Physiology*. 8th ed. St. Louis, MO: Elsevier; 2017.)

5. **Effects of Anesthesia on Pulmonary Mechanics**

The effects of anesthesia on breathing are complex and relate to changes both in position and anesthetic agent.

**Effects on Lung Volumes & Compliance**

Changes in lung mechanics due to general anesthesia occur shortly after induction. The supine position reduces the FRC by 0.8 to 1.0 L, and induction of general anesthesia further reduces the FRC by 0.4 to 0.5 L. FRC reduction is a consequence of alveolar collapse and compression atelectasis due to loss of inspiratory muscle tone, change in chest wall rigidity, and upward shift of the diaphragm. The mechanisms may be more complex; for example, only the dependent (dorsal) part of the diaphragm in the supine position moves cephalad. Other factors are likely due to a change in intrathoracic volume secondary to increased blood volume in the lung and changes in chest wall shape (Figure 23–13). The higher position of the dorsal diaphragm and changes in the thoracic cavity itself decrease lung volumes. This decrease in FRC is not related to anesthetic depth and may persist for several hours or days after anesthesia. Steep head-down (Trendelenburg) position (>30°) may reduce FRC even further as intrathoracic blood volume increases. In contrast, induction of anesthesia in the sitting position seems to have little effect on FRC. Muscle paralysis does not seem to change FRC significantly when the patient is already anesthetized.
With induction of anesthesia in the supine position, the abdominal contents exert cephalad pressure on the diaphragm. At end-expiration, the dorsal portion of the diaphragm is more cephalad and the ventral portion is more caudal than when awake, the thoracic spine is more lordotic, and the rib cage moves inward, all secondary to loss of motor tone.

The effects of anesthesia on closing capacity are more variable. Both FRC and closing capacity, however, are generally reduced to the same extent under anesthesia. Thus, the risk of increased intrapulmonary shunting under anesthesia is similar to that in the conscious state; it is greatest in the elderly, in obese patients, and in those with underlying pulmonary disease.

**Effects on Airway Resistance**

The reduction in FRC associated with general anesthesia would be expected to
increase airway resistance. Increases in airway resistance are not usually observed, however, because of the bronchodilating properties of the volatile inhalation anesthetics. Increased airway resistance is more commonly due to pathological factors (posterior displacement of the tongue; laryngospasm; bronchoconstriction; or secretions, blood, or tumor in the airway) or equipment problems (small tracheal tubes or connectors, malfunction of valves, or obstruction of the breathing circuit).

**Effects on the Work of Breathing**

Increases in the work of breathing under anesthesia are most often secondary to reduced lung and chest wall compliance and, less commonly, increases in airway resistance (see earlier discussion). The problems of increased work of breathing are usually circumvented by controlled mechanical ventilation.

**Effects on the Respiratory Pattern**

Regardless of the agent used, light anesthesia often results in irregular breathing patterns; breath holding is common. Breaths become regular with deeper levels of anesthesia. Inhalation agents generally produce rapid, shallow breaths, whereas nitrous–opioid techniques result in slow, deep breaths.

**VENTILATION/PERFUSION RELATIONSHIPS**

1. **Ventilation**

Ventilation is usually measured as the sum of all exhaled gas volumes in 1 min (minute ventilation, or \( \dot{V} \)).

\[
\text{Minute ventilation} = \text{Respiratory rate} \times \text{Tidal volume}
\]

For the average adult at rest, minute ventilation is about 5 L/min.

Not all of the inspired gas mixture reaches alveoli; some of it remains in the airways and is exhaled without being exchanged with alveolar gases. The part of the \( \dot{V}_T \) not participating in alveolar gas exchange is known as dead space (\( V_D \)). Alveolar ventilation (\( \dot{V}_A \)) is the volume of inspired gases actually taking part in gas exchange in 1 min.

\[
\dot{V}_A = \text{Respiratory rate} \times \dot{V}_T - V_D
\]
Dead space is actually composed of gases in nonrespiratory airways (anatomic dead space) and alveoli that are not perfused (alveolar dead space). The sum of the two components is referred to as physiological dead space. In the upright position, dead space is normally about 150 mL for most adults (approximately 2 mL/kg) and is nearly all anatomic. The weight of an individual in pounds is roughly equivalent to dead space in milliliters. Dead space can be affected by a variety of factors (Table 23–2).

**TABLE 23–2** Factors affecting dead space.

</tr>
</tbody>
</table>

Because \( V_T \) in the average adult is approximately 450 mL (6 mL/kg), \( V_D / V_T \) is normally 33%. This ratio can be derived by the Bohr equation:

\[
\frac{V_D}{V_T} = \frac{P_{ACO_2} - P_{ECO_2}}{P_{ACO_2}}
\]
where $P_{ACO_2}$ is the alveolar $CO_2$ tension and $P_{ECO_2}$ is the mixed expired $CO_2$ tension. This equation is useful clinically if arterial $CO_2$ tension ($P_{ACO_2}$) is used to approximate the alveolar concentration and the $CO_2$ tension in expired air gases is the average measured over several minutes.

**Distribution of Ventilation**

Regardless of body position, alveolar ventilation is unevenly distributed in the lungs. The right lung receives more ventilation than the left lung (53% vs 47%), and the lower (dependent) areas of both lungs tend to be better ventilated than do the upper areas because of a gravitationally induced gradient in intrapleural pressure (transpulmonary pressure). Pleural pressure decreases about 1 cm H$_2$O (becomes less negative) per 3-cm decrease in lung height. This difference places alveoli from different areas at different points on the pulmonary compliance curve (**Figure 23–14**). Because of a higher transpulmonary pressure, alveoli in upper lung areas are near-maximally inflated and relatively noncompliant, and they undergo little expansion during inspiration. In contrast, the smaller alveoli in dependent areas have a lower transpulmonary pressure, are more compliant, and undergo greater expansion during inspiration.
Airway resistance can also contribute to regional differences in pulmonary ventilation. Final alveolar inspiratory volume is solely dependent on compliance only if inspiratory time is unlimited. In reality, inspiratory time is necessarily limited by the respiratory rate and the time necessary for expiration; consequently, an excessively short inspiratory time will prevent alveoli from reaching the expected change in volume. Moreover, alveolar filling follows an exponential function that is dependent on both compliance and airway resistance. Therefore, even with a normal inspiratory time, abnormalities in either compliance or resistance can prevent complete alveolar filling.

**Time Constants**

Lung inflation can be described mathematically by the time constant, \( \tau \).

\[
\tau = \text{Total compliance} \times \text{Airway resistance}
\]

Regional variations in resistance or compliance not only interfere with alveolar filling but can cause asynchrony in alveolar filling during inspiration; some alveolar units may continue to fill as others empty.

Variations in time constants within the normal lung can be demonstrated in normal individuals breathing spontaneously during abnormally high respiratory rates. Rapid shallow breathing reverses the normal distribution of ventilation, preferentially favoring upper (nondependent) areas of the lung over the lower areas.

**2. Pulmonary Perfusion**

Of the approximately 5 L/min of blood flowing through the lungs, only about 70 to 100 mL at any one time are within the pulmonary capillaries undergoing gas exchange. At the alveolar–capillary membrane, this small volume forms a 50 to 100 m\(^2\)-sheet of blood approximately one red cell thick. Moreover, to ensure optimal gas exchange, each capillary perfuses more than one alveolus.

Although capillary volume remains relatively constant, total pulmonary blood volume can vary between 500 mL and 1000 mL. Large increases in either cardiac output or blood volume are tolerated with little change in pressure as a result of passive dilation of open vessels and perhaps some recruitment of collapsed pulmonary vessels. Small increases in pulmonary blood volume
normally occur during cardiac systole and with each normal (spontaneous) inspiration. A shift in posture from supine to erect decreases pulmonary blood volume (up to 27%); Trendelenburg positioning has the opposite effect. Changes in systemic capacitance also influence pulmonary blood volume: Systemic venoconstriction shifts blood from the systemic to the pulmonary circulation, whereas vasodilation causes a pulmonary-to-systemic redistribution. In this way, the lung acts as a reservoir for the systemic circulation.

Local factors are more important than the autonomic system in influencing pulmonary vascular tone. Hypoxia is a powerful stimulus for pulmonary vasoconstriction (the opposite of its systemic effect). Both pulmonary arterial (mixed venous) and alveolar hypoxia induce vasoconstriction, but the latter is a more powerful stimulus. This response seems to be due to either the direct effect of hypoxia on the pulmonary vasculature or increased production of leukotrienes relative to vasodilatory prostaglandins. Inhibition of nitric oxide production may also play a role. Hypoxic pulmonary vasoconstriction is an important physiological mechanism in reducing intrapulmonary shunting and preventing hypoxemia. Hyperoxia has little effect on the pulmonary circulation in normal individuals. Hypercapnia and acidosis have a constrictor effect, whereas hypocapnia causes pulmonary vasodilation, the opposite of what occurs in the systemic circulation.

**Distribution of Pulmonary Perfusion**

Pulmonary blood flow is not uniform. Regardless of body position, dependent areas of the lung receive greater blood flow than nondependent areas. This pattern is the result of a gravitational gradient of 1 cm H₂O/cm lung height. The normally low pressures in the pulmonary circulation allow gravity to exert a significant influence on blood flow. Also, in vivo perfusion scanning in normal individuals has shown an “onion-like” layering distribution of perfusion, with reduced flow at the periphery of the lung and increased perfusion toward the hilum.

Although the pulmonary perfusion pressure is not uniform across the lung, the alveolar distending pressure is relatively constant. The interplay of these pressures results in the dividing of the lung into four distinct zones (ie, the West zones; Figure 23–15). In zone 1 (PA > Pa > Pv), alveolar pressure (PA) is greater than both the arterial pulmonary pressure (Pa) and venous pulmonary pressure (Pv), resulting in obstruction of blood flow and creation of alveolar dead space. West zone 1 is fairly small in a spontaneously breathing individual, but can
enlarge during positive pressure ventilation. In dependent areas of the lungs, $Pa$ progressively increases due to reduced elevation above the heart. In zone 2 ($Pa > Pa > Pv$), $Pa$ is greater than $Pa$, but $Pv$ remains less than both, resulting in blood flow that is dependent on the differential between $Pa$ and $Pa$. The bulk of the lung is described by zone 3 ($Pa > Pv > Pa$), where both $Pa$ and $Pv$ are greater than $Pa$, resulting in blood flow independent of the alveolar pressure. Zone 4, the most dependent part of the lung, is where atelectasis and interstitial pulmonary edema occur, resulting in blood flow that is dependent on the differential between $Pa$ and pulmonary interstitial pressure.

**FIGURE 23–15** Pulmonary blood flow distribution relative to the alveolar pressure ($Pa$), the pulmonary arterial pressure ($Pa$), the pulmonary venous pressure ($Pv$), and the interstitial pressure ($pis$) at various gravitation levels. A: Classic West zones of blood flow distribution in the upright position. (Modified with permission from West JB. *Respiratory Physiology: The Essentials.* 6th ed. Philadelphia, PA: Williams and Wilkins; 2000.) B: In vivo perfusion scanning illustrating central-to-peripheral, in addition to gravitational, blood flow distribution in the upright position. (Reproduced with permission from Lohser J. Evidence based management of one lung ventilation. *Anesthesiol Clin.* 2008 June;26(2):241-272.)

**Ventilation/Perfusion Ratios**

Because alveolar ventilation ($V_A$) is normally about 4 L/min, and pulmonary capillary perfusion ($Q$) is 5 L/min, the overall $V/Q$ ratio is about 0.8. $V/Q$ for individual lung units (each alveolus and its capillary) can range from 0 (no ventilation) to infinity (no perfusion); the former is referred to as *intrapulmonary shunt*, whereas the latter constitutes *alveolar dead space*. $V/Q$ normally ranges between 0.3 and 3.0; the majority of lung areas, however, are close to 1.0
(Figure 23–16A). Because perfusion increases at a greater rate than ventilation, nondependent (apical) areas tend to have higher $\dot{V}/\dot{Q}$ ratios than do dependent (basal) areas (Figure 23–16B).

**FIGURE 23–16** The distribution of $\dot{V}/\dot{Q}$ ratios for the whole lung (A) and according to height (B) in the upright position. Note that blood flow increases more rapidly than ventilation in dependent areas. (Reproduced with permission from West JB. Ventilation/Blood Flow and Gas Exchange. 3rd ed. Oxford, UK: Blackwell Science Ltd; 1977.)

The importance of $\dot{V}/\dot{Q}$ ratios relates to the efficiency with which lung units resaturate venous blood with $O_2$ and eliminate $CO_2$. **Pulmonary venous blood (the effluent) from areas with low $\dot{V}/\dot{Q}$ ratios has a low $O_2$ tension and high $CO_2$ tension—similar to systemic mixed venous blood.** Blood from these units tends to depress arterial $O_2$ tension and elevate arterial $CO_2$ tension. Their effect on arterial $O_2$ tension is much more profound than that on $CO_2$ tension; in fact, arterial $CO_2$ tension often decreases from a hypoxemia-induced reflex increase in alveolar ventilation. An appreciable compensatory increase in $O_2$ uptake cannot take place in remaining areas where $\dot{V}/\dot{Q}$ is normal, because pulmonary end-capillary blood is usually already maximally saturated with $O_2$ (see below).

3. *Shunts*
Shunting denotes the process whereby desaturated, mixed venous blood from the right heart returns to the left heart without being oxygenated in the lungs (Figure 23–17). The overall effect of shunting is to decrease (dilute) arterial $O_2$ content; this type of shunt is referred to as right-to-left. Left-to-right shunts (in the absence of pulmonary congestion) do not produce hypoxemia.

**FIGURE 23–17** A three-compartment model of gas exchange in the lungs, showing dead space ventilation, normal alveolar–capillary exchange, and shunting (venous admixture). (Reproduced with permission from Lumb A. Nunn's Applied Respiratory Physiology. 8th ed. St. Louis, MO: Elsevier; 2017.)

Intrapulmonary shunts are often classified as **absolute** or **relative**. An absolute shunt refers to anatomic shunts and lung units where $\dot{V}/\dot{Q}$ is zero. A relative shunt is an area of the lung with a low $\dot{V}/\dot{Q}$ ratio. Clinically, hypoxemia from a relative shunt can usually be partially corrected by increasing the inspired $O_2$ concentration; hypoxemia caused by an absolute shunt cannot.
**Venous Admixture**

*Venous admixture* is the amount of mixed venous blood that would have to be mixed with pulmonary end-capillary blood to account for the difference in O$_2$ tension between arterial and pulmonary end-capillary blood. Pulmonary end-capillary blood is considered to have the same concentrations as alveolar gas. Venous admixture is usually expressed as a fraction of total cardiac output (Qs/Qt). The equation for Qs/Qt may be derived with the law for the conservation of mass for O$_2$ across the pulmonary bed:

$$\dot{Q}_T \times Cao_2 = (\dot{Q}_s \times C\bar{v}o_2) + (\dot{Q}c' \times Cc'o_2)$$

Where

- Qs = blood flow through the physiologic shunt compartment
- QT = total cardiac output
- Qc' = blood flow across normally ventilated pulmonary capillaries
- $\dot{Q}_T = \dot{Q}c' + \dot{Q}_s$
- Cc'o$_2$ = oxygen content of ideal pulmonary end-capillary blood
- CaO$_2$ = arterial oxygen content
- C\bar{v}O$_2$ = mixed venous content

The simplified equation is:

$$\frac{\dot{Q}s}{\dot{Q}t} = \frac{Cc'o_2 - CaO_2}{Cc'o_2 - C\bar{v}O_2}$$

The formula for calculating the O$_2$ content of blood is given below.

$\dot{Q}s/\dot{Q}t$ can be calculated clinically by obtaining mixed venous and arterial blood gas measurements; the former requires a pulmonary artery catheter. The alveolar gas equation is used to derive pulmonary end-capillary O$_2$ tension.
Pulmonary capillary blood is usually assumed to be 100% saturated for an FiO$_2$ of 0.21 or greater.

The calculated venous admixture assumes that all shunting is intrapulmonary and due to absolute shunts ($\dot{V}/\dot{Q} = 0$). In reality, neither is ever the case; nonetheless, the concept is useful clinically. Normal $\dot{Q}_s/\dot{Q}_r$ is primarily due to communication between deep bronchial veins and pulmonary veins, the thebesian circulation in the heart, and areas of low $\dot{V}/\dot{Q}$ in the lungs (Figure 23–18). The venous admixture in normal individuals (physiological shunt) is typically less than 5%.

**FIGURE 23–18** Components of the normal venous admixture. (Reproduced with permission from Lumb A. Nunn’s Applied Respiratory Physiology. 8th ed. St. Louis, MO: Elsevier; 2017.)

4. **Effects of Anesthesia on Gas Exchange**

Abnormalities in gas exchange during anesthesia are common. They include increased dead space, hypoventilation, and increased intrapulmonary shunting.
There is increased scatter of $V/Q$ ratios. Increases in alveolar dead space are most commonly seen during controlled ventilation, but may also occur during spontaneous ventilation. General anesthesia commonly increases venous admixture to 5% to 10%, probably as a result of atelectasis and airway collapse in dependent areas of the lung. Inhalation agents also can inhibit hypoxic pulmonary vasoconstriction; for volatile agents, the ED$_{50}$ is about twice the minimum alveolar concentration (MAC). Elderly patients seem to have the largest increases in $Q_s/Q_t$. Inspired $O_2$ tensions of 30% to 40% usually prevent hypoxemia, suggesting anesthesia increases relative shunt. PEEP is often effective in reducing venous admixture and preventing hypoxemia during general anesthesia, as long as cardiac output is maintained. Prolonged administration of high inspired $O_2$ concentrations may be associated with atelectasis formation and increases in absolute shunt. Atelectasis in this situation is known as resorption atelectasis and appears in areas with a low $V/Q$ ratio ventilated at an $O_2$-inspired concentration close to 100%. Perfusion results in $O_2$ being transported out of the alveoli at a rate faster than it enters the alveoli, leading to an emptying of the alveoli and collapse.

**ALVEOLAR, ARTERIAL, & VENOUS GAS TENSIONS**

When dealing with gas mixtures, each gas is considered to contribute separately to total gas pressure, and its partial pressure is directly proportional to its concentration. Air has an $O_2$ concentration of approximately 21%; therefore, if the barometric pressure is 760 mm Hg (sea level), the partial pressure of $O_2$ ($P_{O_2}$) in air is normally 159.6 mm Hg:

$$760 \text{ mm Hg} \times 0.21 = 159.6 \text{ mm Hg}$$

In its general form, the equation may be written as follows:

$$P_{O_2} = P_B \times F_{O_2}$$

where $P_B =$ barometric pressure and $F_{O_2} =$ the fraction of inspired $O_2$.

1. **Oxygen**
Alveolar Oxygen Tension

With every breath, the inspired gas mixture is humidified at 37°C in the upper airway. The inspired tension of O₂ (P_{IO₂}) is therefore reduced by the added water vapor. Water vapor pressure is dependent upon temperature and is 47 mm Hg at 37°C. In humidified air, the normal partial pressure of O₂ at sea level is 150 mm Hg:

\[
(760 - 47) \times 0.21 = 150 \text{ mm Hg}
\]

The general equation is:

\[
P_{IO₂} = (P_B - P_{H₂O}) \times F_iO₂
\]

where \(P_{H₂O}\) = the vapor pressure of water at body temperature.

In alveoli, the inspired gases are mixed with residual alveolar gas from previous breaths, O₂ is taken up, and CO₂ is added. The final alveolar O₂ tension (P_{AO₂}) is therefore dependent on all of these factors and can be estimated by the following equation:

\[
P_{AO₂} = P_{IO₂} - \frac{P_{ACO₂}}{RQ}
\]

where \(P_{ACO₂}\) = arterial CO₂ tension and RQ = respiratory quotient.

RQ is usually not measured. Note that large increases in \(P_{ACO₂}\) (>75 mm Hg) readily produce hypoxia (P_{O₂} <60 mm Hg) at room air, but not at high inspired O₂ concentrations.

Pulmonary End-Capillary Oxygen Tension

For all practical purposes, pulmonary end-capillary O₂ tension (Pc’O₂) may be considered identical to P_{AO₂}; the P_{AO₂}–Pc’O₂ gradient is normally minute. Pc’O₂ is dependent on the rate of O₂ diffusion across the alveolar–capillary membrane, as well as on pulmonary capillary blood volume and transit time. The large capillary surface area in alveoli and the 0.4 to 0.5 μm thickness of the alveolar–capillary membrane greatly facilitate O₂ diffusion. Enhanced O₂ binding to hemoglobin at saturations above 80% also augments O₂ diffusion (see below).
Capillary transit time can be estimated by dividing pulmonary capillary blood volume by cardiac output (pulmonary blood flow); thus, normal capillary transit time is 70 mL ÷ 5000 mL/min (0.8 s). Maximum Pc’O₂ is usually attained after only 0.3 s, providing a large safety margin.

The binding of O₂ to hemoglobin seems to be the principal rate-limiting factor in the transfer of O₂ from alveolar gas to blood. Therefore, pulmonary diffusing capacity reflects not only the capacity and permeability of the alveolar–capillary membrane, but also pulmonary blood flow. Moreover, O₂ uptake is normally limited by pulmonary blood flow, not O₂ diffusion across the alveolar–capillary membrane; the latter may become significant during exercise in normal individuals at high altitudes and in patients with extensive destruction of the alveolar–capillary membrane.

O₂ transfer across the alveolar–capillary membrane is expressed as O₂ diffusing capacity (DLO₂):

\[ DLO₂ = \frac{\text{Oxygen uptake}}{\frac{PAO₂}{Pc'O₂}} \]

Because Pc’O₂ cannot be measured accurately, measurement of carbon monoxide diffusion capacity (DLCO) is used instead to assess gas transfer across the alveolar–capillary membrane. Because carbon monoxide has a very high affinity for hemoglobin, there is little or no carbon monoxide in pulmonary capillary blood, so that even when it is administered at low concentration, Pc’CO can be considered zero. Therefore,

\[ DLCO = \frac{\text{Carbon monoxide uptake}}{PAO₂} \]

Reductions in DLCO imply an impediment in gas transfer across the alveolar–capillary membrane. Such impediments may be due to abnormal V/Q ratios, extensive destruction of the gas alveolar–capillary membrane, or very short capillary transit times. Abnormalities are accentuated by increases in O₂ consumption and cardiac output, such as occurs during exercise.

**Arterial Oxygen Tension**

Pao₂ cannot be calculated like PAO₂ but must be measured at room air. The
alveolar-to-arterial $O_2$ partial pressure gradient (A–a gradient) is normally less than 15 mm Hg, but progressively increases with age up to 20 to 30 mm Hg. Arterial $O_2$ tension can be approximated by the following formula (in mm Hg):

$$\text{Pao}_2 = 120 - \frac{\text{Age}}{3}$$

The range is 60 to 100 mm Hg. Decreases are probably the result of a progressive increase in closing capacity relative to FRC (see earlier discussion). Table 23–3 lists the mechanisms of hypoxemia ($\text{Pao}_2 < 60$ mm Hg).

**TABLE 23–3 Mechanisms of hypoxemia.**

$^1\dot{V}'/\dot{Q}'$, ventilation/perfusion.

The most common mechanism for hypoxemia is an increased alveolar–arterial gradient. The A–a gradient for $O_2$ depends on the amount of right-to-left shunting, the amount of $\dot{V}/\dot{Q}$ scatter, and the mixed venous $O_2$ tension (see below). The last depends on cardiac output, $O_2$ consumption, and hemoglobin concentration.

The A–a gradient for $O_2$ is directly proportional to shunt, but inversely
proportional to mixed venous O₂ tension. The effect of each variable on Pao₂ (and consequently the A–a gradient) can be determined only when the other variables are held constant. Figure 23–19 shows the effect of different degrees of shunting on Pao₂. It should also be noted that the greater the shunt, the less likely the possibility that an increase in Fio₂ will correct hypoxemia. Moreover, isoshunt lines seem to be most useful for O₂ concentrations between 35% and 100%. Lower O₂ concentrations require modification of isoshunt lines to account for the effect of V/Q scatter.

![Figure 23–19 Isoshunt curves showing the effect of varying amounts of shunt on Pao₂. Note that there is little benefit in increasing inspired oxygen concentration in patients with very large shunts. (Modified with permission from Benatar SR, Hewlett AM, Nunn JF. The use of isoshunt lines for control of oxygen therapy. Br J Anaesth. 1973 July;45(7):711-718.)](image)

The effect of cardiac output on the A–a gradient (Figure 23–20) is due not only to its secondary effects on mixed venous O₂ tension but also to a direct relationship between cardiac output and intrapulmonary shunting. As can be seen, a low cardiac output tends to accentuate the effect of shunt on Pao₂. A
reduction in venous admixture may be observed with low-normal cardiac outputs secondary to accentuated pulmonary vasoconstriction from a lower mixed venous $O_2$ tension. On the other hand, high cardiac outputs can increase venous admixture by elevating mixed venous $O_2$ tension, which in turn inhibits hypoxic pulmonary vasoconstriction.

**FIGURE 23–20** The effect of cardiac output on the alveolar–arterial $P_{O_2}$ difference with varying degrees of shunting. $V'O_2 = 200$ mL/min and $P_{O_2} = 180$ mm Hg.) (Reproduced with permission from Lumb A. Nunn's Applied Respiratory Physiology. 8th ed. St. Louis, MO: Elsevier; 2017.)

$O_2$ consumption and hemoglobin concentration can also affect $P_{O_2}$ through their secondary effects on mixed venous $O_2$ tension (below). High $O_2$ consumption rates and low hemoglobin concentrations can increase the A–a gradient and depress $P_{O_2}$.

**Mixed Venous Oxygen Tension**

Normal mixed venous $O_2$ tension ($P_{V'O_2}$) is about 40 mm Hg and represents the overall balance between $O_2$ consumption and $O_2$ delivery (Table 23–4). A true mixed venous blood sample contains venous drainage from the superior vena cava, the inferior vena cava, and the heart; it must therefore be obtained from a pulmonary artery catheter.

**TABLE 23–4** Alterations in mixed venous oxygen tension (and saturation).
Decreased $P\tilde{V}O_2$
- Increased $O_2$ consumption
  - Fever
  - Shivering
  - Exercise
  - Malignant hyperthermia
  - Thyroid storm
Decreased $O_2$ delivery
- Hypoxia
- Decreased cardiac output
- Decreased hemoglobin concentration
- Abnormal hemoglobin

Increased $P\tilde{V}O_2$
- Left-to-right shunting
- High cardiac output
- Impaired tissue uptake
  - Cyanide poisoning
- Decreased oxygen consumption
  - Hypothermia
- Combined mechanisms
- Sepsis
- Sampling error
- Wedged pulmonary artery catheter

2. Carbon Dioxide
Carbon dioxide is a by product of aerobic metabolism in mitochondria. Therefore, there are small continuous gradients for CO$_2$ tension from mitochondria to cell cytoplasm, extracellular fluid, venous blood, and alveoli, where the CO$_2$ is finally eliminated.

Mixed Venous Carbon Dioxide Tension
Normal mixed venous CO$_2$ tension ($P\tilde{V}CO_2$) is about 46 mm Hg and is the end
result of mixing of blood from tissues of varying metabolic activity. Venous CO₂ tension is lower in tissues with low metabolic activity (eg, skin), but higher in blood from those with relatively high activity (eg, heart).

**Alveolar Carbon Dioxide Tension**

Alveolar CO₂ tension (PACO₂) is generally considered to represent the balance between total CO₂ production (VCO₂) and alveolar ventilation (elimination):

\[
PACO_2 = \frac{\dot{V}CO_2}{\dot{V}_A}
\]

where \(\dot{V}_A\) is alveolar ventilation (Figure 23–21). During periods of acute hypoventilation or hypoperfusion, body content of carbon dioxide increases. Clinically, PACO₂ is more dependent on variations in alveolar ventilation than in CO₂ production, because CO₂ production does not vary appreciably under most circumstances. However, conditions such as malignant hyperthermia can lead to dramatic increases in CO₂ production, which can overwhelm the body’s buffering system (see below).

![Figure 23–21 The effect of alveolar ventilation on alveolar Pco2 at two rates of CO2 production.](Reproduced with permission from Lumb A. Nunn’s Applied Respiratory Physiology. 8th ed. St. Louis, MO: Elsevier; 2017.)
**Pulmonary End-Capillary Carbon Dioxide Tension**

Pulmonary end-capillary CO₂ tension (Pc'CO₂) is virtually identical to PACO₂ for the same reasons as those discussed in the section about O₂. In addition, the diffusion rate for CO₂ across the alveolar–capillary membrane is 20 times that of O₂.

**Arterial Carbon Dioxide Tension**

Arterial CO₂ tension (Paco₂), which is readily measurable, is identical to Pc'CO₂, and, necessarily, PACO₂. Normal Paco₂ is 38 ± 4 mm Hg (5.1 ± 0.5 kPa); in practice, 40 mm Hg is usually considered normal.

Although low V̇/Q̇ ratios tend to increase Paco₂, whereas high V̇/Q̇ ratios tend to decrease it, significant arterial-to-alveolar gradients for CO₂ develop only in the presence of marked V̇/Q̇ abnormalities (>30% venous admixture); even then the gradient is relatively small (2–3 mm Hg). Moreover, small increases in the gradient appreciably increase CO₂ output into alveoli with relatively normal V̇/Q̇. Even moderate to severe disturbances usually fail to appreciably alter arterial CO₂ because of a reflex increase in ventilation from concomitant hypoxemia.

**End-Tidal Carbon Dioxide Tension**

Because end-tidal gas is primarily alveolar gas and Paco₂ is virtually identical to Paco₂, end-tidal CO₂ tension (PETCO₂) is used clinically as an estimate of Paco₂. The PACO₂–PETCO₂ gradient is normally less than 5 mm Hg and represents dilution of alveolar gas with CO₂-free gas from nonperfused alveoli (alveolar dead space).

**TRANSPORT OF RESPIRATORY GASES IN BLOOD**

1. **Oxygen**

O₂ is carried in blood in two forms: dissolved in solution and in reversible association with hemoglobin.
**Dissolved Oxygen**

The amount of O\(_2\) dissolved in blood can be derived from **Henry’s law**, which states that the concentration of any gas in solution is proportional to its partial pressure. The mathematical expression is as follows:

\[
\text{Gas concentration} = \alpha \times \text{Partial pressure}
\]

where \(\alpha\) = the gas solubility coefficient for a given solution at a given temperature.

The solubility coefficient for O\(_2\) at normal body temperature is 0.003 mL/dL/mm Hg. Even with a Pa\(_{O_2}\) of 100 mm Hg, the maximum amount of O\(_2\) dissolved in blood is very small (0.3 mL/dL) compared with that bound to hemoglobin.

**Hemoglobin**

Hemoglobin is a complex molecule consisting of four heme and four protein subunits. Heme is an iron–porphyrin compound that is an essential part of the O\(_2\)-binding sites; only the divalent form (+2 charge) of iron can bind O\(_2\). The normal hemoglobin molecule (hemoglobin A\(_1\)) consists of two \(\alpha\) and two \(\beta\) chains (subunits); the four subunits are held together by weak bonds between the amino acid residues. Each gram of hemoglobin can theoretically carry up to 1.39 mL of O\(_2\).

**Hemoglobin Dissociation Curve**

Each hemoglobin molecule binds up to four O\(_2\) molecules. The complex interaction between the hemoglobin subunits results in nonlinear (an elongated S shape) binding with O\(_2\) (**Figure 23–22**). Hemoglobin saturation is the amount of O\(_2\) bound as a percentage of its total O\(_2\)-binding capacity. Four separate chemical reactions are involved in binding each of the four O\(_2\) molecules. The change in molecular conformation induced by the binding of the first three molecules greatly accelerates binding of the fourth O\(_2\) molecule. The last reaction is responsible for the accelerated binding between 25% and 100% saturation. At about 90% saturation, the decrease in available O\(_2\) receptors flattens the curve until full saturation is reached.
Factors Influencing the Hemoglobin Dissociation Curve

Clinically important factors altering O$_2$ binding include hydrogen ion concentration, CO$_2$ tension, temperature, and 2,3-diphosphoglycerate (2,3-DPG) concentration. Their effect on hemoglobin–O$_2$ interaction can be expressed by $P_{50}$, the O$_2$ tension at which hemoglobin is 50% saturated (Figure 23–23). Each factor shifts the dissociation curve either to the right (increasing $P_{50}$) or to the left (decreasing $P_{50}$). A rightward shift in the oxygen–hemoglobin dissociation curve lowers O$_2$ affinity, displaces O$_2$ from hemoglobin, and makes more O$_2$ available to tissues; a leftward shift increases hemoglobin’s affinity for O$_2$, reducing its availability to tissues. The normal $P_{50}$ in adults is 26.6 mm Hg.
An increase in blood hydrogen ion concentration reduces $O_2$ binding to hemoglobin (Bohr effect). Because of the shape of the hemoglobin dissociation curve, the effect is more important in venous blood than arterial blood (see Figure 23–23); the net result is facilitation of $O_2$ release to tissue with little impairment in $O_2$ uptake (unless severe hypoxia is present).

The influence of $CO_2$ tension on hemoglobin’s affinity for $O_2$ is important physiologically and is secondary to the associated rise in hydrogen ion concentration when $CO_2$ tension increases. The high $CO_2$ content of venous capillary blood, by decreasing hemoglobin’s affinity for $O_2$, facilitates the release of $O_2$ to tissues; conversely, the lower $CO_2$ content in pulmonary capillaries increases hemoglobin’s affinity for $O_2$ again, facilitating $O_2$ uptake from alveoli.

2,3-DPG is a byproduct of glycolysis and accumulates during anaerobic metabolism. Although its effects on hemoglobin under these conditions are theoretically beneficial, its physiological importance normally seems minor. 2,3-DPG levels may, however, play an important compensatory role in patients with
chronic anemia and may significantly affect the $O_2$-carrying capacity of blood transfusions.

**Abnormal Ligands & Abnormal Forms of Hemoglobins**

Carbon monoxide, cyanide, nitric acid, and ammonia can combine with hemoglobin at $O_2$-binding sites. They can displace $O_2$ and shift the saturation curve to the left. Carbon monoxide is particularly potent, having 200 to 300 times the affinity of $O_2$ for hemoglobin, combining with it to form carboxyhemoglobin. Carbon monoxide decreases hemoglobin’s $O_2$-carrying capacity and impairs the release of $O_2$ to tissues.

Methemoglobin results when the iron in heme is oxidized to its trivalent (+3) form. Nitrates, nitrites, sulfonamides, and other drugs can rarely result in significant methemoglobinemia. Methemoglobin cannot combine with $O_2$ unless reconverted by the enzyme methemoglobin reductase; methemoglobin also shifts the normal hemoglobin saturation curve to the left. Methemoglobinemia, like carbon monoxide poisoning, therefore decreases the $O_2$-carrying capacity and impairs the release of $O_2$. Reduction of methemoglobin to normal hemoglobin is facilitated by such agents as methylene blue or ascorbic acid.

Abnormal hemoglobins can also result from variations in the protein subunit composition. Each variant has its own $O_2$-saturation characteristics. These include fetal hemoglobin, hemoglobin $A_2$, and sickle hemoglobin.

**Oxygen Content**

The total $O_2$ content of blood is the sum of that in solution plus that carried by hemoglobin. In reality, $O_2$ binding to hemoglobin never achieves the theoretical maximum, but is closer to 1.31 mL $O_2$/dL blood per millimeter of mercury. Total $O_2$ content is expressed by the following equation:

$$O_2 \text{ content} = ([0.003 \text{ mL } O_2/\text{dL blood per mm Hg}] \times P_{O_2}) + (S_{O_2} \times Hb \times 1.31 \text{ mL/dL blood})$$

where $Hb$ is hemoglobin concentration in g/dL blood, and $S_{O_2}$ is hemoglobin saturation at the given $P_{O_2}$. 
Using this formula and a hemoglobin of 15 g/dL, the normal O₂ content for both arterial and mixed venous blood and the arteriovenous difference can be calculated as follows:

\[
\text{Cao}_2 = (0.003 \times 100) + (0.975 \times 15 \times 1.39) \\
= 19.5 \text{ mL/dL blood} \\
\text{C\bar{v}o}_2 = (0.003 \times 40) + (0.75 \times 15 \times 1.31) \\
= 14.8 \text{ mL/dL blood} \\
\text{Cao}_2 - \text{C\bar{v}o}_2 = 4.7 \text{ mL/dL blood}
\]

**Oxygen Transport**

O₂ transport is dependent on both respiratory and circulatory function. Total O₂ delivery (\(\dot{D}O_2\)) to tissues is the product of arterial O₂ content and cardiac output:

\[
\dot{D}O_2 = \text{Cao}_2 \times \dot{Q}_T
\]

Note that arterial O₂ content is dependent on \(P_{\text{ao}2}\) as well as hemoglobin concentration. As a result, deficiencies in O₂ delivery may be due to a low \(P_{\text{ao}2}\), a low hemoglobin concentration, or an inadequate cardiac output. Normal O₂ delivery can be calculated as follows:

\[
\text{O₂ delivery} = 20 \text{ mL O}_2/\text{dL blood} \\
\times 50 \text{ dL blood/min} \\
= 1000 \text{ mL O}_2/\text{min}
\]

The Fick equation expresses the relationship between O₂ consumption, O₂ content, and cardiac output:

\[
\text{O₂ consumption} = \dot{V}_O_2 = \dot{Q}_T \times (\text{Cao}_2 - \text{C\bar{v}o}_2)
\]

Rearranging the equation:

\[
\text{Cao}_2 = \frac{\dot{V}_O_2}{\dot{Q}_T} + \text{C\bar{v}o}_2
\]
Consequently, the arteriovenous difference is a good measure of the overall adequacy of O$_2$ delivery.

As calculated above, the arteriovenous difference ($\text{CaO}_2 - \text{CVO}_2$) is about 5 mL O$_2$/dL blood (20 mL O$_2$/dL – 15 mL O$_2$/dL). Note that the normal extraction fraction for O$_2$[$(\text{CaO}_2 - \text{CVO}_2)/\text{CaO}_2$] is 5 mL $\div$ 20 mL, or 25%; thus, the body normally consumes only 25% of the O$_2$ carried on hemoglobin. When O$_2$ demand exceeds supply, the extraction fraction exceeds 25%. Conversely, if O$_2$ supply exceeds demand, the extraction fraction falls below 25%.

When $D$O$_2$ is even moderately reduced, $V$O$_2$ usually remains normal because of increased O$_2$ extraction (mixed venous O$_2$ saturation decreases); $V$O$_2$ remains independent of delivery. With further reductions in $D$O$_2$, however, a critical point is reached beyond which $V$O$_2$ becomes directly proportional to $D$O$_2$. This state of supply-dependent O$_2$ is typically associated with progressive lactic acidosis caused by cellular hypoxia.

**Oxygen Stores**

The concept of O$_2$ stores is important in anesthesia. When the normal flux of O$_2$ is interrupted by apnea, existing O$_2$ stores are consumed by cellular metabolism; if stores are depleted, hypoxia and eventual cell death follow. Theoretically, normal O$_2$ stores in adults are about 1500 mL. This amount includes the O$_2$ remaining in the lungs, that bound to hemoglobin (and myoglobin), and that dissolved in body fluids. Unfortunately, the high affinity of hemoglobin for O$_2$ (the affinity of myoglobin is even higher), and the very limited quantity of O$_2$ in solution, restrict the availability of these stores. The O$_2$ contained within the lungs at FRC (initial lung volume during apnea), therefore, becomes the most important source of O$_2$. Of that volume, however, probably only 80% is usable.

Apnea in a patient previously breathing room air leaves approximately 480 mL of O$_2$ in the lungs. (If $\text{FiO}_2 = 0.21$ and FRC = 2300 mL, O$_2$ content = $\text{FiO}_2 \times \text{FRC}$.) The metabolic activity of tissues rapidly depletes this reservoir (presumably at a rate equivalent to V$\text{O}_2$); severe hypoxemia usually occurs within 90 sec. The onset of hypoxemia can be delayed by increasing the $\text{FiO}_2$ prior to the apnea. Following ventilation with 100% O$_2$, FRC contains about 2300 mL of O$_2$; this delays hypoxemia following apnea for 4 to 5 min. This
concept is the basis for preoxygenation prior to induction of anesthesia.

2. **Carbon Dioxide**

Carbon dioxide is transported in blood in three forms: dissolved in solution, as bicarbonate, and with proteins in the form of carbamino compounds (Table 23–5). The sum of all three forms is the total CO₂ content of blood (routinely reported with electrolyte measurements).

**TABLE 23–5** Contributions to carbon dioxide transport in 1 L of whole blood.¹,²

**Dissolved Carbon Dioxide**

Carbon dioxide is more soluble in blood than O₂, with a solubility coefficient of 0.031 mmol/L/mm Hg (0.067 mL/dL/mm Hg) at 37°C.

**Bicarbonate**

In aqueous solutions, CO₂ slowly combines with water to form carbonic acid and bicarbonate, according to the following reaction:

\[ \text{H}_2\text{O} + \text{CO}_2 \leftrightarrow \text{H}_2\text{CO}_3 \leftrightarrow \text{H}^+ + \text{HCO}_3^- \]

In plasma, although less than 1% of the dissolved CO₂ undergoes this
reaction, the presence of the enzyme **carbonic anhydrase** within erythrocytes and endothelium greatly accelerates the reaction. As a result, bicarbonate represents the largest fraction of the CO$_2$ in blood (see Table 23–5). Administration of acetazolamide, a carbonic anhydrase inhibitor, can impair CO$_2$ transport between tissues and alveoli.

On the venous side of systemic capillaries, CO$_2$ enters red blood cells and is converted to bicarbonate, which diffuses out of red cells into plasma; chloride ions move from plasma into red cells to maintain electrical balance. In the pulmonary capillaries, the reverse occurs: chloride ions move out of red cells as bicarbonate ions reenter them for conversion back to CO$_2$, which diffuses out into alveoli. This sequence is referred to as the chloride or Hamburger shift.

### Carbamino Compounds

Carbon dioxide can react with amino groups on proteins, as shown by the following equation:

$$R - NH_2 + CO_2 \rightarrow RNH - CO_2^- + H^+$$

At physiological pH, only a small amount of CO$_2$ is carried in this form, mainly as carbaminohemoglobin. Deoxygenated hemoglobin (deoxyhemoglobin) has a greater affinity (3.5 times) for CO$_2$ than does oxyhemoglobin. As a result, venous blood carries more CO$_2$ than does arterial blood (Haldane effect; see Table 23–5). P$_{CO_2}$ normally has little effect on the fraction of CO$_2$ carried as carbaminohemoglobin.

### Effects of Hemoglobin Buffering on Carbon Dioxide Transport

The buffering action of hemoglobin also accounts for part of the Haldane effect. Hemoglobin can act as a buffer at physiological pH because of its high content of histidine. Moreover, the acid–base behavior of hemoglobin is influenced by its oxygenation state:

$$H^+ + HbO_2 \rightarrow HbH^+ + O_2$$
Removal of O$_2$ from hemoglobin in tissue capillaries causes the hemoglobin molecule to behave more like a base; by taking up hydrogen ions, hemoglobin shifts the CO$_2$–bicarbonate equilibrium in favor of greater bicarbonate formation:

$$CO_2 + H_2O + HbO_2 \rightarrow HbH^+ + HCO_3^- + O_2$$

As a direct result, deoxyhemoglobin also increases the amount of CO$_2$ that is carried in venous blood as bicarbonate. As CO$_2$ is taken up from tissue and converted to bicarbonate, the total CO$_2$ content of blood increases (see Table 23–5).

In the lungs, the reverse is true. Oxygenation of hemoglobin favors its action as an acid, and the release of hydrogen ions shifts the equilibrium in favor of greater CO$_2$ formation:

$$O_2 + HCO_3^- + HbH^+ \rightarrow H_2O + CO_2 + HbO_2$$

Bicarbonate concentration decreases as CO$_2$ is formed and eliminated, so that the total CO$_2$ content of blood decreases in the lungs. Note that there is a difference between CO$_2$ content (concentration per liter) of whole blood (see Table 23–5) and plasma (Table 23–6).

| TABLE 23–6 Carbon dioxide content of plasma (mmol/L).$^{1,2}$ |
|-----------------------------------|----------|----------|
| **Arterial**                      | **Venous**|
| Dissolved CO$_2$                  | 1.2      | 1.4      |
| Bicarbonate                       | 24.4     | 26.2     |
| Carbamino CO$_2$                  | Negligible | Negligible |
| Total CO$_2$                      | 25.6     | 27.6     |

$^2$Values are expressed in millimoles, except where indicated otherwise.

**Carbon Dioxide Dissociation Curve**
A CO₂ dissociation curve can be constructed by plotting the total CO₂ content of blood against PCO₂. The contribution of each form of CO₂ can also be quantified in this manner (Figure 23–24).

**Figure 23–24** The CO₂ dissociation curve for whole blood. (Reproduced with permission from Lumb A. Nunn's Applied Respiratory Physiology. 8th ed. St. Louis, MO: Elsevier; 2017.)

**Carbon Dioxide Stores**
Carbon dioxide stores in the body are large (approximately 120 L in adults) and primarily in the form of dissolved CO₂ and bicarbonate. When an imbalance occurs between production and elimination, establishing a new CO₂ equilibrium requires 20 to 30 min (compared with less than 4 to 5 min for O₂; see above). Carbon dioxide is stored in the rapid-, intermediate-, and slow-equilibrating compartments. Because of the larger capacity of the intermediate and slow compartments, the rate of rise in arterial CO₂ tension is generally slower than its fall following acute changes in ventilation.

**CONTROL OF BREATHING**

Spontaneous ventilation is the result of rhythmic neural activity in respiratory centers within the brainstem. This activity regulates respiratory muscles to maintain normal tensions of O₂ and CO₂ in the body. The basic neuronal activity is modified by inputs from other areas in the brain, volitional and autonomic, as well as various central and peripheral receptors (sensors).

1. **Central Respiratory Centers**

The basic breathing rhythm originates in the medulla. Two medullary groups of neurons are generally recognized: a dorsal respiratory group, which is primarily active during inspiration, and a ventral respiratory group, which is active during inspiration and expiration.

Two pontine areas influence the dorsal (inspiratory) medullary center. A lower pontine (apneustic) center is excitatory, whereas an upper pontine (pneumotaxic) center is inhibitory. The pontine centers appear to fine-tune respiratory rate and rhythm.

2. **Central Sensors**

The most important of these sensors are chemoreceptors that respond to changes in hydrogen ion concentration. Central chemoreceptors are thought to lie on the anterolateral surface of the medulla and respond primarily to changes in cerebrospinal fluid (CSF) [H⁺]. This mechanism is effective in regulating PaCO₂, because the blood–brain barrier is permeable to dissolved CO₂, but not to bicarbonate ions. Acute changes in PaCO₂, but not in arterial [HCO₃⁻], are reflected in CSF; thus, a change in CO₂ must result in a change in [H⁺]:
\[ \text{CO}_2 + \text{H}_2\text{O} \leftrightarrow \text{H}^+ + \text{HCO}_3^- \]

Over the course of a few days, CSF \([\text{HCO}_3^-]\) can compensate to match any change in arterial \([\text{HCO}_3^-]\).

Increases in \(\text{PaCO}_2\) elevate CSF hydrogen ion concentration and activate the chemoreceptors. Secondary stimulation of the adjacent respiratory medullary centers increases alveolar ventilation (Figure 23–25) and reduces \(\text{Paco}_2\) back to normal. Conversely, decreases in CSF hydrogen ion concentration secondary to reductions in \(\text{PaCO}_2\) reduce alveolar ventilation and elevate \(\text{Paco}_2\). Note that the relationship between \(\text{PaCO}_2\) and minute volume is nearly linear. Also note that very high arterial \(\text{PaCO}_2\) tensions depress the ventilatory response (CO\(_2\) narcosis). The \(\text{Paco}_2\) at which ventilation is zero (x-intercept) is known as the \(\text{apneic threshold}\). Spontaneous respirations are typically absent under anesthesia when \(\text{Paco}_2\) falls below the apneic threshold. (In the awake state, cortical influences prevent apnea, so apneic thresholds are not ordinarily seen.) In contrast to peripheral chemoreceptors (see below), central chemoreceptor activity is depressed by hypoxia.

3. Peripheral Sensors

Peripheral Chemoreceptors

Peripheral chemoreceptors include the carotid bodies (at the bifurcation of the common carotid arteries) and the aortic bodies (surrounding the aortic arch). The carotid bodies are the principal peripheral chemoreceptors in humans and are sensitive to changes in PaO₂, PaCO₂, pH, and arterial perfusion pressure. They interact with central respiratory centers via the glossopharyngeal nerves,
producing reflex increases in alveolar ventilation in response to reductions in \( \text{P} \text{a}_2 \), arterial perfusion, or elevations in \([H^+]\) and \( \text{P} \text{a}_2 \). Peripheral chemoreceptors are also stimulated by cyanide, doxapram, and large doses of nicotine. In contrast to central chemoreceptors, which respond primarily to \( \text{P} \text{a}_2 \) (more specifically, \([H^+]\)), the carotid bodies are most sensitive to \( \text{P} \text{a}_2 \) (Figure 23–26). Note that receptor activity does not appreciably increase until \( \text{P} \text{a}_2 \) decreases below 50 mm Hg. Cells of the carotid body (glomus cells) are thought to be primarily dopaminergic neurons. Anti-dopaminergic drugs (such as phenothiazines), most general anesthetics, and bilateral carotid surgery abolish the peripheral ventilatory response to hypoxemia.

![Graph showing the relationship between \( \text{P} \text{a}_2 \) and minute ventilation at rest and with a normal \( \text{P} \text{a}_2 \).](image)

**Lung Receptors**
Impulses from these receptors are carried centrally by the vagus nerve. Stretch receptors are distributed in the smooth muscle of airways; they are responsible for inhibition of inspiration when the lung is inflated to excessive volumes (Hering–Breuer inflation reflex) and shortening of exhalation when the lung is deflated (deflation reflex). Stretch receptors normally play a minor role in humans. In fact, bilateral vagal nerve blocks have a minimal effect on the normal respiratory pattern.

Irritant receptors in the tracheobronchial mucosa react to noxious gases, smoke, dust, and cold gases; activation produces reflex increases in respiratory rate, bronchoconstriction, and coughing. Juxtacapillary (J) receptors are located in the interstitial space within alveolar walls; these receptors induce dyspnea in response to expansion of interstitial space volume and various chemical mediators following tissue damage.

Other Receptors

These include various muscle and joint receptors on pulmonary muscles and the chest wall. Input from these sources is probably important during exercise and in pathological conditions associated with decreased lung or chest compliance.

4. Effects of Anesthesia on the Control of Breathing

The most important effect of most general anesthetics on breathing is a tendency to promote hypoventilation. The mechanism is probably dual: central depression of the chemoreceptor and depression of external intercostal muscle activity. The magnitude of the hypoventilation is generally proportional to  anesthetic depth. With increasing depth of anesthesia, the slope of the PaCO₂/minute ventilation curve decreases, and the apneic threshold increases (Figure 23–27). This effect is at least partially reversed by surgical stimulation.

The peripheral response to hypoxemia is even more sensitive to anesthetics than the central CO$_2$ response and is nearly abolished by even subanesthetic doses of most inhalation agents (including nitrous oxide) and many intravenous agents.

**NONRESPIRATORY FUNCTIONS OF THE LUNG**

**Filtration & Reservoir Function**

**A. Filtration**

The unique in-series position of the pulmonary capillaries within the circulation allows them to act as a filter for debris in the bloodstream. The high content of heparin and plasminogen activator in the lungs facilitates the breakdown of entrapped fibrin debris. Although pulmonary capillaries have an average diameter of 7 μm, larger particles have been shown to pass through to the left heart.
B. Reservoir Function
The role of the pulmonary circulation as a reservoir for the systemic circulation was discussed earlier.

Metabolism
The lungs are metabolically very active organs. In addition to surfactant synthesis, pneumocytes account for a major portion of extrahepatic mixed-function oxidation. Neutrophils and macrophages in the lung produce $O_2$-derived free radicals in response to infection. The pulmonary endothelium metabolizes a variety of vasoactive compounds, including norepinephrine, serotonin, bradykinin, and a variety of prostaglandins and leukotrienes. Histamine and epinephrine are generally not metabolized in the lungs; in fact, the lungs can be a major site of histamine synthesis and release during allergic reactions.

The lungs are also responsible for converting angiotensin I to its physiologically active form, angiotensin II. The enzyme responsible, angiotensin-converting enzyme, is bound on the surface of the pulmonary endothelium.

CASE DISCUSSION

Unilaterally Diminished Breath Sounds During General Anesthesia
A 67-year-old man with carcinoma is undergoing laparoscopic hemicolectomy under general anesthesia. His history includes an old anterior myocardial infarction and heart failure treated with enalapril, carvedilol, furosemide, and spironolactone. Arterial and central venous catheters are placed preoperatively for monitoring during surgery. Following a smooth induction and an atraumatic intubation, anesthesia is maintained with 40% oxygen, sevoflurane, and vecuronium. Thirty minutes into the operation, the surgeon asks for steep Trendelenburg position to facilitate surgical exposure. The pulse oximeter, which had been reading 99% saturation, suddenly drops and remains at 93%. The pulse oximeter’s signal strength and waveform are unchanged. Auscultation of the lungs reveals diminished breath sounds over the left
What is the most likely explanation?

Unilaterally diminished breath sounds under anesthesia are most commonly caused by accidental placement or migration of the tracheal tube into one of the two main bronchi. As a result, only one lung is ventilated. Other causes of unilaterally diminished breath sounds (such as pneumothorax, a large mucus plug, lobar atelectasis, or undiagnosed bullae) are less easily diagnosed, but are fortunately less common during anesthesia.

The Trendelenburg (head-down) position typically causes the tip of the tracheal tube to advance 1 to 2 cm relative to the carina. In this case, the tube was apparently placed just above the carina with the patient in the supine position, but migrated into the right bronchus when the Trendelenburg position was imposed. The diagnosis is confirmed by drawing the tube back 1 to 2 cm at a time as the chest is auscultated. Breath sounds will become equal again when the tip of the tube reenters the trachea. Following initial placement, tracheal tubes should be routinely checked for correct positioning by auscultating the chest, ascertaining depth of tube insertion by the markings on the tube (normally 20–24 cm at the teeth for an adult), and feeling for the cuff in the suprasternal notch. Tube position relative to the carina can also be quickly confirmed with a flexible fiberoptic bronchoscope.

Are tracheal tubes just as likely to enter either main bronchus?

In most cases of unintentional bronchial intubation, the tracheal tube enters the right bronchus because the latter diverges away from the trachea at a less acute angle than does the left bronchus.

Why did hemoglobin saturation decrease?

Failure to ventilate one lung as it continues to be perfused creates a large intrapulmonary shunt. Venous admixture increases and tends to depress PaO₂ and hemoglobin saturation.

Does a saturation of 93% exclude bronchial intubation?

No; if both lungs continued to have equal blood flow, venous admixture should have theoretically increased to 50%, resulting in severe hypoxemia and very low hemoglobin saturation. Fortunately, hypoxic pulmonary
vasoconstriction is a powerful compensatory response that tends to reduce flow to the hypoxic lung and reduces the expected venous admixture. In fact, if the patient has been receiving a higher inspired O₂ concentration (50–100%), the drop in arterial tension may not be detectable by the pulse oximeter due to the characteristics of the normal hemoglobin saturation curve. For example, bronchial intubation in a patient inspiring 50% O₂ might drop PAO₂ from 250 mm Hg to 95 mm Hg; the resulting change in pulse oximeter readings (100–99 to 98–97) would hardly be noticeable.

Arterial and mixed venous blood gas tensions are obtained with the following results:

\[
\begin{align*}
\text{Pao}_2 &= 69 \text{ mm Hg;} \\
\text{Paco}_2 &= 42 \text{ mm Hg;} \\
\text{Sao}_2 &= 93\%; \\
\text{PvO}_2 &= 40 \text{ mm Hg;} \\
\text{SVo}_2 &= 75\%.
\end{align*}
\]

Hemoglobin concentration is 15 g/dL.

What is the calculated venous admixture?

In this case, \( Pc'O_2 = PAO_2 = (760 - 47 \times 0.4) - 42 = 243 \text{ mm Hg} \).

Therefore, \( Cc'O_2 = (15 \times 1.31 \times 1.0) + (243 \times 0.003) = 20.4 \text{ mL/dL} \).

\[
\begin{align*}
\text{Ca}_2 &= (15 \times 1.31 \times 0.93) + (69 \times 0.003) = 18.5 \text{ mL/dL} \\
\text{Cv–O}_2 &= (15 \times 1.31 \times 0.75) + (40 \times 0.003) = 14.8 \text{ mL/dL} \\
Q'S/Q'T &= (20.4 - 18.5)/(20.4 - 14.8) = 34\%
\end{align*}
\]

How does bronchial intubation affect arterial and end-tidal CO₂ tensions?

\( \text{Paco}_2 \) is typically not appreciably altered as long as the same minute ventilation is maintained (see One-Lung Ventilation, Chapter 25). Clinically, the \( \text{Paco}_2-P_{ETCO}_2 \) gradient often widens, possibly because of increased alveolar dead space (overdistention of the ventilated lung). Thus, \( P_{ETCO}_2 \) may decrease or remain unchanged.

Anesthesia for Patients with Respiratory Disease

**KEY CONCEPTS**

1. In a patient with an acute asthma attack, a normal or high $\text{PaCO}_2$ indicates that the patient can no longer maintain the work of breathing and is often a sign of impending respiratory failure. A pulsus paradoxus and electrocardiographic signs of right ventricular strain (ST-segment changes, right axis deviation, and right bundle-branch block) are also indicative of severe airway obstruction.

2. Asthmatic patients with active bronchospasm presenting for emergency surgery should be treated aggressively. Supplemental oxygen, aerosolized $\beta_2$-agonists, and intravenous glucocorticoids can dramatically improve lung function in a few hours.

3. Intraoperative bronchospasm is usually manifested as wheezing, increasing peak airway pressures (plateau pressure may remain unchanged), decreasing exhaled tidal volumes, or a slowly rising waveform on the capnograph.

4. Other causes can simulate bronchospasm: These include obstruction of the tracheal tube from kinking, secretions, or an overinflated balloon; bronchial intubation; active expiratory efforts (straining); pulmonary edema or embolism; and pneumothorax.

5. Chronic obstructive pulmonary disease (COPD) is currently defined as a disease state characterized by airflow limitation that is not fully reversible. The chronic airflow limitation of this disease is due to a mixture of small and large airway disease (chronic bronchitis/bronchiolitis) and parenchymal destruction (emphysema), with the representation of these two components varying from patient
Cessation of smoking is the long-term intervention that has been shown to reduce the rate of decline in lung function.

Preoperative interventions in patients with COPD aimed at correcting hypoxemia, relieving bronchospasm, mobilizing and reducing secretions, and treating infections may decrease the incidence of postoperative pulmonary complications. Patients at greatest risk of complications are those with preoperative pulmonary function measurements less than 50% of predicted.

Restrictive pulmonary diseases are characterized by decreased lung compliance. Lung volumes are typically reduced, with preservation of normal expiratory flow rates. Thus, both forced expiratory volume in the first second of exhalation (FEV₁) and forced vital capacity (FVC) are reduced, but the FEV₁/FVC ratio is normal.

Intraoperative pulmonary embolism usually presents as sudden cardiovascular collapse, hypoxemia, or bronchospasm. A decrease in end-tidal CO₂ concentration is also suggestive of pulmonary embolism, but is not specific.

The effects of preexisting pulmonary disease during anesthesia and in the postoperative period are predictable: Greater degrees of preoperative pulmonary impairment are associated with more marked intraoperative alterations in respiratory function and higher rates of postoperative pulmonary complications. Failure to recognize patients who are at increased risk may result in patients not receiving appropriate perioperative care. This chapter examines pulmonary risk in general and then reviews the anesthetic approach for patients with the most common types of respiratory disease.

**PULMONARY RISK FACTORS**

Certain risk factors (Table 24–1) may predispose patients to postoperative pulmonary complications. Atelectasis, pneumonia, pulmonary embolism, and respiratory failure are common following surgery, but the incidence varies widely (from 6% to 60%), depending on the patient population studied and the surgical procedures performed. In the general surgery population, the incidence of postoperative pulmonary complications ranges from 2.0% to 5.6%. The two strongest predictors of complications seem to be operative site and a history of
dyspnea, the latter of which correlates with the degree of preexisting pulmonary
disease.

**TABLE 24–1** Risk factors for postoperative pulmonary complications.¹

<sup>2</sup>Within each evidence category, risk factors are listed according to strength of evidence, with the first factor listed having the strongest evidence.

<sup>3</sup>ASA, American Society of Anesthesiologists.

<sup>4</sup>Subsequent evidence indicates that this is a probable risk factor.
The association between smoking and respiratory disease is well established; abnormalities in maximal midexpiratory flow (MMEF) rates are often demonstrable well before symptoms of COPD appear. Most patients who smoke will not have pulmonary function tests (PFTs) performed preoperatively; therefore it is best to assume that such patients have some degree of pulmonary compromise. Even in otherwise normal individuals, advancing age is associated with an increasing prevalence of pulmonary disease and an increase in closing capacity. Obesity per se is not considered to increase the incidence of postoperative pulmonary complications. However, obstructive sleep apnea does contribute to adverse perioperative outcomes.

Thoracic and upper abdominal surgical procedures can have marked effects on pulmonary function. Operations near the diaphragm often result in diaphragmatic dysfunction and a restrictive ventilatory defect (see later discussion). Upper abdominal procedures significantly (>30%) decrease functional residual capacity (FRC). This effect is maximal on the first postoperative day and usually lasts 7 to 10 days. Rapid shallow breathing with an ineffective cough caused by pain (splinting), a decrease in the number of sighs, and impaired mucociliary clearance leads to microatelectasis and loss of lung volume. Subsequent development of ventilation/perfusion mismatch (shunt) produces hypoxemia. Residual anesthetic effects, recumbent position, sedation from opioids, abdominal distention, and restrictive dressings may also be contributory. Complete relief of pain with regional anesthesia can decrease, but does not completely reverse, these abnormalities. Persistent microatelectasis and retention of secretions favor the development of postoperative pneumonia.

Although many adverse effects of general anesthesia on pulmonary function have been described, the superiority of regional over general anesthesia in patients with pulmonary impairment is not firmly established. Nonetheless, enhanced recovery protocols routinely incorporate regional techniques where possible to provide multimodal, opioidsparing postoperative analgesia.

When patients with a history of dyspnea present without the benefit of a previous workup, the differential diagnosis can be quite broad and may include both primary pulmonary and cardiac pathologies. Diagnostic approaches to evaluating such patients are summarized in Figure 24–1.
Obstructive Pulmonary Disease

Obstructive and restrictive diseases are the two most common abnormal patterns as determined by PFTs. The former are by far the more common. Obstructive diseases include asthma, emphysema, chronic bronchitis, cystic fibrosis, bronchiectasis, and bronchiolitis. The primary characteristic of these disorders is resistance to airflow. An MMEF of less than 70% (forced expiratory flow [FEF\textsubscript{25–75%}]) is often the only abnormality early in the course of these disorders. Values for FEF\textsubscript{25–75%} in adult males and females are normally greater than 2.0 L/s and 1.6 L/s, respectively. As the disease progresses, both forced expiratory
volume in the first second of exhalation (FEV₁) and the FEV₁/FVC (forced vital capacity) ratio are less than 70% of the predicted values.

Elevated airway resistance and air trapping increase the work of breathing; respiratory gas exchange is impaired because of ventilation/perfusion (V̇/Q̇) imbalance. The predominance of expiratory airflow resistance results in air trapping; residual volume and total lung capacity (TLC) increase. Wheezing is a common finding and represents turbulent airflow. It is often absent with mild obstruction that may be manifested initially only by prolonged exhalation. Progressive obstruction typically results first in expiratory wheezing only, and then in both inspiratory and expiratory wheezing. With marked obstruction, wheezing may be absent when airflow has nearly ceased.

**ASTHMA**

**Preoperative Considerations**

Asthma is a common disorder, affecting 5% to 7% of the population. Its primary characteristic is airway (bronchiolar) inflammation and hyperreactivity in response to a variety of stimuli. Clinically, asthma is manifested by episodic attacks of dyspnea, cough, and wheezing. Airway obstruction, which is generally reversible, is the result of bronchial smooth muscle constriction, edema, and increased secretions. Classically, the obstruction is precipitated by a variety of airborne substances, including pollens, animal dander, dusts, pollutants, and various chemicals. Some patients also develop bronchospasm following ingestion of aspirin, nonsteroidal antiinflammatory agents, sulfites, or other compounds. Exercise, cold air, emotional excitement, and viral infections also precipitate bronchospasm in many patients. Asthma is classified as acute or chronic. Chronic asthma is further classified as intermittent (mild) and mild, moderate, and severe persistent disease.

The terms *extrinsic* (allergic) asthma (attacks related to environmental exposures) and *intrinsic* (idiosyncratic) asthma (attacks usually occurring without provocation) were used in the past, but these classifications were imperfect; many patients show features of both forms. Moreover, overlap with chronic bronchitis (see later discussion) is common.

**A. Pathophysiology**

The pathophysiology of asthma involves the local release of various chemical mediators in the airway, and, possibly, overactivity of the parasympathetic
nervous system. Inhaled substances can initiate bronchospasm through both specific and nonspecific immune mechanisms by degranulating bronchial mast cells. In classic allergic asthma, antigen binding to immunoglobulin E (IgE) on the surface of mast cells causes degranulation. Bronchoconstriction is the result of the subsequent release of histamine; bradykinin; leukotrienes C, D, and E; platelet-activating factor; prostaglandins (PG) E$_2$, F$_2$α, and D$_2$; and neutrophil and eosinophil chemotactic factors. The parasympathetic nervous system plays a major role in maintaining normal bronchial tone; a normal diurnal variation in tone is recognized in most individuals, with peak airway resistance occurring early in the morning (at about 6:00 AM). Vagal afferents in the bronchi are sensitive to histamine and multiple noxious stimuli, including cold air, inhaled irritants, and instrumentation (eg, tracheal intubation). Reflex vagal activation results in bronchoconstriction, which is mediated by an increase in intracellular cyclic guanosine monophosphate (cGMP).

During an asthma attack, bronchoconstriction, mucosal edema, and secretions increase resistance to gas flow at all levels of the lower airways. As an attack resolves, airway resistance normalizes first in the larger airways (mainstem, lobar, segmental, and subsegmental bronchi), and then in more peripheral airways. Consequently, expiratory flow rates are initially decreased throughout an entire forced exhalation, but during resolution of the attack, the expiratory flow rate is reduced only at low lung volumes. TLC, residual volume (RV), and FRC are all increased. In acutely ill patients, RV and FRC are often increased by more than 400% and 100%, respectively. Prolonged or severe attacks markedly increase the work of breathing and can fatigue respiratory muscles. The number of alveolar units with low ($\bar{V}/\bar{Q}$) ratios increases, resulting in hypoxemia. Tachypnea is likely and typically produces hypocapnia. A normal or high $\text{PaCO}_2$ indicates that the patient can no longer maintain the work of breathing and is often a sign of impending respiratory failure. A pulsus paradoxus and electrocardiographic signs of right ventricular strain (ST-segment changes, right axis deviation, and right bundle-branch block) are also indicative of severe airway obstruction.

**B. Treatment**

Drugs used to treat asthma include β-adrenergic agonists, methylxanthines, glucocorticoids, anticholinergics, leukotriene modifiers, and mast-cell–stabilizing agents. Although devoid of any bronchodilating properties, cromolyn sodium and nedocromil are effective in preventing bronchospasm by blocking the degranulation of mast cells.
Sympathomimetic agents (eg, albuterol) are the most commonly used for acute exacerbations. They produce bronchodilation via β₂-agonist activity. Activation of β₂-adrenergic receptors on bronchiolar smooth muscle stimulates the activity of adenylate cyclase, which results in the formation of intracellular cyclic adenosine monophosphate (cAMP). These agents are usually administered via a metered-dose inhaler or by aerosol. Use of more selective β₂-agonists, such as terbutaline or albuterol, may decrease the incidence of undesirable β₁ cardiac effects, but are often not particularly selective in high doses.

Traditionally, methylxanthines are thought to produce bronchodilation by inhibiting phosphodiesterase, the enzyme responsible for the breakdown of cAMP. Their pulmonary effects seem much more complex and include catecholamine release, blockade of histamine release, and diaphragmatic stimulation. Unfortunately, theophylline has a narrow therapeutic range; therapeutic blood levels are considered to be 10 to 20 mcg/mL. Lower levels, however, may be effective. Aminophylline is the only available intravenous theophylline preparation.

Glucocorticoids are used for both acute treatment and maintenance therapy of patients with asthma because of their antiinflammatory and membranestabilizing effects. Beclomethasone, triamcinolone, fluticasone, and budesonide are synthetic steroids commonly used in metered-dose inhalers for maintenance therapy. Although they are associated with a low incidence of undesirable systemic effects, inhaled administration does not necessarily prevent adrenal suppression. Intravenous hydrocortisone or methylprednisolone is used acutely for severe attacks, followed by tapering doses of oral prednisone. Glucocorticoids usually require several hours to become effective.

Anticholinergic agents produce bronchodilation through their antimuscarinic action and may block reflex bronchoconstriction. Ipratropium, a congener of atropine that can be given by a metered-dose inhaler or aerosol, is a moderately effective bronchodilator without appreciable systemic anticholinergic effects.

**Anesthetic Considerations**

**A. Preoperative Management**

The emphasis in evaluating patients with asthma should be on determining the severity and recent course of the disease, as well as on ascertaining whether the patient is in optimal condition. Patients with poorly controlled asthma or wheezing at the time of anesthesia induction have a greater risk of perioperative
complications. Conversely, well-controlled asthma has not been shown to be a risk factor for intraoperative or postoperative complications. A thorough history and physical examination are of critical importance. The patient should have no or minimal dyspnea, wheezing, or cough. Complete resolution of recent exacerbations should be confirmed by chest auscultation. Patients with frequent or chronic bronchospasm should be placed on an optimal bronchodilating regimen. A chest radiograph identifies air trapping; hyperinflation results in a flattened diaphragm, a small appearing heart, and hyperlucent lung fields. PFTs—particularly expiratory airflow measurements such as FEV₁, FEV₁/FVC, FEF₂₅₋₇₅%, and peak expiratory flow rate—help in assessing the severity of airway obstruction and reversibility after bronchodilator treatment. Comparisons with previous measurements are invaluable.

Asthmatic patients with active bronchospasm presenting for emergency surgery should be treated aggressively. Supplemental oxygen, aerosolized β₂-agonists, and intravenous glucocorticoids can dramatically improve lung function in a few hours. Arterial blood gases may be useful in evaluating severity and adequacy of treatment. Hypoxemia and hypercapnia are typical of moderate or severe disease; even slight hypercapnia is indicative of severe air trapping and may be a sign of impending respiratory failure.

Anticholinergic agents are not customarily given unless very copious secretions are present or if ketamine is to be used for induction of anesthesia. In typical intramuscular doses, anticholinergics are not effective in preventing reflex bronchospasm following intubation. The use of an H₂-blocking agent (such as cimetidine, ranitidine, or famotidine) is theoretically detrimental, since H₂-receptor activation normally produces bronchodilation; in the event of histamine release, unopposed H₁ activation with H₂ blockade may accentuate bronchoconstriction.

Bronchodilators should be continued up to the time of surgery; these include β-agonists, inhaled glucocorticoids, leukotriene modifiers, mast-cell stabilizers, theophyllines, and anticholinergics. Patients who receive chronic glucocorticoid therapy with more than 5 mg/d of prednisone (or its equivalent) should receive a graduated supplementation schedule based on the severity of the illness and complexity of the surgical procedure. Supplemental doses should be tapered to baseline within 1 to 2 days.

**B. Intraoperative Management**
The most critical time for asthmatic patients undergoing anesthesia is during
instrumentation of the airway. General anesthesia with noninvasive ventilation or regional anesthesia will circumvent this problem, but neither eliminates the possibility of bronchospasm. In fact, some clinicians believe that high spinal or epidural anesthesia may aggravate bronchoconstriction by blocking sympathetic tone to the lower airways (T1–T4) and allowing unopposed parasympathetic activity. Pain, emotional stress, or stimulation during light general anesthesia can precipitate bronchospasm. Drugs often associated with histamine release (eg, atracurium, morphine, and meperidine) should be avoided or given very slowly when used.

The choice of induction agent is less important if adequate depth of anesthesia is achieved before intubation or surgical stimulation. Thiopental may occasionally induce bronchospasm as a result of exaggerated histamine release. Propofol and etomidate are suitable induction agents; propofol may also produce bronchodilation. Ketamine has bronchodilating properties and is a good choice for patients with asthma who are also hemodynamically unstable. Ketamine should probably not be used in patients with high theophylline levels, as the combined actions of the two drugs might precipitate seizure activity. Sevoflurane usually provides the smoothest inhalation induction with bronchodilation in asthmatics. Isoflurane and desflurane are more pungent and may result in cough, laryngospasm, and bronchospasm during inhalation induction.

Reflex bronchospasm can be blunted before intubation by an additional dose of the induction agent, ventilating the patient with a 2 to 3 minimum alveolar concentration (MAC) of a volatile agent for 5 min, or administering intravenous or intratracheal lidocaine (1–2 mg/kg). Note that intratracheal lidocaine itself can initiate bronchospasm if an inadequate dose of induction agent has been used. Administration of an anticholinergic agent may block reflex bronchospasm, but causes excessive tachycardia. Although succinylcholine may on occasion induce marked histamine release, it can generally be safely used in asthmatic patients. In the absence of capnography, confirmation of correct tracheal placement by chest auscultation can be difficult in the presence of marked bronchospasm.

Volatile anesthetics are most often used for maintenance of anesthesia to take advantage of their potent bronchodilating properties. Ventilation should incorporate warmed humidified gases whenever possible. Airflow obstruction during expiration is apparent on capnography as a delayed rise of the end-tidal CO₂ value (Figure 24–2); the severity of obstruction is generally inversely related to the rate of rise in end-tidal CO₂. Severe bronchospasm is manifested by rising peak inspiratory pressures and incomplete exhalation. Tidal volumes of 6 mL/kg, with prolongation of the expiratory time, may allow more uniform
distribution of gas flow to both lungs and may help avoid air trapping. The PacO₂ may increase, which is acceptable if there is no contraindication from a cardiovascular or neurologic perspective.

**FIGURE 24–2** Capnograph of a patient with expiratory airway obstruction.

Intraoperative bronchospasm is usually manifested as wheezing, increasing peak airway pressures (plateau pressure may remain unchanged), decreasing exhaled tidal volumes, or a slowly rising waveform on the capnograph. Other causes can simulate bronchospasm: These include obstruction of the tracheal tube from kinking, secretions, or an overinflated balloon; bronchial intubation; active expiratory efforts (straining); pulmonary edema or embolism; and pneumothorax. Bronchospasm should be treated by increasing the concentration of the volatile agent and administering an aerosolized bronchodilator. Infusion of low-dose epinephrine may be needed if bronchospasm is refractory to other interventions.

Intravenous hydrocortisone can be given, particularly in patients with a history of responding to glucocorticoid therapy. At the completion of surgery, the patient should ideally be free of wheezing. Reversal of nondepolarizing neuromuscular blocking agents with anticholinesterase agents generally does not precipitate bronchoconstriction if preceded by the appropriate dose of an anticholinergic agent. Sugammadex avoids the issue of increasing acetylcholine concentration; however, cases of allergic reaction to sugammadex have been reported. Deep extubation (before the return of airway reflexes) reduces the risk of bronchospasm on emergence. Lidocaine as a bolus (1.5–2 mg/kg) may help to
obtund airway reflexes upon emergence.

**CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)**

**Preoperative Considerations**

COPD is the most common pulmonary disorder encountered in anesthetic practice, and its prevalence increases with age. The disorder is strongly associated with cigarette smoking and has a male predominance. COPD is currently defined as a disease state characterized by airflow limitation that is not fully reversible. The chronic airflow limitation of this disease is due to a mixture of small and large airway disease (chronic bronchitis/bronchiolitis) and parenchymal destruction (emphysema), with representation of these two components varying from patient to patient.

Most patients with COPD are asymptomatic or only mildly symptomatic, but show expiratory airflow obstruction upon PFTs. In many patients, the obstruction has an element of reversibility, presumably from bronchospasm (as shown by improvement in response to administration of a bronchodilator). With advancing disease, maldistribution of both ventilation and pulmonary blood flow results in areas of low ($\dot{V}/\dot{Q}$) ratios (intrapulmonary shunt), as well as areas of high ($\dot{V}/\dot{Q}$) ratios (dead space).

**A. Chronic Bronchitis**

The clinical diagnosis of chronic bronchitis is defined by the presence of a productive cough on most days of 3 consecutive months for at least 2 consecutive years. In addition to cigarette smoking, exposure to air pollutants, occupational exposure to dusts, recurrent pulmonary infections, and familial factors may be responsible. Secretions from hypertrophied bronchial mucous glands and mucosal edema from inflammation of the airways produce airflow obstruction. Recurrent pulmonary infections (viral and bacterial) are common and often associated with bronchospasm. RV is increased, but TLC is often normal. Intrapulmonary shunting and hypoxemia are common.

In patients with COPD, chronic hypoxemia leads to erythrocytosis, pulmonary hypertension, and eventually right ventricular failure (cor pulmonale); this combination of findings is often referred to as the “blue bloater” syndrome, but less than 5% of patients with COPD fit this description. (Table
In the course of disease progression, patients gradually develop chronic \( \text{CO}_2 \) retention; the normal ventilatory drive becomes less sensitive to arterial \( \text{CO}_2 \) tension and may be depressed by oxygen administration (see below).

**B. Emphysema**

Emphysema is a pathological disorder characterized by irreversible enlargement of the airways distal to terminal bronchioles and destruction of alveolar septa. The diagnosis can be reliably made with computed tomography (CT) of the chest. Mild apical emphysematous changes are a normal, clinically insignificant consequence of aging. Significant emphysema is more frequently related to cigarette smoking. Less commonly, emphysema occurs at an early age and is associated with a homozygous deficiency of \( \alpha_1 \)-antitrypsin. This is a protease inhibitor that prevents excessive activity of proteolytic enzymes (mainly elastase) in the lungs; these enzymes are produced by pulmonary neutrophils and macrophages in response to infection and pollutants. Emphysema associated
with smoking may similarly be due to a relative imbalance between protease and antiprotease activities in susceptible individuals.

Emphysema may exist in a centrilobular or panlobular form. The centrilobular (or centriacinar) form results from dilation or destruction of the respiratory bronchioles, is more closely associated with tobacco smoking, and has predominantly an upper lobe distribution. The panlobular (or panacinar) form results in a more even dilation and destruction of the entire acinus, is associated with α₁-antitrypsin deficiency, and has predominantly a lower lobe distribution.

Loss of the elastic recoil that normally supports small airways by radial traction allows premature collapse during exhalation, leading to expiratory flow limitation with air trapping and hyperinflation (see Table 24–2). Patients characteristically have increases in RV, FRC, TLC, and the RV/TLC ratio.

Disruption of the alveolar–capillary structure and loss of the acinar structure lead to decreased diffusion lung capacity, \( \dot{V}/\dot{Q} \) mismatch, and impairment of gas exchange. Also, normal parenchyma may become compressed by the hyperinflated portions of the lung, resulting in a further increase in the \( \dot{V}/\dot{Q} \) mismatch. Due to the higher diffusibility of CO₂, its elimination is well preserved until \( \dot{V}/\dot{Q} \) abnormalities become severe. Chronic CO₂ retention occurs slowly and generally results in a compensated respiratory acidosis on blood gas analysis. Arterial oxygen tension is usually normal or slightly reduced. Acute CO₂ retention is a sign of impending respiratory failure.

Destruction of pulmonary capillaries in the alveolar septa leads to the development of mild to moderate pulmonary hypertension. When dyspneic, patients with emphysema often purse their lips to delay closure of the small airways, which accounts for the term “pink puffers” that is often used. However, as mentioned above, most patients diagnosed with COPD have a combination of bronchitis and emphysema.

C. Treatment

Treatment for COPD is primarily supportive. Cessation of smoking is the long-term intervention that has been shown to reduce the rate of decline in lung function. Various guidelines have been suggested to aid in the primary medical management of patients with COPD. In general, spirometry is employed to assess the severity of airflow reduction characteristic of obstruction, and whether there is a response to bronchodilators. For bronchodilator-responsive patients,
short-acting bronchodilators are recommended when \( \text{FEV}_1 \) is greater than 80% of predicted and longer-acting bronchodilators and inhaled corticosteroids are suggested as \( \text{FEV}_1 \) and patient symptoms worsen. Inhaled \( \beta_2 \)-adrenergic agonists, glucocorticoids, and ipratropium are routinely employed. Hypoxemia is treated with supplemental oxygen. Patients with chronic hypoxemia (\( \text{PaO}_2 <55 \) mm Hg) and pulmonary hypertension require low-flow oxygen therapy (1–2 L/min). \( \text{CO}_2 \) retention may be exacerbated in patients with reduced hypoxic ventilatory drive. Consequently, oxygen therapy is targeted to a hemoglobin oxygen saturation of 90%.

Pulmonary rehabilitation may improve the functional status of the patient by improving physical symptoms and exercise capacity.

**Anesthetic Considerations**

**A. Preoperative Management**

Patients with COPD should be prepared prior to elective surgical procedures in the same way as patients with asthma (see earlier discussion). They should be questioned about recent changes in dyspnea, sputum, and wheezing. Patients with an \( \text{FEV}_1 \) less than 50% of predicted (1.2–1.5 L) usually have dyspnea on exertion, whereas those with an \( \text{FEV}_1 \) less than 25% (<1 L in men) typically have dyspnea with minimal activity. The latter finding, in patients with predominantly chronic bronchitis, is also often associated with \( \text{CO}_2 \) retention and pulmonary hypertension. PFTs, chest radiographs, and arterial blood gas measurements, if available, should be reviewed carefully. The presence of bullous changes on the radiograph should be noted. Many patients have concomitant cardiac disease and should also receive a careful cardiovascular evaluation.

In contrast to asthma, only limited improvement in respiratory function may be seen after a short period of intensive preoperative preparation. Nonetheless, preoperative interventions in patients with COPD aimed at correcting hypoxemia, relieving bronchospasm, mobilizing and reducing secretions, and treating infections may decrease the incidence of postoperative pulmonary complications. Patients at greatest risk of complications are those with preoperative pulmonary function measurements less than 50% of predicted. The possibility that postoperative ventilation may be necessary in high-risk patients should be discussed with both the patient and the surgeon.

**Smoking should be discontinued for at least 6 to 8 weeks before the**
operation to decrease secretions and to reduce pulmonary complications. Cigarette smoking increases mucus production and decreases clearance. Both gaseous and particulate phases of cigarette smoke can deplete glutathione and vitamin C and may promote oxidative injury to tissues. Cessation of smoking for as little as 24 h has theoretical beneficial effects on the oxygen-carrying capacity of hemoglobin; acute inhalation of cigarette smoke releases carbon monoxide, which increases carboxyhemoglobin levels, as well as nitric oxide, and nitrogen dioxide, which can lead to formation of methemoglobin.

Long-acting bronchodilators and mucolytics should be continued, including on the day of surgery. COPD exacerbations should be treated aggressively.

Preoperative chest physiotherapy and lung expansion interventions with incentive spirometry, deep breathing exercises, cough, chest percussion, and postural drainage may be beneficial in decreasing postoperative pulmonary complications.

B. Intraoperative Management

Although regional anesthesia is often considered preferable to general anesthesia, high spinal or epidural anesthesia can decrease lung volumes, restrict the use of accessory respiratory muscles, and produce an ineffective cough, leading to dyspnea and retention of secretions. Loss of proprioception from the chest and positions such as lithotomy or lateral decubitus may accentuate dyspnea in awake patients. Concerns about hemidiaphragmatic paralysis may make interscalene blocks a less attractive option in the lung disease patient.

Preoxygenation prior to induction of general anesthesia prevents the rapid oxygen desaturation often seen in these patients. The selection of anesthetic agents and general intraoperative management must be tailored to the specific needs and goals of every patient. Unfortunately, the use of bronchodilating anesthetics improves only the reversible component of airflow obstruction; significant expiratory obstruction may still present, even under deep anesthesia. Expiratory airflow limitation, especially under positive pressure ventilation, may lead to air trapping, dynamic hyperinflation, and elevated intrinsic positive end-expiratory pressure (iPEEP). Dynamic hyperinflation may result in volutrauma to the lungs, hemodynamic instability, hypercapnia, and acidosis. Interventions to mitigate air trapping include: (1) allowing more time to exhale by decreasing both the respiratory rate and inspiratory/expiratory (I:E) ratio; (2) allowing permissive hypercapnia; (3) applying low levels of extrinsic PEEP; and (4) aggressively treating bronchospasm.

Intraoperative causes of hypotension in these patients include (in addition to
the usual “suspects”) pneumothorax and right heart failure due to hypercapnia and acidosis. A pneumothorax may manifest as hypoxemia, increased peak airway pressures, decreasing tidal volumes, and abrupt cardiovascular collapse unresponsive to fluid and vasopressor administration.

Nitrous oxide should be avoided in patients with bullae and pulmonary hypertension. Inhibition of hypoxic pulmonary vasoconstriction by inhalation anesthetics is usually not clinically apparent at usual doses. However, due to increased dead space, patients with severe COPD have unpredictable uptake and distribution of inhalational agents, and the end-tidal volatile anesthetic concentration is inaccurate.

Although pulse oximetry accurately detects significant arterial desaturation, direct measurement of arterial oxygen tensions may be necessary to detect more subtle changes in intrapulmonary shunting. Moreover, arterial CO₂ measurements can guide ventilation because increased dead space widens the normal arterial-to-end-tidal CO₂ gradient. Moderate hypercapnia with a PaCO₂ of up to 70 mm Hg may be well tolerated in the short term, assuming a reasonable cardiovascular reserve. Hemodynamic support with inotropic agents may be required in more compromised patients. Hemodynamic monitoring should be dictated by any underlying cardiac dysfunction, as well as the extent of the surgery and the established enhanced recovery protocols in your unit. Successful extubation at the end of the procedure depends on multiple factors: adequate pain control, reversal of neuromuscular blockade, absence of significant bronchospasm and secretions, absence of significant hypercapnia and acidosis, and absence of respiratory depression due to residual anesthetic agents. Patients with an FEV₁ below 50% may require a period of postoperative ventilation, particularly following upper abdominal and thoracic operations.

---

**Restrictive Pulmonary Disease**

Restrictive pulmonary diseases are characterized by decreased lung compliance. Lung volumes are typically reduced, with preservation of normal expiratory flow rates. Thus, both FEV₁ and FVC are reduced, but the FEV₁/FVC ratio is normal.

Restrictive pulmonary diseases include many acute and chronic intrinsic pulmonary disorders, as well as extrinsic (extrapulmonary) disorders involving the pleura, chest wall, diaphragm, or neuromuscular function. Reduced lung compliance increases the work of breathing, resulting in a characteristic rapid,
but shallow, breathing pattern. Respiratory gas exchange is usually maintained until the disease process is advanced.

**ACUTE INTRINSIC PULMONARY DISORDERS**

Acute intrinsic pulmonary disorders include pulmonary edema (including the acute respiratory distress syndrome [ARDS]), infectious pneumonia, and aspiration pneumonitis.

**Preoperative Considerations**

Reduced lung compliance in these disorders is primarily due to an increase in extravascular lung water, from an increase in either pulmonary capillary pressure or pulmonary capillary permeability. Increased pressure occurs with left ventricular failure, whereas fluid overload and increased permeability are present with ARDS. Localized or generalized increases in permeability also occur following aspiration or infectious pneumonitis.

**Anesthetic Considerations**

**A. Preoperative Management**

Patients with acute pulmonary disease should be spared elective surgery. In preparation for emergency procedures, oxygenation and ventilation should be optimized preoperatively to the greatest extent possible. Fluid overload should be treated with diuretics; heart failure may also require treatment. Large pleural effusions may require drainage before anesthesia. Similarly, massive abdominal distention should be relieved by nasogastric suction or drainage of ascites. Persistent hypoxemia may require mechanical ventilation.

**B. Intraoperative Management**

Selection of anesthetic agents should be tailored to each patient. Surgical patients with acute pulmonary disorders, such as ARDS, cardiogenic pulmonary edema, or pneumonia, are critically ill; anesthetic management should be a continuation of their preoperative intensive care. Increased inspired oxygen concentrations and PEEP may be required. The decreased lung compliance results in high peak inspiratory pressures during positive-pressure ventilation and increases the risk of barotrauma and volutrauma. Tidal volumes for these patients should be reduced to 4 to 6 mL/kg, with a compensatory increase in the
ventilatory rate (14–18 breaths/min), even if the result is an increase in end-tidal CO₂. Airway pressure should generally not exceed 30 cm H₂O. Right ventricular function may be challenged due to increases in pulmonary vascular resistance secondary to permissive hypercapnia.

**CHRONIC INTRINSIC PULMONARY DISORDERS**

Chronic intrinsic pulmonary disorders are also often referred to as interstitial lung diseases. Regardless of etiology, the disease process is generally characterized by an insidious onset, chronic inflammation of alveolar walls and perialveolar tissue, and progressive pulmonary fibrosis. The latter can eventually interfere with gas exchange and ventilatory function. The inflammatory process may be primarily confined to the lungs or may be part of a generalized multiorgan process. Causes include hypersensitivity pneumonitis from occupational and environmental pollutants, drug toxicity (bleomycin and nitrofurantoin), radiation pneumonitis, idiopathic pulmonary fibrosis, autoimmune diseases, and sarcoidosis. Chronic pulmonary aspiration, oxygen toxicity, and severe ARDS can also produce chronic fibrosis.

**Preoperative Considerations**

Patients typically present with dyspnea on exertion and sometimes a nonproductive cough. Symptoms of cor pulmonale are present only with advanced disease. Physical examination may reveal fine (dry) crackles over the lung bases, and, in late stages, evidence of right ventricular failure. The chest radiograph progresses from a “ground-glass” appearance to prominent reticulonodular markings, and, finally, to a “honeycomb” appearance. Arterial blood gases usually show mild hypoxemia with normocarbia. PFTs are typical of a restrictive ventilatory defect (see above), and carbon monoxide diffusing capacity is reduced.

Treatment is directed at abating the disease process and preventing further exposure to the causative agent (if known). If the patient has chronic hypoxemia, oxygen therapy may be started to prevent, or attenuate, right ventricular failure.

**Anesthetic Considerations**

**A. Preoperative Management**
Preoperative evaluation should focus on the underlying disease process and the degree of pulmonary impairment. A history of dyspnea on exertion (or at rest) should be evaluated further with PFTs and arterial blood gas analysis. A vital capacity of less than 15 mL/kg is indicative of severe dysfunction (normal is >70 mL/kg). A chest radiograph is helpful in assessing disease severity.

B. Intraoperative Management
The management of these patients is complicated by their predisposition to hypoxemia and their need for controlled ventilation to ensure optimum gas exchange. The reduction in FRC (and oxygen stores) predisposes these patients to rapid hypoxemia following induction of anesthesia. Because these patients may be more susceptible to oxygen-induced toxicity, particularly patients who have received bleomycin, the inspired fractional concentration of oxygen should be kept to the minimum concentration compatible with acceptable oxygenation (SpO₂ of >90%). Protective ventilation strategies employed in ventilated patients in the intensive care unit should be continued through to the operating room. Nitric oxide may be used to reduce pulmonary vascular resistance and reduce the work of the right ventricle.

Extracorporeal membrane oxygenation (ECMO) is increasingly used in the management of acute respiratory failure. Following anticoagulation, blood is drained from venous cannulae and delivered to a membrane oxygenator. Oxygenated blood can then either be returned either to the venous system, if cardiac function is preserved, or pumped into the arterial circulation, bypassing the heart and lungs. Consequently, ECMO can provide transient support for both cardiac and pulmonary failure.

EXTRINSIC RESTRICTIVE PULMONARY DISORDERS
Extrinsic restrictive pulmonary disorders alter gas exchange by interfering with normal lung expansion. They include pleural effusions, pneumothorax, mediastinal masses, kyphoscoliosis, pectus excavatum, neuromuscular disorders, and increased intraabdominal pressure from ascites, pregnancy, or bleeding. Marked obesity also produces a restrictive ventilatory defect. Anesthetic considerations are similar to those discussed for intrinsic restrictive disorders.

Pulmonary Embolism
Preoperative Considerations

Pulmonary embolism results from the entry of blood clots, fat, tumor cells, air, amniotic fluid, or foreign material into the venous system. Clots from the lower extremities, pelvic veins, or, less commonly, the right side of the heart are usually responsible. Venous stasis or hypercoagulability is often contributory (Table 24–3). Pulmonary embolism can also occur intraoperatively.

A. Pathophysiology

Embolic occlusions in the pulmonary circulation increase dead space, and, if minute ventilation does not change, this increase in dead space should theoretically increase PaCO₂. However, in practice, hypoxemia is more often seen. Pulmonary emboli acutely increase pulmonary vascular resistance by reducing the cross-sectional area of the pulmonary vasculature, causing reflex and humoral vasoconstriction. Localized or generalized reflex bronchoconstriction further increases areas with low (V/Q) ratios. The net effect is an increase in (V/Q) mismatch and hypoxemia. The affected area loses its surfactant within hours and may become atelectatic within 24 to 48 h.
Pulmonary infarction occurs if the embolus involves a large vessel and collateral blood flow from the bronchial circulation is insufficient for that part of the lung (incidence <10%). In previously healthy persons, occlusion of more than 50% of the pulmonary circulation (massive pulmonary embolism) is necessary before sustained pulmonary hypertension is seen. Patients with preexisting cardiac or pulmonary disease can develop acute pulmonary hypertension with occlusions of lesser magnitude. A sustained increase in right ventricular afterload can precipitate acute right ventricular failure and hemodynamic collapse. If the patient survives acute pulmonary thromboembolism, the thrombus usually begins to resolve within 1 to 2 weeks.

**B. Diagnosis**

Clinical manifestations of pulmonary embolism include sudden tachypnea, dyspnea, chest pain, or hemoptysis. The latter generally implies lung infarction. Symptoms are often absent or mild and nonspecific unless massive embolism has occurred. Wheezing may be present on auscultation. Arterial blood gas analysis typically shows mild hypoxemia with respiratory alkalosis (the latter due to an increase in ventilation). The chest radiograph is commonly normal, but may show an area of oligemia (radiolucency), a wedge-shaped density with an infarct, atelectasis with an elevated diaphragm, or an asymmetrically enlarged proximal pulmonary artery with acute pulmonary hypertension. Cardiac signs include tachycardia and wide fixed splitting of the S₂ heart sound; hypotension with elevated central venous pressure is usually indicative of right ventricular failure. The electrocardiogram frequently shows tachycardia and may show signs of acute cor pulmonale, such as new right axis deviation, right bundle-branch block, and tall peaked T waves. Ultrasound studies of the lower extremities also may be helpful in demonstrating deep venous thrombosis (DVT). The diagnosis of embolism is more difficult to make intraoperatively (see below).

Computed tomography angiography is performed emergently when pulmonary embolism is suspected. Echocardiography can also be used to assist in the diagnosis under emergent conditions in unstable patients perioperatively. Right ventricular overload is seen following significant pulmonary embolism. Sometimes clot can be seen in the right heart and pulmonary artery confirming the diagnosis. At other times, only the signs of right ventricular overload are seen (eg, tricuspid regurgitation, right ventricular dilation). The left ventricle may be relatively under-loaded secondary to the inadequate delivery of blood across the pulmonary circulation as a consequence of the embolus.
C. Treatment and Prevention
The best treatment for perioperative pulmonary embolism is prevention. Various regimens for DVT prophylaxis are employed, including heparin (unfractionated heparin 5000 U subcutaneously every 12 h begun preoperatively or immediately postoperatively in high-risk patients), enoxaparin, fondaparinux, and, most importantly, early ambulation after surgery. Patients at risk for thrombophilia are treated with warfarin. Newer anticoagulants such as factor Xa inhibitors (eg, rivaroxaban, apixaban) and the direct thrombin inhibitor dabigatran will likely assume a greater role in DVT prophylaxis. The use of intermittent pneumatic compression of the legs may decrease the incidence of venous thrombosis in the legs, but not in the pelvis or the heart.

After a pulmonary embolism, parenteral anticoagulation prevents the formation of new blood clots or the extension of existing clots. Low-molecular-weight heparin (LMWH) or fondaparinux are now preferred over intravenous unfractionated heparin for initial anticoagulation following a pulmonary embolism for most patients. All patients should start warfarin therapy concurrent with starting parenteral therapy, and the two should overlap for a minimum of 5 days. The international normalized ratio should also be within the therapeutic range (>2.0) for at least 24 h before discontinuation of parenteral DVT prophylaxis. Warfarin should be continued for 3 to 12 months. Thrombolytic therapy is indicated in patients with massive pulmonary embolism and hypotension. Recent surgery and active bleeding are contraindications to anticoagulation and thrombolytic therapy. In these cases, an inferior vena cava filter may be placed to prevent recurrent pulmonary emboli. Pulmonary embolectomy may be lifesaving for hemodynamically unstable patients with massive embolism in whom thrombolytic therapy is contraindicated or ineffective.

Anesthetic Considerations
A. Preoperative Management
Patients with acute pulmonary embolism may present in the operating room for placement of an inferior vena cava filter, or, rarely, for pulmonary embolectomy. In most instances, the patient will have a history of pulmonary embolism and presents for unrelated surgery; in this group of patients, the risk of interrupting anticoagulant therapy perioperatively is unknown. If the acute episode is more than 1 year old, the risk associated with temporarily stopping anticoagulant therapy is probably small. Moreover, except in the case of chronic recurrent
pulmonary emboli, pulmonary function has usually returned to normal. The emphasis in the perioperative management of these patients should be in preventing new episodes of embolism (see earlier discussion).

B. Intraoperative Management
Vena cava filters are usually placed percutaneously under local anesthesia with sedation.

Patients presenting for emergency pulmonary embolectomy are critically ill. They are usually already intubated, but tolerate positive-pressure ventilation poorly. Inotropic support is usually necessary until they are placed on cardiopulmonary bypass to facilitate clot removal. Inotropic support may be required to separate from cardiopulmonary bypass.

C. Intraoperative Pulmonary Embolism
Significant pulmonary embolism is rare during anesthesia. Diagnosis requires a high index of suspicion. Air emboli are common but are often overlooked unless large amounts are entrained. Fat embolism, as well as embolism of microthrombi and bone debris, can occur during orthopedic procedures; amniotic fluid embolism is a rare, unpredictable, and often fatal, complication of late pregnancy and obstetrical delivery. Thromboembolism may occur intraoperatively during prolonged procedures. The clot may have been present prior to surgery or may form intraoperatively; surgical manipulations or a change in the patient’s position may then dislodge the venous thrombus. Manipulation of tumors with intravascular extension (eg, renal cell carcinoma invading the vena cava) can similarly produce pulmonary embolism.

Intraoperative pulmonary embolism usually presents as sudden cardiovascular collapse, hypoxemia, or bronchospasm. A decrease in end-tidal CO₂ concentration is also suggestive of pulmonary embolism but is not specific. Invasive monitoring may reveal elevated central venous pressure. Depending on the type and location of an embolism, a transesophageal echocardiogram may be helpful; this may not reveal the embolus but will often demonstrate right heart distention and dysfunction. If air is identified in the right atrium, or if it is suspected, emergent central vein cannulation and aspiration of the air may be lifesaving. For all other emboli, treatment is supportive, with intravenous fluids and inotropes. Placement of a vena cava filter may be considered postoperatively.
Laparoscopic Surgery

A 45-year-old woman is scheduled for a laparoscopic cholecystectomy. Known medical problems include morbid obesity and a history of smoking.

What are the advantages of laparoscopic cholecystectomy compared with open cholecystectomy?

Laparoscopic techniques have rapidly increased in popularity because of the multiple benefits associated with much smaller incisions than with traditional open techniques. These benefits include decreased postoperative pain, less postoperative pulmonary impairment, a reduction in postoperative ileus, shorter hospital stays, earlier ambulation, and smaller surgical scars. Thus, laparoscopic surgery can provide substantial medical and economic advantages.

How does laparoscopic surgery affect intraoperative pulmonary function?

The hallmark of laparoscopy is the creation of a pneumoperitoneum with pressurized CO₂. The resulting increase in intraabdominal pressure displaces the diaphragm cephalad, causing a decrease in lung compliance and an increase in peak inspiratory pressure. Atelectasis, diminished FRC, ventilation/perfusion mismatch, and pulmonary shunting contribute to a decrease in arterial oxygenation. These changes should be exaggerated in this obese patient with a long history of tobacco use.

The high solubility of CO₂ increases systemic absorption by the vasculature of the peritoneum. This, combined with smaller tidal volumes because of poor lung compliance, leads to increased arterial CO₂ levels and decreased pH.

Why does patient position affect oxygenation?

A head-down (Trendelenburg) position causes a cephalad shift in abdominal viscera and the diaphragm. FRC, total lung volume, and pulmonary compliance will be decreased. Although these changes are
usually well tolerated by healthy patients, this patient’s obesity and presumed preexisting lung disease increase the likelihood for hypoxemia. A head-down position also tends to shift the trachea upward, so that a tracheal tube anchored at the mouth may migrate into the right mainstem bronchus. This tracheobronchial shift may be exacerbated during insufflation of the abdomen.

After insufflation, the patient’s position is usually changed to a steep head-up position (reverse Trendelenburg) to facilitate surgical dissection. The respiratory effects of the head-up position are the opposite of the head-down position.

**Does laparoscopic surgery affect cardiac function?**

Moderate insufflation pressures usually leave heart rate, central venous pressure, and cardiac output unchanged or slightly elevated. This seems to result from increased effective cardiac filling because blood tends to be forced out of the abdomen and into the chest. Higher insufflation pressures (>25 cm H2O or 18 mm Hg), however, tend to collapse the major abdominal veins (particularly the inferior vena cava), which decreases venous return and leads to a drop in preload and cardiac output in some patients.

Hypercarbia will stimulate the sympathetic nervous system and increase blood pressure, heart rate, and the risk of arrhythmias. Attempting to compensate by increasing the tidal volume or respiratory rate will increase the mean intrathoracic pressure, further hindering venous return and increasing mean pulmonary artery pressures. These effects can prove particularly challenging in patients with restrictive lung disease, impaired cardiac function, or intravascular volume depletion.

Although the Trendelenburg position increases preload, mean arterial pressure and cardiac output usually either remain unchanged or decrease. These seemingly paradoxical responses may be explained by carotid and aortic baroreceptor-mediated reflexes. The reverse Trendelenburg position decreases preload, cardiac output, and mean arterial pressure.

**Describe the advantages and disadvantages of alternative anesthetic techniques for this patient.**

Anesthetic approaches to laparoscopic surgery have in the past included infiltration of local anesthetic with an intravenous sedative, epidural or spinal anesthesia, or general anesthesia. Experience with local anesthesia
has been largely limited to brief gynecological procedures (laparoscopic tubal sterilization, intrafallopian transfers) in young, healthy, and motivated patients. Although postoperative recovery is rapid, patient discomfort and suboptimal visualization of intraabdominal organs preclude the use of this local anesthesia technique for laparoscopic cholecystectomy.

Epidural or spinal anesthesia represents another rarely chosen alternative for laparoscopic surgery. A high level is required for complete muscle relaxation and to prevent diaphragmatic irritation caused by gas insufflation and surgical manipulations. An obese patient with lung disease may not be able to increase spontaneous ventilation to maintain normocarbia in the face of a T2 level regional block during insufflation and a 20° Trendelenburg position. Another disadvantage of a regional technique is the occasional occurrence of referred shoulder pain from diaphragmatic irritation.

**Does a general anesthetic technique require tracheal intubation?**

Tracheal intubation with positive-pressure ventilation is usually favored for many reasons: the risk of regurgitation from increased intraabdominal pressure during insufflation; the necessity for controlled ventilation to prevent hypercapnia; the relatively high peak inspiratory pressures required because of the pneumoperitoneum; the need for neuromuscular blockade during surgery to allow lower insufflation pressures, provide better visualization, and prevent unexpected patient movement; and the placement of a nasogastric tube and gastric decompression to minimize the risk of visceral perforation during trocar introduction and optimize visualization. The obese patient presented here would benefit from intubation to decrease the likelihood of hypoxemia, hypercarbia, and aspiration. In lower risk patients, second-generation supraglottic airway devices are increasingly employed for a variety of surgical procedures, including those performed laparoscopically.

**What special monitoring should be considered for this patient?**

Monitoring end-tidal CO₂ normally provides an adequate guide for determining the minute ventilation required to maintain normocarbia. This assumes a constant gradient between arterial CO₂ and end-tidal CO₂, which is generally valid in healthy patients undergoing laparoscopy. This assumption would not apply if alveolar dead space changes during surgery. For example, any significant reduction in lung perfusion increases alveolar
dead space and therefore increases the gradient between arterial and end-tidal CO₂. This may occur during laparoscopy if cardiac output drops because of high inflation pressures, the reverse Trendelenburg position, or gas embolism. Furthermore, abdominal distention lowers pulmonary compliance. Large tidal volumes are usually avoided because they are associated with high peak inspiratory pressures and can cause considerable movement of the surgical field.

**What are some possible complications of laparoscopic surgery?**

Surgical complications include hemorrhage, if a major abdominal vessel is lacerated, or peritonitis, if a viscus is perforated during trocar introduction. Significant intraoperative hemorrhage may go unrecognized because of the limitations of laparoscopic visualization. Fulguration has been associated with bowel burns and bowel gas explosions. The use of pressurized gas introduces the possibility of extravasation of CO₂ along tissue planes, resulting in subcutaneous emphysema, pneumomediastinum, or pneumothorax. Nitrous oxide should be discontinued and insufflating pressures decreased as much as possible. Patients with this complication may benefit from the continuation of mechanical ventilation into the immediate postoperative period.

Venous CO₂ embolism resulting from unintentional insufflation of gas into an open vein may lead to hypoxemia, pulmonary hypertension, pulmonary edema, and cardiovascular collapse. Unlike air embolism, end-tidal CO₂ may transiently increase during CO₂ gas embolism. Treatment includes immediate release of the pneumoperitoneum, discontinuation of nitrous oxide, insertion of a central venous catheter for gas aspiration, and placement of the patient in a head-down left lateral decubitus position.

Vagal stimulation during trocar insertion, peritoneal insufflation, or manipulation of viscera can result in bradycardia and even sinus arrest. Although this usually resolves spontaneously, elimination of the stimulus (eg, deflation of the peritoneum) and administration of a vagolytic drug (eg, atropine sulfate) should be considered. Intraoperative hypotension may be more common during laparoscopic compared with open procedures secondary to impaired venous return as a consequence of increased abdominal pressure related to CO₂ insufflation. Support of the blood pressure may be necessary to maintain a suitable mean arterial pressure (≥65 mm Hg).
Even though laparoscopic procedures are associated with less muscle trauma and incisional pain than open surgery, pulmonary dysfunction can persist for at least 24 h postoperatively. For example, FEV$_1$, FVC, and forced expiratory flow are reduced by approximately 25% following laparoscopic cholecystectomy, compared with a 50% reduction following open cholecystectomy. The cause of this dysfunction may be related to diaphragmatic tension during the pneumoperitoneum.

GUIDELINES

See www.guidelines.gov for additional guidelines from multiple organizations on deep vein thrombosis prophylaxis and pulmonary embolism.

Anesthesia for Thoracic Surgery

KEY CONCEPTS

1. During one-lung ventilation, the mixing of unoxygenated blood from the collapsed upper lung with oxygenated blood from the still-ventilated dependent lung widens the alveolar-to-arterial (A-a) O₂ gradient and often results in hypoxemia.

2. There are certain clinical situations in which the use of a right-sided double-lumen tube is recommended: (1) distorted anatomy of the left main bronchus by an intrabronchial or extrabronchial mass; (2) compression of the left main bronchus due to a descending thoracic aortic aneurysm; (3) left-sided pneumonectomy; (4) left-sided single lung transplantation; and (5) left-sided sleeve resection.

3. If epidural or intrathecal opioids are to be used for postoperative pain control, intravenous opioids should be limited during surgery to prevent excessive postoperative respiratory depression.

4. Postoperative hemorrhage complicates about 3% of thoracotomies and may be associated with up to 20% mortality. Signs of hemorrhage include increased chest tube drainage (>200 mL/h), hypotension, tachycardia, and a falling hematocrit.

5. Bronchopleural fistula presents as a sudden large air leak from the chest tube that may be associated with an increasing pneumothorax and partial lung collapse.

6. Acute herniation of the heart into the operative hemithorax can occur through the pericardial defect that is left following a radical pneumonectomy.

7. Nitrous oxide is contraindicated in patients with cysts or bullae because it can expand the air space and cause rupture. The latter may be signaled by sudden hypotension, bronchospasm, or an abrupt rise in
peak inflation pressure and requires immediate placement of a chest tube.

Following transplantation, peak inspiratory pressures should be maintained at the minimum pressure compatible with good lung expansion, and the inspired oxygen concentration should be maintained as close to room air as allowed by a PaO₂ greater than 60 mm Hg.

Regardless of the procedure, a common anesthetic concern for patients with esophageal disease is the risk of pulmonary aspiration.

Indications and techniques for thoracic surgery continually evolve. Common indications now include thoracic malignancies (mainly of the lungs and esophagus), chest trauma, esophageal disease, and mediastinal tumors. Diagnostic procedures such as bronchoscopy, mediastinoscopy, and open-lung biopsies are also common. Anesthetic techniques for providing lung separation have allowed the refinement of surgical techniques to the point that many procedures are increasingly performed thoracoscopically.

---

**Physiological Considerations During Thoracic Anesthesia**

Thoracic surgery presents a unique set of physiological problems for the anesthesiologist. These include physiological derangements caused by placing the patient in the lateral decubitus position, opening the chest (open pneumothorax), and the need for one-lung ventilation.

**THE LATERAL DECUBITUS POSITION**

The lateral decubitus position provides optimal access for most operations on the lungs, pleura, esophagus, the great vessels, other mediastinal structures, and vertebrae. Unfortunately, this position may significantly alter the normal pulmonary ventilation/perfusion relationships. These derangements are further accentuated by anesthetics, mechanical ventilation, neuromuscular blockade, opening the chest, and surgical retraction. Although perfusion continues to favor the dependent lung (under anesthesia in the supine position the dependent part of the lung is toward the back, rather than toward the feet, as would be true in an awake, standing patient), ventilation progressively favors the less perfused,
superior part of the lung. The resulting ventilation/perfusion mismatch increases the risk of hypoxemia.

**The Awake State**

When a supine patient assumes the lateral decubitus position, ventilation/perfusion matching is preserved during spontaneous ventilation. The dependent (lower) lung receives more perfusion than does the upper lung due to gravitational influences on blood flow distribution in the pulmonary circulation. The dependent lung also receives more ventilation because (1) contraction of the dependent hemidiaphragm is more efficient compared with the nondependent (upper) hemidiaphragm, and (2) the dependent lung is on a more favorable part of the compliance curve (Figure 25–1). However, spontaneous ventilation in this position is the exception, not the rule.

![FIGURE 25–1 The effect of the lateral decubitus position on lung compliance.](image)

**Induction of Anesthesia**

The decrease in functional residual capacity (FRC) with induction of general anesthesia moves the upper lung to a more favorable part of the compliance curve, but moves the lower lung to a less favorable position (Figure 25–2). As a result, the upper lung is ventilated more than the dependent lower lung;
ventilation/perfusion mismatching occurs because the dependent lung continues to have greater perfusion.

**FIGURE 25–2** The effect of anesthesia on lung compliance in the lateral decubitus position. The upper lung assumes a more favorable position, and the lower lung becomes less compliant.

**Positive-Pressure Ventilation**

Controlled positive-pressure ventilation favors the upper lung in the lateral position because it is more compliant than the lower lung. Neuromuscular blockade enhances this effect by allowing the abdominal contents to rise up further against the dependent hemidiaphragm and impede ventilation of the lower lung. Using a rigid “bean bag” to maintain the patient in the lateral decubitus position further restricts movement of the dependent hemithorax. Finally, opening the nondependent side of the chest further accentuates differences in compliance between the two sides because the upper lung is now less restricted in movement. All of these effects worsen ventilation/perfusion mismatching and predispose the patient to hypoxemia.

**THE OPEN PNEUMOTHORAX**

The lungs are normally kept expanded by a negative pleural pressure—the net
result of the tendency of the lung to collapse and the chest wall to expand. When one side of the chest is opened, the negative pleural pressure is lost, and the elastic recoil of the lung on that side tends to collapse it. Spontaneous ventilation with an open pneumothorax in the lateral position results in paradoxical respirations and mediastinal shift. These two phenomena can cause progressive hypoxemia and hypercapnia, but, fortunately, their effects are overcome by the use of positive-pressure ventilation during general anesthesia and thoracotomy.

**Mediastinal Shift**

During spontaneous ventilation in the lateral position, inspiration causes pleural pressure to become more negative on the dependent side, but not on the side of the open pneumothorax. This results in a downward shift of the mediastinum during inspiration and an upward shift during expiration (Figure 25–3). The major effect of the mediastinal shift is to decrease the contribution of the dependent lung to the tidal volume.

![Mediastinal shift in a spontaneously breathing patient in the lateral decubitus position.](image)

**Paradoxical Respiration**

Spontaneous ventilation in a patient with an open pneumothorax also results in to-and-fro gas flow between the dependent and nondependent lung (paradoxical respiration [*pendeluft*]). During inspiration, the pneumothorax increases, and gas flows from the upper lung across the carina to the dependent lung. During expiration, the gas flow reverses and moves from the dependent to the upper lung (Figure 25–4).
ONE-LUNG VENTILATION

Intentional collapse of the lung on the operative side facilitates most thoracic procedures, but complicates anesthetic management. Because the collapsed lung continues to be perfused and is deliberately no longer ventilated, the patient develops a large right-to-left \( \bullet \) intrapulmonary shunt (20–30%). During one-lung ventilation, the mixing of unoxygenated blood from the collapsed upper lung with oxygenated blood from the still-ventilated dependent lung widens the alveolar-to-arterial (A-a) \( \text{O}_2 \) gradient and often results in hypoxemia.

Fortunately, blood flow to the nonventilated lung is decreased by hypoxic pulmonary vasoconstriction (HPV) and possibly surgical compression of the upper lung. The surgeon can also clamp the pulmonary arterial supply to the collapsed lung when all else fails.

Factors known to inhibit HPV (thereby increasing venous admixture), and thus worsen the right-to-left shunting, include pulmonary hypertension; hypcapnia alkalosis; increased cardiac output and increased mixed venous \( \text{Po}_2 \); hypothermia; vasodilators such as nitroglycerin, nitroprusside, and nitric oxide; phosphodiesterase inhibitors (milrinone, enoximone, inamrinone), \( \beta \)-adrenergic agonists; calcium channel blockers; and inhalation anesthetics.

Factors that decrease blood flow to the ventilated lung can be equally detrimental; they counteract the effect of HPV by indirectly increasing blood flow to the collapsed lung. Such factors include (1) high mean airway pressures in the ventilated lung due to high positive end-expiratory pressure (PEEP), hyperventilation, or high peak inspiratory pressures; (2) a low \( \text{FiO}_2 \), which produces hypoxic pulmonary vasoconstriction in the ventilated lung; (3)
vasoconstrictors that may have a greater effect on normoxic vessels than hypoxic ones; and (4) intrinsic PEEP that develops due to inadequate expiratory times.

Elimination of CO$_2$ is usually unchanged by one-lung ventilation, provided that minute ventilation is unchanged; arterial CO$_2$ tension is usually not appreciably altered. One-lung ventilation can result in injury to both ventilated and nonventilated lungs. The dependent, ventilated lung is subject to hyperperfusion as well as ventilator-induced trauma secondary to large tidal volume ventilation. The nonventilated, nondependent lung is exposed to both surgical trauma and ischemia reperfusion injuries. We recommend the use of tidal volumes of no more than 4 to 5 mL/kg of predicted body weight, rather than earlier recommendations to use the same tidal volume as during two-lung ventilation.

### Techniques for One-Lung Ventilation

One-lung ventilation can also be utilized to isolate a lung or to facilitate ventilatory management under certain conditions (Table 25–1). Three techniques can be employed: (1) placement of a double-lumen bronchial tube; (2) use of a single-lumen tracheal tube in conjunction with a bronchial blocker; or (3) insertion of a conventional endotracheal tube into a mainstem bronchus. Double-lumen tubes are most often used.

DOUBLE-LUMEN BRONCHIAL TUBES

The principal advantages of double-lumen tubes are relative ease of placement, the ability to ventilate one or both lungs, and the ability to suction either lung.

All double-lumen tubes share the following characteristics:

- A longer bronchial lumen that enters either the right or left main bronchus and another shorter tracheal lumen that terminates in the lower trachea
- A preformed curve that when properly “aimed” allows preferential entry into a bronchus
- A bronchial cuff
- A tracheal cuff

Ventilation can be delivered to only one lung by clamping the tube delivering gas to either the bronchial or tracheal lumen with both cuffs inflated; disconnecting the appropriate connection distal to the clamp site allows the ipsilateral lung to collapse. Because of differences in bronchial anatomy between the two sides, tubes are designed specifically for either the right or left bronchus. A right-sided double-lumen tube incorporates a modified cuff and a proximal portal on the endobronchial side for ventilation of the right upper lobe. The most commonly used double-lumen tubes are available in several sizes: 35, 37, 39, and 41FR.

Anatomic Considerations

On average, the adult trachea is 11 to 13 cm long. It begins at the level of the cricoid cartilage (C6) and bifurcates at the level of the carina behind the sternomanubrial joint (T5). Major differences between the right and left main bronchi are as follows: (1) the larger diameter right bronchus diverges away from the trachea at a less acute angle in relation to the trachea, whereas the left
bronchus diverges at a more horizontal angle (Figure 25–5); (2) the right bronchus has upper, middle, and lower lobe branches, whereas the left bronchus divides into only upper and lower lobe branches; and (3) the orifice of the right upper lobe bronchus is typically about 1 to 2.5 cm from the carina, whereas the bifurcation of the left main bronchus is typically about 5 cm distal to the carina. There is considerable anatomic variation: for example, the right upper lobe bronchus will occasionally arise from the trachea itself.

![Diagram of the tracheobronchial tree](image)

As previously noted, right-sided double-lumen tubes must have a portal through the bronchial cuff for ventilating the right upper lobe (Figure 25–6). Anatomic variations among individuals in the distance between the carina and the right upper lobe orifice will occasionally result in difficulty ventilating that lobe with right-sided tubes. Either a left-sided or right-sided double-lumen tube can be used in most surgical procedures, irrespective of the operative side; for simplicity, many practitioners prefer to use left-sided tubes for nearly every case. There are certain clinical situations in which the use of a right-sided double-lumen tube is recommended: (1) distorted anatomy of the left main bronchus by an intrabronchial or extrabronchial mass; (2) compression of the left main bronchus due to a descending thoracic aortic aneurysm; (3) left-sided pneumonectomy; (4) left-sided single lung transplantation; and (5) left-sided
sleeve resection. Finally, despite concerns about right upper lobe atelectasis and potentially difficult placement, studies have failed to detect differences in clinical performance of right- and left-sided double-lumen tubes when used clinically.

FIGURE 25–6 Correct position of a left- and right-sided double-lumen tube.

**Placement of Double-Lumen Tubes**

Laryngoscopy with a curved (MacIntosh) blade usually provides better intubating conditions than does a straight blade because the curved blade typically provides more room for manipulation of the large double-lumen tube. Video laryngoscopy can also be employed to facilitate tube placement. The double-lumen tube is passed with the distal curvature concave anteriorly and is rotated 90° (toward the side of the bronchus to be intubated) after the tip passes the vocal cords and enters the larynx (Figure 25–7). At this point, the operator has two options: the tube can be advanced until resistance is felt (the average depth of insertion is about 29 cm [at the teeth]), or alternatively, the fiberoptic bronchoscope can be inserted through the bronchial limb and advanced into the desired bronchus. The double-lumen tube can be advanced over the bronchoscope into the desired bronchus. Correct tube placement should be
established using a preset protocol (Figure 25–8 and Table 25–2) and confirmed by flexible fiberoptic bronchoscopy. When problems are encountered in intubating the patient with the double-lumen tube, placement of a single-lumen endotracheal tube should be attempted; once positioned in the trachea, the latter can be exchanged for the double-lumen tube by using a specially designed catheter guide ("tube exchanger"). We have found that double-lumen tubes placed in this way will often, as expected, find their way into the right main stem bronchus.

**FIGURE 25–7** Placement of a left-sided double-lumen tube. Note that the tube is turned 90° as soon as it enters the larynx. **A**: Initial position. **B**: Rotated 90°. **C**: Final position.
FIGURE 25–8 Results of unilateral clamping of the bronchial lumen tube when the double-lumen tube is in the correct position.

1. Inflate the tracheal cuff (5–10 mL of air).
2. Check for bilateral breath sounds. Unilateral breath sounds indicate that the tube is too far down (tracheal opening is bronchial).
3. Inflate the bronchial cuff (1–2 mL).
4. Clamp the tracheal lumen.
5. Check for unilateral left-sided breath sounds.
   a. Persistence of right-sided breath sounds indicates that the bronchial opening is still in the trachea (tube should be advanced).
   b. Unilateral right-sided breath sounds indicate incorrect entry of the tube in the right bronchus.
   c. Absence of breath sounds over the entire right lung and the left upper lobe indicates that the tube is too far down the left bronchus.
6. Unclamp the tracheal lumen and clamp the bronchial lumen.
7. Check for unilateral right-sided breath sounds. Absence or diminution of breath sounds indicates that the tube is not far enough down and that the bronchial cuff is occluding the distal trachea.

Most double-lumen tubes easily accommodate bronchoscopes with a 3.6- to 4.2-mm outer diameter. When the bronchoscope is introduced into the tracheal lumen and advanced through the tracheal orifice, the carina should be visible ([Figure 25–9]), and the bronchial limb of the tube should be seen entering the respective bronchus; additionally, the top of the bronchial cuff (usually colored blue) should be visible, but should not extend above the carina. If the bronchial cuff of a left-sided double-lumen tube is not visible, the bronchial limb may have been inserted sufficiently far to allow the bronchial cuff to obstruct the orifice of the left upper or lower lobe; the tube should be withdrawn until the cuff can be identified distal to the carina. The optimal position of a right-sided double-lumen tube is confirmed by placing the fiberoptic scope through the endobronchial lumen, which should show alignment of the endobronchial side portal with the opening of the right upper lobe bronchus. The bronchial cuff should be inflated only to the point at which the audible leak from the open tracheal lumen disappears while ventilating only through the bronchial lumen.
Tube position should be reconfirmed after the patient is positioned for surgery because the tube may move relative to the carina as the patient is turned into the lateral decubitus position. Malpositioning of a double-lumen tube within the tracheobronchial tree may lead to failure of the operative lung to collapse, apparent poor lung compliance, and low exhaled tidal volume. Problems with left-sided double-lumen tubes are usually related to one of three possibilities: (1) the tube tip is too distal; (2) the tube tip is too proximal; or (3) the tube is in the right bronchus (the wrong side). If the tube tip is located too distally, the bronchial cuff can obstruct the left upper or the left lower lobe orifice, and the bronchial lumen can be inserted into the orifice of the left lower or left upper lobe bronchus, respectively. When the tube is not advanced distally enough, the inflated bronchial cuff may be above the carina and also occlude the tracheal lumen. In both instances, deflation of the bronchial cuff improves ventilation to the lung and helps to identify the problem. In some patients, the bronchial lumen may be within the left upper or left lower lobe bronchus but with the tracheal opening remaining above the carina; this situation is suggested by collapse of only one of the left lobes when the bronchial lumen is clamped. In the same situation, if the surgical procedure is in the right thorax, clamping of the tracheal lumen will lead to ventilation of only the left upper or left lower lobe; hypoxia usually develops rapidly.

Right-sided double-lumen tubes can be accidentally inserted into the left mainstem bronchus, inserted too distally or too proximally, or have
misalignment of the endobronchial side portal with the opening of the right upper lobe bronchus. If the tube enters the wrong bronchus, the fiberoptic bronchoscope can be used to redirect it into the correct side: (1) the bronchoscope is passed through the bronchial lumen to the tip of the tube; (2) under direct vision, the tube and the bronchoscope are withdrawn together into the trachea just above the carina; (3) the bronchoscope alone is then advanced into the correct bronchus; and (4) the double-lumen tube is gently advanced over the bronchoscope, which functions as a stylet to guide the bronchial lumen into the correct bronchus.

**Complications of Double-Lumen Tubes**

Major complications of double-lumen tubes include (1) hypoxemia due to tube malplacement, tube occlusion, or excessive degrees of venous admixture with one-lung ventilation; (2) traumatic laryngitis; (3) tracheobronchial rupture resulting from traumatic placement or overinflation of the bronchial cuff; and (4) inadvertent suturing of the tube to a bronchus during surgery (detected as the inability to withdraw the tube during attempted extubation).

**SINGLE-LUMEN TRACHEAL TUBES WITH A BRONCHIAL BLOCKER**

Bronchial blockers are inflatable devices that are passed alongside or through a single-lumen tracheal tube to selectively occlude a bronchial orifice. The bronchial blocker must be advanced, positioned, and inflated under direct visualization via flexible bronchoscope.

The major advantage of a single-lumen tube with a bronchial blocker is that, unlike a double-lumen tube, it does not need to be replaced with a conventional tracheal tube if the patient will remain intubated postoperatively (see later discussion). Its major disadvantage is that the “blocked” lung collapses slowly (and sometimes incompletely) because of the small size of the channel within the blocker catheter.

There are several types of bronchial blockers. They come in different sizes (7FR and 9FR) and have a 1.4-mm diameter inner lumen. Bronchial blockers have a high-volume low-pressure cuff with either an elliptical or spherical shape. The spherical shape of the cuff facilitates adequate blockade of the right mainstem bronchus. The spherical or the elliptical cuff can be used for the left mainstem bronchus. The inner lumen contains a nylon wire, which exits the
distal end as a wireloop. The placement of the bronchial blocker involves inserting the endobronchial blocker through the endotracheal tube and using the fiberoptic bronchoscope and the distal loop of the guidewire to direct the blocker into a mainstem bronchus. The fiberoptic bronchoscope must be advanced beyond the bronchus opening so that the blocker enters the bronchus while it is being advanced. When the deflated cuff is beyond the entrance of the bronchus, the fiberoptic bronchoscope is withdrawn, and the blocker is secured in position. In order to obtain bronchial blockade, the cuff is fully inflated under fiberoptic visualization with 4 to 8 mL of air. The placement must be reconfirmed when the patient is placed in the lateral position. Bronchial blockers may be good choices for lung separation in intubated critically ill patients who require one-lung ventilation, patients who are difficult to intubate using direct laryngoscopy, patients with prior tracheostomies, and patients who may require postoperative mechanical ventilation. However, bronchial blockers are more prone to dislodgement compared with double-lumen endotracheal tubes, and their small central lumens do not allow efficient suctioning of secretions or rapid collapse of the lung.

In smaller children, an inflatable Fogarty embolectomy catheter can be used as a bronchial blocker in conjunction with a conventional tracheal tube (with the embolectomy catheter placed either inside or alongside the tracheal tube); a guidewire in the catheter can be used to facilitate placement. This technique is occasionally used to collapse one lung when other techniques do not work. As the embolectomy catheter does not have a communicating channel in the center, it also does not allow suctioning or ventilation of the isolated lung, and the catheter can be easily dislodged. Nonetheless, such bronchial blockers may be useful for one-lung anesthesia in pediatric patients and for tamponading bronchial bleeding in adult patients (see later discussion).

---

**Anesthesia for Lung Resection**

---

**PREOPERATIVE CONSIDERATIONS**

Lung resections are usually carried out for the diagnosis and treatment of pulmonary tumors, and, less commonly, for traumatic lung injury, bullae, complications of necrotizing pulmonary infections, or bronchiectasis.

1. **Tumors**
Pulmonary tumors can be either benign or malignant, and, with the widespread use of bronchoscopic sampling (often guided by endobronchial ultrasound), diagnosis is usually available prior to surgery. Hamartomas account for 90% of benign tumors; they are usually peripheral pulmonary lesions and represent disorganized normal pulmonary tissue. Bronchial adenomas are usually central pulmonary lesions that are typically benign, but occasionally may be locally invasive and rarely metastasize. These tumors include pulmonary carcinoids, cylindromas, and mucoepidermoid adenomas. They often obstruct the bronchial lumen and cause recurrent pneumonia distal to the obstruction in the same area. Primary pulmonary carcinoids may secrete multiple hormones, including adrenocorticotropic hormone (ACTH) and arginine vasopressin; however, manifestations of the carcinoid syndrome are uncommon and are more likely with metastatic disease.

Malignant pulmonary tumors are divided into small ("oat") cell and non-small cell carcinomas. The latter group includes squamous cell (epidermoid) tumors, adenocarcinomas, and large cell (anaplastic) carcinomas. Epidermoid and small cell carcinomas usually present as central masses with bronchial lesions; adenocarcinoma and large cell carcinomas are more typically peripheral lesions that often involve the pleura.

**Clinical Manifestations**

Symptoms may include cough, hemoptysis, wheezing, weight loss, productive sputum, dyspnea, or fever. Pleuritic chest pain or pleural effusion suggests pleural extension. Involvement of mediastinal structures is suggested by hoarseness that results from compression of the recurrent laryngeal nerve, Horner’s syndrome caused by involvement of the sympathetic nerve, an elevated hemidiaphragm caused by compression of the phrenic nerve, dysphagia caused by compression of the esophagus, or the superior vena cava syndrome caused by compression or invasion of the superior vena cava. Pericardial effusion or cardiomegaly suggests cardiac involvement. Extension of apical (superior sulcus) tumors can result in either shoulder or arm pain, or both, because of involvement of the C7–T2 roots of the brachial plexus (Pancoast syndrome). Distant metastases most commonly involve the brain, bone, liver, and adrenal glands.

Lung carcinomas—particularly small cell—can produce remote effects that are not related to malignant spread (paraneoplastic syndromes). Mechanisms include ectopic hormone production and immunological cross-reactivity between the tumor and normal tissues. Cushing’s syndrome, hyponatremia (syndrome of
inappropriate antidiuretic hormone secretion [SIADH]), and hypercalcemia may be encountered, resulting from ectopic secretion of ACTH, arginine vasopressin, and parathyroid hormone, respectively. Lambert–Eaton (myasthenic) syndrome is characterized by a proximal myopathy in which muscle strength increases with repeated effort (in contrast to myasthenia gravis). Other paraneoplastic syndromes include peripheral neuropathy and migratory thrombophlebitis.

**Treatment**

Surgery is the treatment of choice to reduce the tumor burden in nonmetastatic lung cancer. Various perioperative chemotherapy and radiation treatments are likewise employed, but there is wide variation among tissue types in their sensitivity to chemotherapy and radiation.

**Resectability & Operability**

Resectability is determined by the anatomic stage of the tumor, whereas operability is dependent on the interaction between the extent of the procedure required for cure and the physiological status of the patient. Anatomic staging is accomplished using chest radiography, computed tomography (CT) or magnetic resonance (MR) imaging, bronchoscopy, and (sometimes) mediastinoscopy. The extent of the surgery should maximize the chances for a cure but still allow for adequate residual pulmonary function postoperatively. Lobectomy via a posterior thoracotomy, through the fifth or sixth intercostal space, or (more commonly) using video-assisted thoracoscopic surgery (VATS), is the procedure of choice for most lesions. Segmental or wedge resections may be performed for initial diagnosis or for definitive treatment of small peripheral lesions. Pneumonectomy is necessary for curative treatment of lesions involving the left or right main bronchus or when the tumor extends toward the hilum. A sleeve resection may be employed for patients with proximal lesions and limited pulmonary reserve as an alternative to pneumonectomy; in such instances, the involved lobar bronchus, together with part of the right or left main bronchus, is resected, and the distal bronchus is reanastomosed to the proximal bronchus or the trachea. Sleeve pneumonectomy may be considered for tumors involving the trachea.

The incidence of pulmonary complications after thoracotomy and lung resection is about 30% and is related not only to the amount of lung tissue resected, but also to the disruption of chest wall mechanics due to the thoracotomy. Postoperative pulmonary dysfunction seems to be less after VATS than “open” thoracotomy. The mortality rate for pneumonectomy is generally
more than twice that for a lobectomy. Mortality is greater for right-sided than left-sided pneumonectomy, possibly because of greater loss of lung tissue.

## Evaluation for Lung Resection

A comprehensive preoperative assessment is necessary to assess and modify perioperative risk; minimize perioperative complications, hospital length-of-stay, and hospital readmission risk; and optimize outcomes. Preoperative assessment of respiratory function may include determinations of respiratory mechanics, gas exchange, and cardiorespiratory interaction. Spirometry and diffusion capacity are initially assessed and can be used to predict postoperative values. In a fit, younger patient undergoing VATS for a peripheral “coin” lesion, not all of these tests will be needed. For example:

\[
\text{Postoperative FEV}_1 = \text{preoperative FEV}_1 \times (1 - \text{the percentage of functional lung tissue removed divided by 100})
\]

Removal of extensively diseased lung (nonventilated but perfused) does not necessarily adversely affect pulmonary function and may actually improve oxygenation. Mortality and morbidity are significantly increased if postoperative FEV\(_1\) is less than 30% to 40% of normative FEV\(_1\). Gas exchange will sometimes be characterized by diffusion lung capacity for carbon monoxide (DLCO). DLCO correlates with the total functioning surface area of the alveolar–capillary interface. Predictive postoperative DLCO can be calculated in the same fashion as postoperative FEV\(_1\). If both the predicted DLCO and FEV\(_1\) are greater than 60%, the patient is generally at lower risk for lung resection. Cardiopulmonary exercise testing is warranted when either of the tests is less than 30%. Ventilation/perfusion (\(\dot{V}/\dot{Q}\)) scintigraphy provides the relative contribution of each lobe to overall pulmonary function and may further refine the assessment of predicted postoperative lung function in patients when pneumonectomy is the indicated surgical procedure and there is concern about whether a single lung will be adequate to support life.

Patients considered at greater risk of perioperative complications (predicted FEV\(_1\) or DLCO between 60% and 30%) based on standard spirometry testing and calculation of postoperative function should undergo exercise testing for evaluation of cardiopulmonary interaction. Stair climbing is the easiest way to assess exercise capacity and cardiopulmonary reserve. Patients capable of climbing two or three flights of stairs have decreased mortality and morbidity.
Conversely, the ability to climb less than two flights of stairs is associated with increased perioperative risk. The gold standard for evaluating cardiopulmonary interaction is by cardiopulmonary exercise testing (CPET) and measurement of maximal minute oxygen consumption. \( \dot{V}_{O_2} \) of greater than 20 mL/kg is not associated with a significant increase in perioperative mortality or morbidity, whereas minute consumption of less than 10 mL/kg is associated with an increased perioperative risk.

A combination of tests to evaluate the patient for thoracotomy and major pulmonary resection is recommended by the American College of Chest Physicians (Figure 25–10).

**FIGURE 25–10** Physiological evaluation resection algorithm. (a) For pneumonectomy candidates, we suggest using Q scan to calculate predicted postoperative (PPO) FEV\(_1\) or DLCO values (PPO values = preoperative values \( \times \) \([1 – \text{fraction of total perfusion for the resected lung}]\)), where the preoperative values are taken as the best measured postbronchodilator values. For lobectomy patients, segmental counting is indicated to calculate PPO FEV\(_1\) or DLCO values (PPO values = preoperative values \( \times \) \([1 – y/z]\)), where the preoperative values are taken as the best measured postbronchodilator value and the number of functional or unobstructed lung segments to be removed is y and the total
number of functional segments is $z$. (b) ppoFEV$_1$ or ppoDLCO cutoff values of 60% predicted values have been chosen based on indirect evidence and expert consensus opinion. (c) For patients with a positive high-risk cardiac evaluation deemed to be stable to proceed to surgery, we suggest performing both pulmonary function tests and cardiopulmonary exercise testing (CPET) for a more precise definition of risk. (d) Definition of risk is as follows: Low risk: The expected risk of mortality is below 1%. Major anatomic resections can be safely performed in this group. Moderate risk: Morbidity and mortality rates may vary according to the values of split lung functions, exercise tolerance, and extent of resection. Risks and benefits of the operation should be thoroughly discussed with the patient. High risk: The risk of mortality after standard major anatomic resections may be higher than 10%. Considerable risk of severe cardiopulmonary morbidity and residual functional loss is expected. Patients should be counseled about alternative surgical (minor resections or minimally invasive surgery) or nonsurgical options. m, meters; ppoDLCO, predicted postoperative diffusion capacity for carbon monoxide; ppoDLCO%, percent predicted postoperative diffusion capacity for carbon monoxide; ppoFEV$_1$, predicted postoperative FEV$_1$; ppoFEV1%, percent predicted postoperative FEV$_1$; SCT, stair climb test; SWT, shuttle walk test; VO$_{2\text{max}}$, maximal oxygen consumption. Physiologic evaluation of the patient with lung cancer being considered for resectional surgery: Diagnosis and management of lung cancer, 3rd ed: American College of Chest Physicians evidence-based clinical practice guidelines. Chest. 2013 May;143(5 Suppl):e166S-e190S.)

2. Infection

Pulmonary infections may present as a solitary nodule or cavitary lesion (necrotizing pneumonitis). VATS may be carried out to exclude malignancy and diagnose the infectious agent. Lung resection is also indicated for cavitary lesions that are refractory to antibiotic treatment, are associated with refractory empyema, or result in massive hemoptysis. Responsible organisms include both bacteria and fungi.

3. Bronchiectasis

Bronchiectasis is a permanent dilation of bronchi. It is usually the end result of severe or recurrent inflammation and obstruction of bronchi. Causes include cigarette smoking; a variety of viruses, bacteria, nontuberculous mycobacteria, and fungi; as well as inhalation of toxic gases, aspiration of gastric acid, and defective mucociliary clearance (cystic fibrosis and disorders of ciliary
dysfunction). Bronchial muscle and elastic tissue are typically replaced by very vascular fibrous tissue. The latter predisposes to bouts of hemoptysis. Pulmonary resection is usually indicated for massive hemoptysis when conservative measures have failed and the disease is localized. Patients with diffuse bronchiectasis have a chronic obstructive ventilatory defect.

**ANESTHETIC CONSIDERATIONS**

1. **Preoperative Management**

The majority of patients undergoing pulmonary resections have underlying lung disease. It should be emphasized that smoking is a risk factor for both chronic obstructive pulmonary disease and coronary artery disease; both disorders commonly coexist in patients presenting for thoracotomy. Echocardiography is useful for assessing baseline cardiac function and may suggest evidence of cor pulmonale (right ventricular enlargement or hypertrophy) in patients with poor exercise tolerance. Stress echocardiography (exercise or dobutamine) may be useful in diagnosing coronary artery disease when indicated by suggestive signs and symptoms.

Patients with tumors should be queried regarding signs and symptoms of local extension of the tumor and paraneoplastic syndromes (see above). Preoperative chest radiographs and CT or MR images should be reviewed. Tracheal or bronchial deviation can make tracheal intubation and proper positioning of bronchial tubes much more difficult. Moreover, airway compression can lead to difficulty in ventilating the patient following induction of anesthesia. Pulmonary consolidation, atelectasis, and large pleural effusions predispose to hypoxemia. The location of any bullous cysts or abscesses should be noted.

Patients undergoing thoracic procedures are at increased risk of postoperative pulmonary and cardiac complications. Perioperative arrhythmias, particularly supraventricular tachycardias, are common and thought to result from surgical manipulations or distention of the right atrium following reduction of the pulmonary vascular bed. The incidence of arrhythmias increases with age and the amount of pulmonary resection.

2. **Intraoperative Management**

**Preparation**

As with anesthesia for cardiac surgery, optimal preparation may help to prevent potentially catastrophic problems. Limited pulmonary reserve, anatomic
abnormalities, or compromise of the airways, and the need for one-lung ventilation predispose these patients to the rapid onset of hypoxemia. A well-thought-out plan to deal with potential difficulties is necessary. Moreover, in addition to items for basic airway management, specialized and properly functioning equipment—such as multiple sizes of single- and double-lumen tubes, a flexible (pediatric) fiberoptic bronchoscope, a small-diameter “tube exchanger” of adequate length to accommodate a double lumen tube, a continuous positive airway pressure (CPAP) delivery system, and an anesthesia circuit adapter for administering bronchodilators—should be immediately available.

Patients undergoing open-lung resections (segmentectomy, lobectomy, and pneumonectomy) often receive postoperative thoracic epidural analgesia, unless there is a contraindication. However, patients are increasingly being treated with numerous antiplatelet and anticoagulant medications, which may preclude epidural catheter placement. Opioid-sparing, multimodal analgesia regimens, including paravertebral blocks, local injection of liposomal bupivacaine, and wound infusion catheters, are increasingly a part of enhanced recovery programs for thoracic surgery patients.

**Venous Access**

At least one large-bore (14- or 16-gauge) intravenous line is mandatory for all open thoracic surgical procedures. A blood warmer and a rapid infusion device are also desirable if extensive blood loss is anticipated.

**Monitoring**

Direct monitoring of arterial pressure is indicated for resections of large tumors (particularly those with mediastinal or chest wall extension), and any procedure performed in patients who have limited pulmonary reserve or significant cardiovascular disease. Central venous access (preferably on the side of the thoracotomy to avoid the risk of pneumothorax on the side that will be ventilated intraoperatively) with monitoring of central venous pressure (CVP) is commonly used for pneumonectomies and resections of large tumors; however, less invasive measures of cardiac output through use of thoracic bioimpedance, pulse contour analysis, or transpulmonary thermodilution provide better estimates of cardiac function and volume responsiveness (see Chapter 5). Pulmonary artery catheters are very rarely used. In patients with significant coronary artery disease or pulmonary hypertension, intraoperative diagnosis of hypovolemia or reduced
right or left ventricular performance can be easily accomplished with transesophageal echocardiography.

**Induction of Anesthesia**

The selection of an induction agent should be based on the patient’s preoperative status. All patients should receive adequate preoxygenation before induction. An adequate depth of anesthesia will help prevent reflex bronchospasm and exaggerated cardiovascular pressor responses to laryngoscopy. This may be accomplished by incremental doses of the induction agent, an opioid, or deepening the anesthesia with a volatile inhalation agent (the latter is particularly useful in patients with reactive airways). Moreover, volatile anesthetic agents may protect the lung from injury during one-lung ventilation.

Tracheal intubation with a single-lumen tracheal tube (or with a laryngeal mask airway [LMA]) may be necessary, if the surgeon performs diagnostic bronchoscopy (see below) prior to surgery. Once the bronchoscopy is completed, the single-lumen tracheal tube (or LMA) can be replaced with a double-lumen bronchial tube (see above). Controlled positive-pressure ventilation helps prevent atelectasis, paradoxical breathing, and mediastinal shift; it also allows control of the operative field to facilitate the surgery.

**Positioning**

Following induction, intubation, and confirmation of correct tracheal or bronchial blocker position, additional venous access and monitoring may be obtained before the patient is positioned for surgery. Most lung resections are performed with the patient in the lateral decubitus position. Proper positioning avoids injuries and facilitates surgical exposure. The lower arm is flexed and the upper arm is extended in front of the head, pulling the scapula away from the operative field (**Figure 25–11**). Pillows are placed between the arms and legs, and an axillary (chest) roll is usually positioned just beneath the dependent axilla to reduce pressure on the inferior shoulder (it is assumed, but not proven, that the axillary roll helps protect the brachial plexus); care is taken to avoid pressure on the eyes and the dependent ear.
Maintenance of Anesthesia

All current anesthetic techniques have been successfully used for thoracic surgery, but the ideal techniques must provide the ability to administer high concentrations of inspired oxygen and all must permit rapid adjustments in anesthetic depth. Potent halogenated agents (isoflurane, sevoflurane, or desflurane) are often used in North American practice. Advantages of the halogenated agents versus total intravenous techniques include potent, dose-related bronchodilation and consistent depression of airway reflexes. Halogenated agents generally have minimal effects on HPV in doses less than 1 minimum alveolar concentration (MAC). Advantages of opioids include (1) generally minimal hemodynamic effects; (2) depression of airway reflexes; and (3) residual postoperative analgesia. If epidural or intrathecal opioids are to be used for postoperative analgesia, intravenous opioids should be minimized during surgery to prevent excessive postoperative respiratory depression. Maintenance of neuromuscular blockade with a nondepolarizing neuromuscular blocker (NMB) during surgery facilitates rib spreading as well as anesthetic management. Excessive fluid administration in thoracic surgical patients has been associated with acute lung injury in the postoperative period. Excessive fluid administration in the lateral decubitus position may promote a “lower lung syndrome” (ie, gravity-dependent transudation of fluid into the dependent lung). The latter increases intrapulmonary shunting and promotes hypoxemia, particularly during one-lung ventilation. While we manage lung resections with a relative fluid restriction, we acknowledge that definitive studies on an ideal goal-directed fluid management strategy are lacking.

The collapsed lung may be prone to acute lung injury due to surgical retraction during the procedure and possible ischemia–reperfusion injury. During lung resections, the bronchus (or remaining lung tissue) is usually divided with
an automated stapling device. The bronchial stump is then tested for an air leak under water by transiently sustaining 30 cm of positive pressure to the airway. Prior to completion of chest closure, all remaining lung segments should be fully expanded manually under direct vision. Controlled mechanical ventilation is then resumed and continued until thoracostomy tubes are connected to suction.

**Management of One-Lung Ventilation**

Although still an intraoperative problem, hypoxemia has become less frequent due to better lung isolation methods, ventilation techniques, and the use of anesthetic agents with less detrimental effects on hypoxic pulmonary vasoconstriction. Attention has currently shifted toward avoidance of acute lung injury (ALI). Fortunately, ALI occurs infrequently, with an incidence of 2.5% of all lung resections combined, and an incidence of 7.9% after pneumonectomy. However, when it occurs, ALI is associated with a risk of mortality or major morbidity of about 40%.

Based on current data, it seems that protective lung ventilation strategies may minimize the risk of ALI after lung resection. This ventilatory strategy includes the use of lower tidal volumes (<6 mL/kg), lower Fio$_2$ (50–80%) and lower ventilatory pressures (plateau pressure <25 cm H$_2$O; peak airway pressure <35 cm H$_2$O) through the use of pressure-controlled ventilation. Permissive hypercapnia is reasonable for those rare patients with elevated CO$_2$ tensions despite adequate oxygen saturation and a reasonable minute ventilation. The use of tidal volumes less than 3 mL/kg per lung may lead to lung derecruitment, atelectasis, and hypoxemia. Lung derecruitment may be avoided by application of PEEP and recruitment maneuvers. Although the management of one-lung ventilation has long included the use of 100% oxygen, evidence for oxygen toxicity has accumulated both experimentally and clinically. Although there is no unequivocal evidence that one mode of ventilation may be more beneficial than the other, pressure-controlled ventilation may diminish the risk of barotrauma by limiting peak and plateau airway pressures, and the flow pattern results in a more homogenous distribution of the tidal volume and reduced dead space ventilation.

At the end of the procedure, the operative lung is inflated gradually to a peak inspiratory pressure of less than 30 cm H$_2$O to prevent disruption of the staple line. During reinflation of the operative lung, it may be helpful to clamp the lumen serving the dependent lung to limit overdistention.

Periodic arterial blood gas analysis is helpful to ensure adequate ventilation.
End-tidal CO₂ measurement is useful as a trend monitor but may not be accurate due to increased dead-space and an unpredictable gradient between the arterial and end-tidal CO₂ partial pressure.

**Management of Hypoxia**

**Hypoxemia during one-lung anesthesia requires one or more of the following interventions:**

1. Adequate position of the bronchial tube (or bronchial blocker) must be confirmed, as its position relative to the carina can change as a result of surgical manipulations or traction; repeat fiberoptic bronchoscopy through the tracheal lumen can quickly detect this problem. Both lumens of the tube should also be suctioned to exclude excessive secretions or obstruction as a factor.

2. Increase Fio₂ to 1.0.

3. Recruitment maneuvers on the dependent, ventilated lung may eliminate atelectasis and improve shunt.

4. Ensure that there is sufficient (but not excessive) PEEP to the dependent, nonoperative lung to eliminate atelectasis.

5. CPAP or blow-by oxygen to the operative lung will decrease shunting and improve oxygenation. However, uncontrolled inflation of the operative lung during VATS will make identification and visualization of the lung structures difficult for the surgeon; therefore, such maneuvers should be applied carefully and cautiously.

6. Two-lung ventilation should be instituted for severe hypoxemia. If possible, pulmonary artery clamp can also be placed during pneumonectomy to eliminate shunt.

7. In patients with chronic obstructive lung disease, one should always be suspicious of pneumothorax on the dependent, ventilated side as a cause of severe hypoxemia. This complication requires immediate detection and treatment by aborting the surgical procedure, reexpanding the operative lung, and immediately inserting a chest tube in the contralateral chest.

8. If other causes and maneuvers have failed to improve oxygen saturation and one-lung anesthesia is required to complete the anesthetic, one can discontinue all medications known to inhibit HPV (inhalation anesthetics, vasodilators, β-agonists, etc) in favor of alternative drugs and techniques (eg,
Alternatives to One-Lung Ventilation

Ventilation can be stopped for short periods if 100% oxygen is insufflated at a rate greater than oxygen consumption \textit{(apneic oxygenation)} \textit{into an unobstructed tracheal tube}. Adequate oxygenation can often be maintained for prolonged periods, but progressive respiratory acidosis limits the use of this technique to 10 to 20 min in most patients. Arterial \(\text{PCO}_2\) rises 6 mm Hg in the first minute, followed by a rise of 3 to 4 mm Hg during each subsequent minute.

High-frequency positive-pressure ventilation and high-frequency jet ventilation have been used during thoracic procedures as alternatives to one-lung ventilation. A standard tracheal tube may be used with either technique. Small tidal volumes (<2 mL/kg) allow decreased lung excursion, which may facilitate the surgery but still allow ventilation of both lungs. Unfortunately, mediastinal “bounce”—a to-and-fro movement—often interferes with the surgery.

3. Postoperative Management

General Care

Most patients are extubated shortly after surgery to decrease the risk of pulmonary barotrauma (particularly “blowout” [rupture] of the bronchial suture line). All patients (and especially those with marginal pulmonary reserve) should remain intubated until standard extubation criteria are met. When postoperative mechanical ventilation will be required, double-lumen tubes should be replaced with a regular single-lumen tube at the end of surgery. We routinely use a catheter guide (“tube exchanger”) for this purpose and always use this technique when the original laryngoscopy was difficult.

Patients are observed in the postanesthesia care unit, and, in most instances, at least overnight in a monitored or intensive care unit. Atelectasis and shallow breathing (“splinting”) from incisional pain commonly lead to hypoxemia and respiratory acidosis. Gravity-dependent transudation of fluid into the intraoperative dependent lung may also be contributory. Reexpansion edema of the collapsed nondependent lung can also occur.

Postoperative hemorrhage complicates about 3% of thoracotomies and may be associated with up to 20% mortality. Signs of hemorrhage include increased chest tube drainage (>200 mL/h), hypotension, tachycardia, and a falling hematocrit. Postoperative supraventricular tachyarrhythmias are common and
usually require immediate treatment. Routine postoperative care should include semiupright (>30°) positioning, supplemental oxygen (40–50%), incentive spirometry, electrocardiographic and hemodynamic monitoring, a postoperative chest radiograph (to confirm proper position of all thoracostomy tube drains and central lines and to confirm expansion of both lung fields), and adequate analgesia.

**Postoperative Analgesia**

The importance of adequate pain management in the thoracic surgical patient cannot be overstated. Inadequate pain control in these high-risk patients will result in splinting, poor respiratory effort, and the inability to cough and clear secretions, with an end result of airway closure, atelectasis, shunting, and hypoxemia. Irrespective of the modality used, there must be a comprehensive plan for pain management.

A balance between comfort and respiratory depression in patients with marginal lung function is difficult to achieve with parenteral opioids alone. Patients who have undergone thoracotomy clearly benefit from the use of other techniques (described later) that may reduce the need for parenteral opioids. If parenteral opioids are used alone, they are best administered via a patient-controlled analgesia device.

In the absence of an epidural catheter, intercostal or paravertebral nerve blocks with long-acting local anesthetics may facilitate extubation and contribute to postoperative analgesia, but have a limited duration of action, so additional means of pain management must be employed. Alternatives to epidural, intercostal, or paravertebral techniques include infusion of local anesthetic through a catheter placed in the surgical wound during closure or injection of liposomal bupivacaine into the wound, which will markedly reduce the requirement for parenteral opioids and improve the overall quality of analgesia relative to parenteral opioids alone.

Epidural analgesia provides excellent pain relief and continuous therapy and avoids side effects associated with administration of systemic opioids. On the other hand, epidural techniques require around-the-clock attention from the acute pain team for the duration of the infusion and subject the patient to the long list of epidural-related side effects and complications. Most practitioners use a combination of opioid (fentanyl, morphine, hydromorphone) and local anesthetic (bupivacaine or ropivacaine), with the epidural catheter placed at a thoracic level. Gabapentin and low-dose ketamine and lidocaine intravenous infusions
have all been employed as a part of multimodal analgesia regimens following thoracotomy. Oral or intravenous acetaminophen and oral or intravenous nonsteroidal antiinflammatory agents are likewise routinely used in combination with other modalities to reduce or eliminate opioid use for postoperative analgesia.

**Postoperative Complications**

Postoperative complications following thoracotomy are relatively common, but fortunately most are minor and resolve uneventfully. Blood clots and thick secretions may obstruct the airways and result in atelectasis; suctioning may be necessary. Therapeutic bronchoscopy should be considered for persistent atelectasis, particularly when associated with thick secretions. Air leaks from the operative hemithorax are common following segmental and lobar resections. Most air leaks stop after a few days. Bronchopleural fistula presents as a sudden large air leak from the chest tube that may be associated with an increasing pneumothorax and partial lung collapse. When it occurs within the first 24 to 72 h, it is usually the result of inadequate surgical closure of the bronchial stump. Delayed presentation is usually due to necrosis of the suture line associated with inadequate blood flow or infection.

Some complications are rare, but deserve special consideration because they can be life-threatening and require immediate exploratory thoracotomy. Postoperative bleeding is reviewed above. Torsion of a lobe or segment can occur as the remaining lung on the operative side expands to occupy the hemithorax. The torsion usually occludes the pulmonary vein to that part of the lung, causing venous outflow obstruction. Hemothorax and infarction can rapidly follow. The diagnosis is suggested by an enlarging homogeneous density on the chest radiograph and a closed lobar orifice on bronchoscopy. Acute herniation of the heart into the operative hemithorax can occur through the pericardial defect that may remain following a pneumonectomy. A large pressure differential between the two hemithoraces is thought to trigger this catastrophic event. Cardiac herniation into the right hemithorax results in sudden severe hypotension with an elevated CVP because of torsion of the central veins. Cardiac herniation into the left hemithorax following left pneumonectomy results in sudden compression of the myocardium, resulting in hypotension, ischemia, and infarction. A chest radiograph shows a shift of the cardiac shadow into the operative hemithorax.

Extensive mediastinal dissections can injure the phrenic, vagus, and left recurrent laryngeal nerves. Postoperative phrenic nerve palsy presents as
elevation of the ipsilateral hemidiaphragm together with difficulty in weaning the patient from the ventilator. Large chest wall resections may include part of the diaphragm, causing a similar problem, in addition to a flail chest. If an epidural catheter has been placed, any loss of motor function or unexplained back pain should immediately trigger imaging to rule out epidural hematoma.

**SPECIAL CONSIDERATIONS FOR PATIENTS UNDERGOING LUNG RESECTION**

**Massive Pulmonary Hemorrhage**

Massive hemoptysis is usually defined as more than 500 to 600 mL of blood loss from the tracheobronchial tree within 24 h. The etiology is usually tuberculosis, bronchiectasis, a neoplasm, a complication of transbronchial or transthoracic biopsies, or (more commonly in the past) pulmonary artery rupture from overinflation of a pulmonary artery catheter balloon. Emergency surgical management with lung resection is reserved for potentially lethal massive hemoptysis. In most cases, surgery is carried out on an urgent rather than on a true emergent basis whenever possible; even then, operative mortality may exceed 20% (compared with >50% for medical management). Embolization of involved bronchial arteries may be attempted. The most common cause of death is asphyxia secondary to blood or clot in the airway. Patients may be brought to the operating room for rigid bronchoscopy when localization is not possible with fiberoptic flexible bronchoscopy. A bronchial blocker or Fogarty catheter (see earlier discussion) may be placed to tamponade the bleeding, or laser coagulation may be attempted.

Multiple large-bore intravenous catheters should be placed. Sedating drugs should not be given to awake, nonintubated, spontaneously ventilating patients because they are usually already hypoxic; 100% oxygen should be given continuously. If the patient is already intubated and has bronchial blockers in place, sedation is helpful to prevent coughing. The bronchial blocker should be left in position until the lung is resected. When the patient is not intubated, a rapid sequence induction (ketamine or etomidate with succinylcholine) is used. Patients usually swallow a large amount of blood and must be considered to have a full stomach. A large double-lumen bronchial tube is ideal for protecting the normal lung from blood and for suctioning each lung separately. If any difficulty is encountered in placing the double-lumen tube, or its relatively small lumens occlude easily, a large (>8.0-mm inner diameter) single-lumen tube may be used.
with a bronchial blocker to provide lung isolation.

**Pulmonary Cyst & Bulla**

Pulmonary cysts or bullae may be congenital or acquired as a result of emphysema. Large bullae can impair ventilation by compressing the surrounding lung. These air cavities often behave as if they have a one-way valve, predisposing them to progressively enlarge. Lung resection may be undertaken for progressive dyspnea or recurrent pneumothorax. The greatest risk of anesthesia is rupture of the air cavity during positive-pressure ventilation, resulting in tension pneumothorax; the latter may occur on either side prior to thoracotomy or on the nonoperative side during the lung resection. Induction of anesthesia with maintenance of spontaneous ventilation is desirable until the side with the cyst or bullae is isolated with a double-lumen tube, or until a chest tube is placed; most patients have a large increase in dead space, so assisted ventilation is necessary to avoid excessive hypercarbia. Nitrous oxide is contraindicated in patients with cysts or bullae because it can expand the air space and cause rupture. The latter may be signaled by sudden hypotension, bronchospasm, or an abrupt rise in peak inflation pressure and requires immediate placement of a chest tube.

**Lung Abscess**

Lung abscesses result from primary pulmonary infections, obstructing pulmonary neoplasms (see earlier discussion), or, rarely, hematogenous spread of systemic infections. The two lungs should be isolated to prevent contamination of the healthy lung. A rapid-sequence intravenous induction with tracheal intubation with a double-lumen tube is generally recommended, with the affected lung in a dependent position. As soon as the double-lumen tube is placed, both bronchial and tracheal cuffs should be inflated. The bronchial cuff should make a tight seal before the patient is turned into the lateral decubitus position, with the diseased lung in a nondependent position. The diseased lung should be frequently suctioned during the procedure to decrease the likelihood of contaminating the healthy lung.

**Bronchopleural Fistula**

Bronchopleural fistulas occur following lung resection (usually pneumonectomy), rupture of a pulmonary abscess into a pleural cavity,
pulmonary barotrauma, or spontaneous rupture of bullae. The majority of patients are treated (and cured) conservatively; patients come to surgery when chest tube drainage has failed. **Anesthetic management may be complicated by the inability to effectively ventilate the patient with positive pressure because of a large air leak, the potential for a tension pneumothorax, and the risk of contaminating the other lung if an empyema is present.** The empyema is usually drained, prior to closure of the fistula.

A correctly placed double-lumen tube greatly simplifies anesthetic management by isolating the fistula and allowing one-lung ventilation to the normal lung. The patient should be extubated as soon as possible after the repair.

---

**Anesthesia for Tracheal Resection**

**Preoperative Considerations**

Tracheal resection is most commonly performed for tracheal stenosis, tumors, or, less commonly, congenital abnormalities. Tracheal stenosis can result from penetrating or blunt trauma, as well as tracheal intubation and tracheostomy. Squamous cell and adenoid cystic carcinomas account for the majority of tumors. Progressive compromise of the tracheal lumen produces dyspnea. Wheezing or stridor may be evident only with exertion. The dyspnea may be worse when the patient is lying down, with progressive airway obstruction. Hemoptysis can also complicate tracheal tumors. CT or MR imaging is valuable in localizing the lesion. **Measurement of flow–volume loops confirms the location of the obstruction and aids the clinician in evaluating the severity of the lesion (Figure 25–12).**
Anesthetic Considerations

Little premedication is given, as most patients presenting for tracheal resection have moderate to severe airway obstruction. Use of an anticholinergic agent to dry secretions is controversial because of the theoretical risk of inspissation. Monitoring should include direct arterial pressure measurements.
An inhalation induction (in 100% oxygen) is carried out in patients with severe obstruction. Sevoflurane is preferred because it is the potent anesthetic that is least irritating to the airway. Spontaneous ventilation is maintained throughout induction. NMBs are generally avoided because of the potential for complete airway obstruction following neuromuscular blockade. Laryngoscopy is performed only when the patient is judged to be under deep anesthesia. Intravenous lidocaine (1–2 mg/kg) can deepen the anesthesia without depressing respirations. The surgeon may then perform rigid bronchoscopy to evaluate and possibly dilate the lesion. Following bronchoscopy, the patient is intubated with a tracheal tube small enough to be passed distal to the obstruction whenever possible.

A collar incision is utilized for high tracheal lesions. The surgeon divides the trachea in the neck and advances a sterile armored tube into the distal trachea, passing off a sterile connecting breathing circuit to the anesthesiologist for ventilation during the resection. Following the resection and completion of the posterior part of the reanastomosis, the armored tube is removed, and the original tracheal tube is advanced distally, past the anastomosis (Figure 25–13). Alternatively, high-frequency jet ventilation may be employed during the anastomosis by passing the jet cannula past the obstruction and into the distal trachea (Figure 25–14). Return of spontaneous ventilation and early extubation at the end of the procedure are desirable. Patients should be positioned with the neck flexed immediately after the operation to minimize tension on the suture line (Figure 25–15).

**FIGURE 25–13** A–D: Airway management of a high tracheal lesion.
FIGURE 25–14  Tracheal resection using high-frequency jet ventilation. A: The catheter is advanced past the obstruction, and the cuff is deflated when jet ventilation is initiated. B: The catheter is advanced distally by the surgeon. Jet ventilation can be continued without interruption during resection and reanastomosis.
FIGURE 25–15 Position of the patient before (A) and after (B) tracheal resection and reanastomosis with the patient’s neck flexed for the first 24 to 48 h.

Surgical management of low tracheal lesions requires a median sternotomy or right posterior thoracotomy. Anesthetic management may include more complicated techniques, such as high-frequency ventilation or even cardiopulmonary bypass (CPB) in complex congenital cases.

Anesthesia for Video-Assisted Thoracoscopic Surgery (VATS)

VATS is now used for most lung resections. Most procedures are performed through three or more small incisions in the chest, with the patient in the lateral decubitus position. Anesthetic management is similar to that for open procedures, except that one-lung ventilation is required (as opposed to being
Anesthesia for Diagnostic Thoracic Procedures

Bronchoscopy

Rigid bronchoscopy for removal of foreign bodies or tracheal dilation is usually performed under general anesthesia. These procedures are complicated by the need to share the airway with the surgeon or pulmonologist; fortunately, these procedures are often brief. After a standard intravenous induction, anesthesia is often maintained with total intravenous anesthesia, and a short- or intermediate-acting NMB. One of three techniques can then be used during rigid bronchoscopy: (1) apneic oxygenation using a small catheter positioned alongside the bronchoscope to insufflate oxygen (see above); (2) conventional ventilation through the side arm of a ventilating bronchoscope (when the proximal window of this instrument is opened for suctioning or biopsies, ventilation must be interrupted); or (3) jet ventilation through an injector-type bronchoscope.

Mediastinoscopy

Mediastinoscopy, much more commonly employed in the past than at present, provides access to the mediastinal lymph nodes and is used to establish either the diagnosis or the resectability of intrathoracic malignancies (see above). Preoperative CT or MR imaging is useful for evaluating tracheal distortion or compression.

Mediastinoscopy is performed under general tracheal anesthesia with neuromuscular paralysis. Venous access with a large-bore (14- to 16-gauge) intravenous catheter is mandatory because of the risk of bleeding and the difficulty in controlling bleeding when it occurs. Because the innominate artery may be compressed during the procedure, blood pressure should be measured in the left arm.

Complications associated with mediastinoscopy include (1) vagally mediated reflex bradycardia from compression of the trachea or the great vessels; (2) excessive hemorrhage; (3) cerebral ischemia from compression of the innominate artery (detected with a right radial arterial line or pulse oximeter on the right hand); (4) pneumothorax (usually presents postoperatively); (5) air embolism (because of a 30° head elevation, the risk is greatest during
spontaneous ventilation); (6) recurrent laryngeal nerve damage; and (7) phrenic nerve injury.

**Bronchoalveolar Lavage**

Bronchoalveolar lavage may be employed for patients with pulmonary alveolar proteinosis. These patients produce excessive quantities of surfactant and fail to clear it. They present with dyspnea and bilateral consolidation on the chest radiograph. In such patients, bronchoalveolar lavage may be indicated for severe hypoxemia or worsening dyspnea. Often, one lung is lavaged, allowing the patient to recover for a few days before the other lung is lavaged; the “sicker” lung is therefore lavaged first.

Unilateral bronchoalveolar lavage is performed under general anesthesia with a double-lumen bronchial tube. The cuffs on the tube should be properly positioned and should make a watertight seal to prevent spillage of fluid into the other side. The procedure is normally done in the supine position; although lavage with the lung in a dependent position helps to minimize contamination of the other lung, this position can cause severe ventilation/perfusion mismatch. Warm normal saline is infused into the lung to be treated and is drained by gravity. At the end of the procedure, both lungs are well suctioned, and the double-lumen tracheal tube is replaced with a single-lumen tracheal tube.

**Anesthesia for Lung Transplantation**

**PREOPERATIVE CONSIDERATIONS**

Lung transplantation is indicated for end-stage pulmonary parenchymal disease or pulmonary hypertension. Candidates are functionally incapacitated by dyspnea and have a poor prognosis. Criteria vary according to the primary disease process. Common etiologies are listed in Table 25–3. Lung transplantation (as is true for all solid organ transplants) is limited by the availability of suitable organs, not by the availability of recipients. Patients typically have dyspnea at rest or with minimal activity and resting hypoxemia ($P_{O_2} < 50$ mm Hg) with increasing oxygen requirements. Progressive $CO_2$ retention is also very common. Patients may be ventilator dependent or may be supported by extracorporeal membrane oxygenation (ECMO).

**TABLE 25–3  Indications for isolated lung transplantation.**
ANESTHETIC CONSIDERATIONS

1. Preoperative Management

Effective coordination between the organ-retrieval team and the transplant team minimizes graft ischemia time and avoids unnecessary prolongation of pretransplant anesthesia time. These procedures are performed on an emergency basis; therefore, patients may have little time to fast for surgery. Oral cyclosporine also may be given preoperatively. Administration of a clear antacid, an H₂ blocker, or metoclopramide should be considered. Any premedication is usually administered only in the operating room when the patient is directly attended and monitored. Immunosuppressants and antibiotics are also administered after induction and prior to surgical incision.

2. Intraoperative Management

Monitoring

Strict asepsis should be observed for invasive monitoring procedures. Central venous access might be accomplished only after induction of anesthesia because patients may not be able to lie flat while awake. Patients with a patent foramen ovale are at risk of paradoxical embolism because of potentially high right atrial pressures. Transesophageal echocardiography is used to assess right ventricular function, integrity of the intraatrial septum, and pulmonary vein flow following anastomosis.

Induction & Maintenance of Anesthesia
Induction with ketamine, etomidate, an opioid, or a combination of these agents is employed, avoiding precipitous drops in blood pressure. An NMB is used to facilitate laryngoscopy. Permissive hypercapnia and protective lung ventilation strategies are employed. Inspired oxygen concentration is adjusted to maintain \( \text{Sao}_2 \) above 92%. Tidal volumes are maintained below 6 mL/kg using pressure-controlled ventilation. Inhalational agents are administered as tolerated for anesthesia and to provide a possible lung-protective effect.

Hypercarbia and acidosis may lead to pulmonary vasoconstriction and acute right heart failure, and hemodynamic support with inotropes may be required for these patients.

**Single-Lung Transplantation**

Whether to employ CPB (see Chapter 22) or ECMO during transplantation of one lung is based on the patient’s response to collapsing the lung to be replaced and clamping its pulmonary artery as well as institutional practices. Persistent arterial hypoxemia (\( \text{SpO}_2 < 88\% \)) or right heart failure may require institution of CPB. Drugs such as milrinone may be used for inotropic support, and inhaled nitric oxide can be delivered to dilate the pulmonary vasculature. After the recipient lung is removed, the pulmonary artery, left atrial cuff (with the pulmonary veins), and bronchus of the donor lung are anastomosed. Flexible bronchoscopy is used to examine the bronchial suture line after its completion.

**Double-Lung or Heart–Lung Transplantation**

A “clamshell” transverse sternotomy can be used for double-lung transplantation. Heart–lung transplantation is performed through median sternotomy with CPB.

**Posttransplantation Management**

After anastomosis of the donor organ or organs, ventilation to both lungs is resumed. Following transplantation, peak inspiratory pressures should be maintained at the minimum pressure compatible with good lung expansion, and the inspired oxygen concentration should be maintained as close to room air as allowed by a \( \text{Pao}_2 \) greater than 60 mm Hg. If transplantation has been performed on CPB, the patient is separated from CPB. Pulmonary vasodilators, inhaled nitric oxide, and inotropes (see earlier discussion) may be necessary.
Transesophageal echocardiography is helpful in identifying right or left ventricular dysfunction, as well as in evaluating blood flow in the pulmonary vessels after transplantation.

Transplantation disrupts the neural innervation, lymphatic drainage, and bronchial circulation of the transplanted lung. The respiratory pattern is unaffected, but the cough reflex is abolished below the carina. Bronchial hyperreactivity is observed in some patients. Hypoxic pulmonary vasoconstriction remains normal. Loss of lymphatic drainage increases extravascular lung water and predisposes the transplanted lung to pulmonary edema. Consequently, fluid overload should be avoided. Loss of the bronchial circulation predisposes to ischemic breakdown of the bronchial suture line.

3. Postoperative Management

Patients are extubated after surgery as soon as is feasible. A thoracic epidural catheter may be employed for postoperative analgesia when coagulation studies are normal. The postoperative course may be complicated by acute rejection, infections, and renal and hepatic dysfunction. Deteriorating lung function may result from rejection or reperfusion injury. Occasionally, temporary ECMO may be necessary. Frequent bronchoscopy with transbronchial biopsies and lavage are necessary to differentiate between rejection and infection. Nosocomial gram-negative bacteria, cytomegalovirus, Candida, Aspergillus, and Pneumocystis jiroveci are common pathogens. Other postoperative surgical complications include damage to the phrenic, vagus, and left recurrent laryngeal nerves.

Anesthesia for Esophageal Surgery

PREOPERATIVE CONSIDERATIONS

Common indications for esophageal surgery include tumors, gastroesophageal reflux, and motility disorders (achalasia). Surgical procedures include simple endoscopy, esophageal dilation, cervical esophagomyotomy, open or thoracoscopic distal esophagomyotomy, insertion or removal of esophageal stents, and open or minimally invasive esophagectomy. Squamous cell carcinomas account for the majority of esophageal tumors; adenocarcinomas are less common, whereas benign tumors (leiomyomas) are rare. Most tumors occur in the distal esophagus. Operative treatment may be palliative or curative. After esophageal resection, the stomach is pulled up into the thorax, or the esophagus
is functionally replaced with part of the colon (*colonic interposition*).

Gastroesophageal reflux is treated surgically when the esophagitis is refractory to medical management or results in complications such as stricture, recurrent pulmonary aspiration, or a Barrett esophagus (columnar epithelium). A variety of antireflux operations may be performed (Nissen, Belsey, Hill, or Collis-Nissen) via thoracic or abdominal approaches, often laparoscopically.

Achalasia and systemic sclerosis (scleroderma) account for the majority of surgical procedures performed for motility disorders. The former usually occurs as an isolated finding, whereas the latter is part of a generalized collagen–vascular disorder. Cricopharyngeal muscle dysfunction can be associated with a variety of neurogenic or myogenic disorders and often results in a Zenker diverticulum.

**ANESTHETIC CONSIDERATIONS**

Regardless of the procedure, a common anesthetic concern in patients with esophageal disease is the risk of pulmonary aspiration. This may result from obstruction, altered motility, or abnormal sphincter function. In fact, most patients typically complain of dysphagia, heartburn, regurgitation, coughing, or wheezing when lying flat. Dyspnea on exertion may also be prominent when chronic aspiration results in pulmonary fibrosis. Patients with malignancies may present with anemia and weight loss. Esophageal cancer patients usually have a history of cigarette smoking and alcohol consumption, so patients should be evaluated for coexisting chronic obstructive pulmonary disease, coronary artery disease, and liver dysfunction. Patients with systemic sclerosis (scleroderma) should be evaluated for involvement of other organs, particularly the kidneys, heart, and lungs; Raynaud phenomena is also common.

In patients with reflux, consideration should be given to administering one or more of the following preoperatively: metoclopramide, an H$_2$-receptor blocker, sodium citrate, or a proton-pump inhibitor. In such patients, a rapid-sequence induction should be used. A double-lumen tube is used for procedures involving thoracoscopy or thoracotomy. The anesthesiologist may be asked to pass a large-diameter bougie into the esophagus as part of the surgical procedure; great caution must be exercised to help avoid pharyngeal or esophageal injury.

Transhiatal (blunt) and thoracic esophagectomies deserve special consideration. The former requires an upper abdominal incision and a left cervical incision, whereas the latter requires posterolateral thoracotomy, an abdominal incision, and, finally, a left cervical incision. Parts of the procedure
may be performed using laparoscopy or VATS. Direct monitoring of arterial pressure is indicated. During the transhiatal approach to esophagectomy, substernal and diaphragmatic retractors can interfere with cardiac function. Moreover, as the esophagus is freed up blindly from the posterior mediastinum by blunt dissection, the surgeon’s hand transiently interferes with cardiac filling and produces profound hypotension. The dissection can also induce marked vagal stimulation.

Colonic interposition involves forming a pedicle graft of the colon and passing it through the posterior mediastinum up to the neck to take the place of the esophagus. This procedure is lengthy, and maintenance of an adequate blood pressure, cardiac output, and hemoglobin concentration is necessary to ensure graft viability. Graft ischemia may be heralded by a progressive metabolic acidosis. Both too much and too little fluid administration can negatively impact outcome. Goal-directed fluid therapy using hemodynamic measures (eg, stroke volume variation) may be helpful in perioperative fluid management of the esophagectomy patient.

Lung protective ventilation and multimodal perioperative analgesia should be used postoperatively.

CASE DISCUSSION

**Mediastinal Adenopathy**

A 9-year-old boy with mediastinal lymphadenopathy seen on a chest radiograph presents for biopsy of a cervical lymph node.

**What is the most important preoperative consideration?**

Is there any evidence of airway compromise? Tracheal compression may produce dyspnea (proximal obstruction) or a nonproductive cough (distal obstruction).

Asymptomatic compression is also common and may be evident only as tracheal deviation on physical or radiographic examinations. A CT scan of the chest provides invaluable information about the presence, location, and severity of airway compression. Flow–volume loops will also detect subtle airway obstruction and provide important information regarding the location and functional importance of the obstruction (see earlier discussion).
**Does the absence of any preoperative dyspnea make severe intraoperative respiratory compromise less likely?**

No. Severe airway obstruction can occur following induction of anesthesia in these patients even in the absence of any preoperative symptoms. This mandates that the chest radiograph and CT scan be reviewed for evidence of asymptomatic airway obstruction. The point of obstruction is typically distal to the tip of the tracheal tube. Moreover, loss of spontaneous ventilation can precipitate complete airway obstruction.

**What is the superior vena cava syndrome?**

Superior vena cava syndrome is the result of progressive enlargement of a mediastinal mass and compression of mediastinal structures, particularly the vena cava. Lymphomas are most commonly responsible, but primary pulmonary or mediastinal neoplasms can also produce the syndrome. Superior vena cava syndrome is often associated with severe airway obstruction and cardiovascular collapse on induction of general anesthesia. Caval compression produces venous engorgement and edema of the head, neck, and arms. Direct mechanical compression, as well as mucosal edema, severely compromise airflow in the trachea. Most patients favor an upright posture, as recumbency worsens the airway obstruction. Cardiac output may be severely depressed due to impeded venous return from the upper body, direct mechanical compression of the heart, and (with malignancies) pericardial invasion. An echocardiogram is useful in evaluating cardiac function and detecting pericardial fluid.

**What is the anesthetic of choice for a patient with superior vena cava syndrome?**

The absence of signs or symptoms of airway compression or superior vena cava syndrome does not preclude potentially life-threatening complications following induction of general anesthesia. Therefore, biopsy of a peripheral node (usually cervical or scalene) under local anesthesia is safest whenever possible. Although establishing a diagnosis is of prime importance, the presence of significant airway compromise or the superior vena cava syndrome may dictate empiric treatment with corticosteroids prior to tissue diagnosis at surgery (cancer is the most common cause); preoperative radiation therapy or chemotherapy may also be considered. The patient can usually safely undergo surgery with general anesthesia once
airway compromise and other manifestations of the superior vena cava syndrome are alleviated.

General anesthesia may be indicated for establishing a diagnosis in young or uncooperative patients who have no evidence of airway compromise or the superior vena cava syndrome, and, rarely, for patients unresponsive to steroids, radiation, and chemotherapy.

**How does the presence of airway obstruction and the superior vena cava syndrome influence management of general anesthesia?**

1. **Premedication:** If any drug is given it should be only an anticholinergic. The patient should be transported to the operating room in a semiupright position with supplemental oxygen.

2. **Monitoring:** In addition to standard monitors, an arterial line is helpful, but it should be placed after induction in young patients. At least one large-bore intravenous catheter should be placed in a lower extremity, as venous drainage from the upper body may be unreliable.

3. **Airway management:** Difficulties with ventilation and intubation should be anticipated. Following preoxygenation, awake intubation with an armored tracheal tube may be safest in a cooperative patient. Use of a flexible bronchoscope is advantageous in the presence of airway distortion and will define the site and degree of obstruction. Coughing or straining, however, may precipitate complete airway obstruction because the resultant positive pleural pressure increases intrathoracic tracheal compression. Passing the armored tube beyond the area of compression may obviate this problem. Uncooperative patients require a sevoflurane inhalation induction.

4. **Induction:** The goal should be a smooth induction maintaining spontaneous ventilation and hemodynamic stability. The ability to ventilate the patient with a good airway should be established prior to use of an NMB. Using 100% oxygen, one of three induction techniques can be used: (1) intravenous ketamine (because it results in greater hemodynamic stability in patients with reduced cardiac output); (2) inhalational induction with a volatile agent (usually sevoflurane); or (3) incremental small doses of propofol or etomidate.

Positive-pressure ventilation can precipitate severe hypotension, and volume loading prior to induction may partly offset impaired ventricular
filling secondary to caval obstruction.

5. **Maintenance of anesthesia:** The technique selected should be tailored to the patient’s hemodynamic status. Following intubation, neuromuscular blockade prevents coughing or straining.

6. **Extubation:** At the end of the procedure, patients should be left intubated until the airway obstruction has resolved, as determined by flexible bronchoscopy or the presence of an air leak around the tracheal tube when the tracheal cuff is deflated.

**SUGGESTED READINGS**

Cerebral perfusion pressure is the difference between mean arterial pressure and intracranial pressure (or central venous pressure, whichever is greater).

The cerebral autoregulation curve is shifted to the right in patients with chronic arterial hypertension.

The most important extrinsic influences on cerebral blood flow (CBF) are respiratory gas tensions—particularly $\text{PaCO}_2$. CBF is directly proportionate to $\text{PaCO}_2$ between tensions of 20 and 80 mg Hg. Blood flow changes approximately 1 to 2 mL/100 g/min per mm Hg change in $\text{PaCO}_2$.

CBF changes 5% to 7% per 1°C change in temperature. Hypothermia decreases both cerebral metabolic rate and CBF, whereas pyrexia has the reverse effect.

The movement of a given substance across the blood–brain barrier is governed simultaneously by its size, charge, lipid solubility, and degree of protein binding in blood.

The blood–brain barrier may be disrupted by severe hypertension, tumors, trauma, strokes, infection, marked hypercapnia, hypoxia, and sustained seizure activity.

The cranial vault is a rigid structure with a fixed total volume, consisting of brain (80%), blood (12%), and cerebrospinal fluid (8%). Any increase in one component must be offset by an equivalent decrease in another to prevent a rise in intracranial pressure.

With the exception of ketamine, all intravenous agents either have little effect on or reduce cerebral metabolic rate and CBF.

With normal autoregulation and an intact blood–brain barrier,
Anesthetic agents may have profound effects on cerebral metabolism, blood flow, cerebrospinal fluid (CSF) dynamics, and cerebral blood volume and pressure. In some instances, these alterations are deleterious, whereas in others they may be beneficial. This chapter reviews important physiological concepts and discusses the cerebral effects of commonly used anesthetics.

Cerebral Physiology

CEREBRAL METABOLISM

The brain normally consumes 20% of total body oxygen. Most cerebral oxygen consumption (60%) is used to generate adenosine triphosphate (ATP) to support neuronal electrical activity (Figure 26–1). The cerebral metabolic rate (CMR) is usually expressed in terms of oxygen consumption (CMRO$_2$) and averages 3 to 3.8 mL/100 g/min (50 mL/min) in adults. CMRO$_2$ is greatest in the gray matter of the cerebral cortex and generally parallels cortical electrical activity. Because of the rapid oxygen consumption and the absence of significant oxygen reserves, interruption of cerebral perfusion usually results in unconsciousness within 10 s. If blood flow is not reestablished within 3 to 8 min under most conditions, ATP stores are depleted, and irreversible cellular injury occurs. The more rostral “higher” brain regions (cortex, hippocampus) are more sensitive to hypoxic injury than the brainstem.
Neuronal cells normally utilize glucose as their primary energy source. Brain glucose consumption is approximately 5 mg/100 g/min, of which more than 90% is metabolized aerobically. CMR$_{O_2}$ therefore normally parallels glucose consumption. This relationship is not maintained during starvation, when ketone bodies (acetoacetate and β-hydroxybutyrate) also become major energy substrates. Although the brain can also take up and metabolize lactate, cerebral function is normally dependent on a continuous supply of glucose. Acute sustained hypoglycemia is injurious to the brain. Paradoxically, hyperglycemia can exacerbate global and focal hypoxic brain injury by accelerating cerebral acidosis and cellular injury. Adequate control of perioperative blood glucose concentration is advocated in part to prevent adverse effects of hyperglycemia during ischemia; however, overzealous blood glucose control can likewise produce injury through iatrogenic hypoglycemia.

CEREBRAL BLOOD FLOW

Cerebral blood flow (CBF) varies with metabolic activity. There are a variety of methods available to directly measure CBF, including positron emission tomography, xenon washout, and computed tomography perfusion scans. Except in research environments, these methods do not lend themselves to bedside monitoring of CBF. Regional CBF parallels metabolic activity and can vary from 10 to 300 mL/100 g/min. For example, motor activity of a limb is associated with a rapid increase in regional CBF of the corresponding motor cortex. Similarly, visual activity is associated with an increase in regional CBF of the corresponding occipital visual cortex.

Although overall CBF averages 50 mL/100 g/min at a PaCO$_2$ of 40 mmHg,
flow in gray matter is roughly 80 mL/100 g/min, whereas that in white matter is 20 mL/100 g/min. Total CBF in adults averages 750 mL/min (15–20% of cardiac output). Flow rates below 20 to 25 mL/100 g/min are usually associated with cerebral impairment, as evidenced by slowing on the electroencephalogram (EEG). CBF rates below 20 mL/100 g/min typically produce a flat (isoelectric) EEG, whereas rates below 10 mL/100 g/min are usually associated with irreversible brain damage.

Indirect measures are often used to estimate the adequacy of CBF and brain tissue oxygen delivery in clinical settings. These methods include:

• The velocity of CBF can be measured using transcranial Doppler (TCD); see Chapter 5 for a discussion of the Doppler effect. An ultrasound probe (2 mHz, pulse wave Doppler) is placed in the temporal area above the zygomatic arch, which allows insonation of the middle cerebral artery. Normal velocity in the middle cerebral artery is approximately 55 cm/s. Velocities greater than 120 cm/s can indicate cerebral artery vasospasm following subarachnoid hemorrhage or hyperemic blood flow. Comparison between the velocities in the extracranial internal carotid artery and the middle cerebral artery (the Lindegaard ratio) can distinguish between these conditions. Middle cerebral artery velocity three times that of the velocity measured in the extracranial internal carotid artery more likely reflects cerebral artery vasospasm.

• Near-infrared spectroscopy was discussed in Chapter 6. Decreased saturation is associated with impaired cerebral oxygen delivery, although near-infrared spectroscopy primarily reflects cerebral venous oxygen saturation.

• Brain tissue oximetry measures the oxygen tension in brain tissue through placement of a bolt with a Clark electrode oxygen sensor. Brain tissue CO$_2$ tension can also be measured using a similarly placed infrared sensor. Normal brain tissue oxygen tension varies from 20 to 50 mm Hg. Brain tissue oxygen tensions less than 20 mm Hg warrant interventions, and values less than 10 mm Hg are indicative of brain ischemia.

**REGULATION OF CEREBRAL BLOOD FLOW**

1. **Cerebral Perfusion Pressure**

Cerebral perfusion pressure (CPP) is the difference between mean arterial pressure (MAP) and intracranial pressure (ICP) (or central venous pressure [CVP], if it is greater than ICP). MAP – ICP (or CVP) = CPP. CPP is normally
80 to 100 mm Hg. Moreover, because ICP is normally less than 10 mm Hg, CPP is primarily dependent on MAP.

Moderate to severe increases in ICP (>30 mm Hg) can compromise CPP and CBF, even in the presence of a normal MAP. Patients with CPP values less than 50 mm Hg often show slowing on the EEG, whereas those with a CPP between 25 and 40 mm Hg typically have a flat EEG. Sustained perfusion pressures less than 25 mm Hg may result in irreversible brain damage.

2. Autoregulation

Much like the heart and kidneys, the brain normally tolerates a wide range of blood pressure, with little change in blood flow. The cerebral vasculature rapidly (10–60 s) adapts to changes in CPP. Decreases in CPP result in cerebral vasodilation, whereas elevations induce vasoconstriction. In normal individuals, CBF remains nearly constant between MAPs of about 60 and 160 mm Hg (Figure 26–2), although the lower limit of this autoregulation may be increased in some patients. Outside these limits, blood flow becomes pressure dependent. Pressures above 150 to 160 mm Hg can disrupt the blood–brain barrier (see below) and may result in cerebral edema and hemorrhage.

FIGURE 26–2 Normal cerebral autoregulation curve.

The cerebral autoregulation curve (Figure 26–2) is shifted to the right in patients with chronic arterial hypertension. Both upper and lower limits are
shifted. Flow becomes more pressure dependent at low “normal” arterial pressures in return for cerebral protection at higher arterial pressures. Studies suggest that long-term antihypertensive therapy can restore cerebral autoregulation limits toward normal. Myogenic, neurogenic, and metabolic mechanisms may contribute to cerebral autoregulation.

3. Extrinsic Mechanisms

Respiratory Gas Tensions

The most important extrinsic influences on CBF are respiratory gas tensions—particularly PaCO₂. CBF is directly proportionate to PaCO₂ between tensions of 20 and 80 mm Hg (Figure 26–3). Blood flow changes approximately 1 to 2 mL/100 g/min per millimeter of mercury change in PaCO₂. This effect is almost immediate and is thought to be secondary to changes in the pH of CSF and cerebral tissue. Because ions do not readily cross the blood–brain barrier (see below) but CO₂ does, acute changes in PaCO₂ but not HCO₃⁻ affect CBF. Thus, acute metabolic acidosis has little effect on CBF because hydrogen ions (H⁺) cannot readily cross the blood–brain barrier. After 24 to 48 h, CSF HCO₃⁻ ion concentration adjusts to compensate for the change in PaCO₂, so that the effects of hypocapnia and hypercapnia are diminished. Marked hyperventilation (PaCO₂ <20 mm Hg) shifts the oxygen–hemoglobin dissociation curve to the left, and, with changes in CBF, may result in EEG changes suggestive of cerebral impairment, even in normal individuals.
Only marked changes in PaO₂ alter CBF. Whereas hyperoxia may be associated with only minimal decreases (−10%) in CBF, severe hypoxemia (PaO₂ < 50 mm Hg) greatly increases CBF (Figure 26–3).

**Temperature**

CBF changes 5% to 7% per 1°C change in temperature. Hypothermia decreases both CMR and CBF, whereas hyperthermia has the reverse effect. Between 17°C and 37°C, the Q10 for humans is approximately 2—that is, for every 10° increase in temperature, the CMR doubles. Conversely, the CMR decreases by 50% if the temperature of the brain falls by 10°C (e.g., from 37°C to 27°C) and another 50% if the temperature decreases from 27°C to 17°C. At 20°C, the EEG is isoelectric, but further decreases in temperature continue to reduce CMR throughout the brain. Hyperthermia (above 42°C) may result in neuronal cell injury.

**Viscosity**

The most important determinant of blood viscosity is hematocrit. A decrease in hematocrit decreases viscosity and can improve CBF; unfortunately, a reduction
in hematocrit also decreases the oxygen-carrying capacity and thus can potentially impair oxygen delivery. Elevated hematocrit, as may be seen with marked polycythemia, increases blood viscosity and can reduce CBF. Some studies suggest that optimal cerebral oxygen delivery may occur at hematocrits of approximately 30%.

**Autonomic Influences**

Intracranial vessels are innervated by the sympathetic (vasoconstrictive) and parasympathetic (vasodilatory) systems. Intense sympathetic stimulation induces vasoconstriction in these vessels, which can limit CBF. Autonomic innervation may also play an important role in cerebral vasospasm following brain injury and stroke.

**BLOOD–BRAIN BARRIER**

Cerebral blood vessels are unique in that the junctions between vascular endothelial cells are nearly fused. The paucity of pores is responsible for what is termed the blood–brain barrier. This lipid barrier allows the passage of lipid-soluble substances, but restricts the movement of those that are ionized or have large molecular weights. Thus, the movement of a given substance across the blood–brain barrier is governed simultaneously by its size, charge, lipid solubility, and degree of protein binding in blood. Carbon dioxide, oxygen, and lipid-soluble molecules (such as most anesthetics) freely enter the brain, whereas most ions, proteins, and large substances (such as mannitol) penetrate poorly.

Water moves freely across the blood–brain barrier as a consequence of bulk flow, whereas movement of even small ions is impeded (the equilibration half-life of Na$^+$ is 2–4 h). As a result, rapid changes in plasma electrolyte concentrations (and, secondarily, osmolality) produce a transient osmotic gradient between plasma and the brain. Acute hypertonicity of plasma results in net movement of water out of the brain, whereas acute hypotonicity causes a net movement of water into the brain. These effects are short-lived, as equilibration eventually occurs, but, when marked, they can cause rapid fluid shifts in the brain. Mannitol, an osmotically active substance that does not normally cross the blood–brain barrier, causes a sustained decrease in brain water content and is often used to decrease brain volume.

The blood–brain barrier may be disrupted by severe hypertension, tumors, trauma, strokes, infection, marked hypercapnia, hypoxia, and sustained seizure activity. Under these conditions, fluid movement across the blood–brain barrier
becomes dependent on hydrostatic pressure rather than osmotic gradients.

**CEREBROSPINAL FLUID**

CSF is found in the cerebral ventricles and cisterns and in the subarachnoid space surrounding the brain and spinal cord. CSF cushions the central nervous system (CNS) against trauma and helps clear waste products.

Classical (but currently controversial) teaching is that most of the CSF is formed by the choroid plexuses of the lateral ventricles. Smaller amounts are formed directly by the ventricles’ ependymal cell linings, and yet smaller quantities are formed from fluid leaking into the perivascular spaces surrounding cerebral vessels (blood–brain barrier leakage). In adults, normal total CSF production is about 21 mL/h (500 mL/d), yet total CSF volume is only about 150 mL. Classical teaching (also currently controversial) is that CSF flows from the lateral ventricles through the intraventricular foramina (of Monro) into the third ventricle, through the cerebral aqueduct (of Sylvius) into the fourth ventricle, and through the median aperture of the fourth ventricle (foramen of Magendie) and the lateral apertures of the fourth ventricle (foramina of Luschka) into the cerebellomedullary cistern (cisterna magna) (Figure 26–4). From the cerebellomedullary cistern, CSF enters the subarachnoid space, circulating around the brain and spinal cord before being absorbed in arachnoid granulations over the cerebral hemispheres. Whether there is actual unidirectional “circulation” of the CSF is currently in dispute.
FIGURE 26–4  The flow of cerebrospinal fluid in the central nervous system, per classic dogma. As noted in the text, unidirectional flow of CSF is now
CSF formation involves active secretion of sodium in the choroid plexuses. The resulting fluid is isotonic with plasma despite lower potassium, bicarbonate, and glucose concentrations. Its protein content is limited to the very small amounts that leak into perivascular fluid. Carbonic anhydrase inhibitors (acetazolamide), corticosteroids, spironolactone, furosemide, isoflurane, and vasoconstrictors decrease CSF production.

Absorption of CSF involves the translocation of fluid from the arachnoid granulations into the cerebral venous sinuses. Smaller amounts are absorbed at nerve root sleeves and by meningeal lymphatics. Because the brain and spinal cord lack lymphatics, absorption of CSF is also the principal means by which perivascular and interstitial protein is returned to the blood.

**INTRACRANIAL PRESSURE**

The cranial vault is a rigid structure with a fixed total volume, consisting of brain (80%), blood (12%), and CSF (8%). Any increase in one component must be offset by an equivalent decrease in another to prevent a rise in ICP. By convention, ICP means supratentorial CSF pressure measured in the lateral ventricles or over the cerebral cortex and is normally 10 mm Hg or less. Minor variations may occur, depending on the site measured, but, in the lateral recumbent position, lumbar CSF pressure normally approximates supratentorial pressure.

Intracranial elastance is determined by measuring the change in ICP in response to a change in intracranial volume. Normally, small increases in volume of one component are initially well compensated (Figure 26–5). A point is eventually reached, however, at which further increases produce precipitous rises in ICP. Major compensatory mechanisms include (1) an initial displacement of CSF from the cranial to the spinal compartment, (2) an increase in CSF absorption, (3) a decrease in CSF production, and (4) a decrease in total cerebral blood volume (primarily venous).
The concept of total intracranial compliance is useful clinically, even though compliance probably varies in the different compartments of the brain and is affected by arterial blood pressure and PaCO₂. Cerebral blood volume is estimated to increase 0.05 mL/100 g of brain per 1 mm Hg increase in PaCO₂. Blood pressure effects upon cerebral blood volume are dependent on the autoregulation of CBF.

Sustained elevations in ICP (when isolated to the intracranial space) can lead to catastrophic herniation of the brain. Herniation may occur at one of four sites (Figure 26–6): (1) the cingulate gyrus under the falx cerebri, (2) the uncinate gyrus through the tentorium cerebelli, (3) the cerebellar tonsils through the foramen magnum, or (4) any area beneath a defect in the skull (transcalvarial).

Effect of Anesthetic Agents on Cerebral Physiology

Overall, most general anesthetics have a favorable effect on brain energy consumption by reducing electrical activity. The effects of the specific agents are complicated by concomitant administration of other drugs, surgical stimulation, intracranial compliance, blood pressure, and CO₂ tension. For example, hypocapnia blunts the increases in CBF and ICP that usually occur with ketamine and volatile agents.

This section describes the changes generally associated with each drug when given alone. Table 26–1 summarizes and compares the effects of the various anesthetics. The effects of vasoactive agents and neuromuscular blocking agents are also discussed.

TABLE 26–1 Comparative effects of anesthetic agents on cerebral physiology.¹
EFFECT OF INHALATION AGENTS

1. Volatile Anesthetics

Cerebral Metabolic Rate

Halothane, desflurane, sevoflurane, and isoflurane produce concentration-dependent decreases in CMR. Isoflurane produces the greatest maximal depression (up to 50% reduction), whereas halothane has the least effect (<25% reduction). The effects of desflurane and sevoflurane are nearly the same as those of isoflurane. No further reduction in CMR is produced by doses of anesthetics or other drugs greater than the doses that render the EEG isoelectric.

Cerebral Blood Flow & Volume

At normocarbia, volatile anesthetics dilate cerebral vessels and impair autoregulation in a concentration-dependent manner (Figure 26–7). Halothane has the greatest effect on CBF; at concentrations greater than 1%, it nearly abolishes cerebral autoregulation. Moreover, the increase in blood flow is generalized throughout all parts of the brain. At an equivalent minimum alveolar concentration (MAC) and blood pressure, halothane increases CBF up to 200%, compared with 20% for isoflurane or desflurane. Sevoflurane produces the least cerebral vasodilation. The effect of volatile agents on CBF also seems to be time dependent, because, with continued administration (2–5 h), blood flow begins to return to normal.
The response of the cerebral vasculature to CO$_2$ is generally retained with all volatile agents. Hyperventilation (hypocapnia) can therefore abolish or blunt the initial effects of these agents on CBF. With halothane, the timing of the hyperventilation is important. Only if hyperventilation is initiated prior to the administration of halothane will halothane-induced increases in CBF be prevented. In contrast, simultaneous hyperventilation with administration of the other agents can prevent increases in CBF and ICP.

Increases in cerebral blood volume (10–12%) generally parallel increases in CBF, but the relationship is not necessarily linear. Expansion of cerebral blood volume can markedly elevate ICP in patients with reduced intracranial compliance. Hypocapnia can blunt the increase in cerebral blood volume associated with volatile anesthetic administration.

**Altered Coupling of Cerebral Metabolic Rate & Blood Flow**

As is apparent from the preceding discussion, volatile agents alter, but do not
uncouple, the normal relationship of CBF and CMR. The combination of a decrease in neuronal metabolic demand with an increase in CBF (metabolic supply) has been termed *luxury perfusion*. In contrast to this potentially beneficial effect during global ischemia, a detrimental *circulatory steal phenomenon* is possible with volatile anesthetics in the setting of focal ischemia. Volatile agents can increase blood flow in normal areas of the brain, but not in ischemic areas, where arterioles are already maximally vasodilated. The end result may be a redistribution (“steal”) of blood flow away from ischemic to normal areas.

### Cerebrospinal Fluid Dynamics

Volatile anesthetics affect both formation and absorption of CSF. Halothane impedes absorption of CSF, but only minimally retards formation. Isoflurane, on the other hand, facilitates absorption and is therefore an agent with favorable effects on CSF dynamics.

### Intracranial Pressure

The net effect of volatile anesthetics on ICP is the result of immediate changes in cerebral blood volume, delayed alterations on CSF dynamics, and arterial CO$_2$ tension.

#### 2. Nitrous Oxide

The effects of nitrous oxide are influenced by other agents or changes in CO$_2$ tension. Thus, when combined with intravenous agents, nitrous oxide has minimal effects on CBF, CMR, and ICP. Adding this agent to a volatile anesthetic, however, can in theory further increase CBF. When given alone, nitrous oxide causes cerebral vasodilation and can potentially increase ICP.

### EFFECT OF INTRAVENOUS AGENTS

#### 1. Induction Agents

With the exception of ketamine, all intravenous agents either have little effect on or reduce CMR and CBF. Moreover, with some exceptions, changes in blood flow generally parallel those in metabolic rate. Cerebral autoregulation and CO$_2$ responsiveness are preserved with all agents.
**Barbiturates**

Barbiturates have four major actions on the CNS: (1) hypnosis, (2) depression of CMR, (3) reduction of CBF due to increased cerebral vascular resistance, and (4) anticonvulsant activity. Barbiturates produce dose-dependent decreases in CMR and CBF until the EEG becomes isoelectric. At that point, maximum CMR reductions of nearly 50% are observed; additional barbiturate dosing does not further reduce CMR. Unlike isoflurane, barbiturates reduce metabolic rate uniformly throughout the brain. CMR is depressed slightly more than CBF, such that metabolic supply exceeds metabolic demand (as long as CPP is maintained). Because barbiturate-induced cerebral vasoconstriction occurs only in normal areas, these agents tend to redistribute blood flow from normal to ischemic areas in the brain. The cerebral vasculature in ischemic areas remains maximally dilated because of ischemic vasomotor paralysis.

Barbiturates also seem to facilitate absorption of CSF. The resultant reduction in CSF volume, combined with decreases in CBF and cerebral blood volume, makes barbiturates highly effective in lowering ICP. Their anticonvulsant properties are also advantageous in neurosurgical patients who are at increased risk of seizures.

**Opioids**

Opioids generally have minimal effects on CBF, CMR, and ICP, unless $\text{Paco}_2$ rises secondary to respiratory depression. Increases in ICP have been reported in some patients with intracranial tumors following administration of opioids. The mechanism seems to be a precipitous drop in blood pressure; reflex cerebral vasodilation likely increases intracranial blood volume and potentially ICP. Significant decreases in blood pressure can adversely affect CPP, regardless of the opioid selected.

**Etomidate**

Etomidate decreases the CMR, CBF, and ICP in much the same way as barbiturates. Its effect on CMR is nonuniform, affecting the cortex more than the brainstem. Etomidate also decreases production and enhances absorption of CSF. Induction with etomidate is associated with a frequent incidence of myoclonic movements, but no seizure activity on the EEG in normal individuals. Reports of seizure activity following etomidate suggest that the drug is best avoided in patients with a history of epilepsy.
**Propofol**

Propofol reduces CBF and CMR, similar to barbiturates and etomidate. Although it has been associated with dystonic and choreiform movements, propofol seems to have significant anticonvulsant activity. Its short elimination half-life makes it a useful agent for neuroanesthesia. Propofol infusion is commonly used for maintenance of total intravenous anesthesia in patients with or at risk of intracranial hypertension. Propofol is by far the most common induction agent for neuroanesthesia.

**Benzodiazepines**

Benzodiazepines lower CBF and CMR, but to a lesser extent than barbiturates, etomidate, or propofol. Benzodiazepines also have useful anticonvulsant properties. Midazolam is the benzodiazepine of choice in neuroanesthesia because of its short half-life. Midazolam used as an induction agent may cause decreases in blood pressure and CPP and may result in prolonged emergence.

**Ketamine**

Ketamine is the only intravenous anesthetic that dilates the cerebral vasculature and increases CBF (50–60%). Selective activation of certain areas (limbic and reticular) is partially offset by depression of other areas (somatosensory and auditory) such that total CMR does not change. Seizure activity in thalamic and limbic areas is also described. Ketamine may also impede absorption of CSF without affecting formation. Increases in CBF, cerebral blood volume, and CSF volume can potentially increase ICP markedly in patients with decreased intracranial compliance. However, ketamine administration does not increase ICP in neurologically impaired patients under controlled ventilation with concomitant administration of propofol or a benzodiazepine. Additionally, ketamine may offer neuroprotective effects, according to some investigations. Ketamine’s blockade of the N-methyl-D-aspartate (NMDA) receptor during periods of increased glutamate concentrations, as occurs during brain injury, may be protective against neuronal cell death (Figure 26–8). In spite of theoretical concerns regarding ketamine’s ability to increase ICP in patients with traumatic injury, it has been used in brain-injured patients without deleterious effects upon ICP.
Pharmacological effects reported for racemic and S(+) ketamine, which are presumed to be relevant for neuroprotection. After onset of brain injury, blockade of excessive stimulation of N-methyl-D-aspartate (NMDA) receptors by ketamine reduces calcium influx through the receptor channel (1). This attenuates supraphysiological increases in the assembly and interaction of NMDA receptor subunits, postsynaptic density proteins, and other intracellular signaling systems such as protein kinases (2). Thus, several kinase transduction cascades become less activated. This improves preservation of metabolism and maintenance of the mitochondrial transmembrane potential (3). This, in turn, reduces pathological activation of transcription factors (4). Proteins involved in apoptosis are less activated, which is associated with less DNA fragmentation (5). A better preservation of synaptic proteins occurs, and the expression of growth proteins indicating regeneration in adult neurons is enhanced (6, 7). The prevention of pathological amplification of NMDA receptor signaling finally results in increased cellular survival, preserved cellular and synaptic integrity, and regenerative efforts (8). *Superiority of effects induced by S(+)-ketamine, only. (Reproduced with permission from Himmelseher S, Durieux ME. Revising a dogma: ketamine for patients with neurological injury? Anesth Analg. 2005 Aug;101(2):524-534.)

2. Anesthetic Adjuncts
Intravenous lidocaine decreases CMR, CBF, and ICP, but to a lesser degree than other agents. Its principal advantage is that it decreases CBF (by increasing cerebral vascular resistance) without causing other significant hemodynamic effects. Lidocaine may also have neuroprotective effects. Lidocaine infusions are used in some centers as a supplement to general anesthesia to reduce emergence delirium and the requirement for opioids.

   Droperidol has little or no effect on CMR and minimally reduces CBF. Droperidol and opioids were once mainstays of neuroanesthesia. Droperidol’s prolongation of the QT interval and risk of fatal arrhythmia have retarded its use.

   Reversal of opioids or benzodiazepines with naloxone or flumazenil, respectively, can reverse any beneficial reductions in CBF and CMR. Reversal of narcotics or benzodiazepines in chronic users can lead to symptoms of substance withdrawal.

3. **Vasopressors**

   With normal autoregulation and an intact blood–brain barrier, vasopressors increase CBF only when mean arterial blood pressure is below 50 to 60 mm Hg or above 150 to 160 mm Hg. In the absence of autoregulation, vasopressors increase CBF by their effect on CPP. Changes in CMR generally parallel those in blood flow. β-Adrenergic agents seem to have a greater effect on the brain when the blood–brain barrier is disrupted; central β₁-receptor stimulation increases CMR and blood flow. β-Adrenergic blockers generally have no direct effect on CMR or CBF. Excessive elevations in blood pressure with any agent can disrupt the blood–brain barrier.

4. **Vasodilators**

   In the absence of hypotension, most vasodilators induce cerebral vasodilation and increase CBF in a dose-related fashion. When these agents decrease blood pressure, CBF is usually maintained and may even increase. The resultant increase in cerebral blood volume can elevate ICP in patients with decreased intracranial compliance.

5. **Neuromuscular Blocking Agents**

   Neuromuscular blockers (NMBs) lack direct action on the brain but can have important secondary effects. Hypertension and histamine-mediated cerebral vasodilation increase ICP, whereas systemic hypotension (from histamine release or ganglionic blockade) lowers CPP. Succinylcholine can increase ICP to a
generally minimal and clinically unimportant extent. Moreover, a small (defasciculating) dose of a nondepolarizing NMB seems to blunt the increase, although this appears to be a dated practice. In the majority of instances, increases in ICP following administration of an NMB are the result of a hypertensive response due to light anesthesia during laryngoscopy and tracheal intubation. Acute elevations in ICP will also be seen if hypercapnia or hypoxemia results from prolonged apnea.

**Physiology of Brain Protection**

**PATHOPHYSIOLOGY OF CEREBRAL ISCHEMIA**

The brain is very vulnerable to ischemic injury because of its relatively high oxygen consumption and near-total dependence on aerobic glucose metabolism (see earlier discussion). Interruption of cerebral perfusion, metabolic substrate (glucose), or severe hypoxemia rapidly results in functional impairment; reduced perfusion also impairs clearance of potentially toxic metabolites. If normal oxygen tension, blood flow, and glucose supply are not quickly reestablished, under most conditions ATP stores are depleted, and irreversible neuronal injury begins. When CBF decreases below 10 mL/100 g/min, cell function is deranged, and ion pumps fail to maintain cellular vitality. The ratio of lactate to pyruvate is increased secondary to anaerobic metabolism. During ischemia, intracellular K\(^+\) decreases and intracellular Na\(^+\) increases. More importantly, intracellular Ca\(^{2+}\) increases because of failure of ATP-dependent pumps to either extrude the ion extracellularly or into intracellular cisterns, increased intracellular Na\(^+\) concentration, and release of the excitatory neurotransmitter glutamate. Glutamate acts at the NMDA receptor, further enhancing Ca\(^{2+}\) entry into the cell, hence the potential benefit of NMDA blockers for neuroprotection. Sustained increases in intracellular Ca\(^{2+}\) activate lipases and proteases, which initiate and propagate structural damage to neurons. Increases in free fatty acid concentration and cyclooxygenase and lipoxygenase activities result in the formation of prostaglandins and leukotrienes, some of which are potent mediators of cellular injury. Accumulation of toxic metabolites impairs cellular function and interferes with repair mechanisms. Lastly, reperfusion of ischemic tissues can cause additional tissue damage due to the formation of oxygen-derived free radicals. Likewise, inflammation and edema can promote further neuronal damage, leading to cellular apoptosis.
STRATEGIES FOR BRAIN PROTECTION

Ischemic brain injury is usually classified as focal (incomplete) or global (complete). Global ischemia may result from total circulatory arrest as well as global hypoxia. Cessation of perfusion may be caused by cardiac arrest or deliberate circulatory arrest, whereas global hypoxia may be caused by severe respiratory failure, drowning, and asphyxia (including anesthetic mishaps). Focal ischemia includes embolic, hemorrhagic, and atherosclerotic strokes, as well as blunt, penetrating, and surgical trauma.

In some instances, interventions aimed at restoring perfusion and oxygenation are possible; these include reestablishing effective circulation, normalizing arterial oxygenation and oxygen-carrying capacity, or reopening and stenting an occluded vessel. With focal ischemia, the brain tissue surrounding a severely damaged area may suffer marked functional impairment but still remain viable. Such areas are thought to have very marginal perfusion (<15 mL/100 g/min), but, if further injury can be limited and normal flow is rapidly restored, these areas (the “ischemic penumbra”) may recover completely. When these interventions are not applicable or available, the emphasis must be on limiting the extent of brain injury.

From a practical point of view, efforts aimed at preventing or limiting neuronal tissue damage are often similar whether the ischemia is focal or global. Clinical goals are usually to optimize CPP, decrease metabolic requirements (basal and electrical), and possibly block mediators of cellular injury. Clearly, the most effective strategy is prevention, because once injury has occurred, measures aimed at cerebral protection become less effective.

Hypothermia

Hypothermia is a suggested method for protecting the brain during focal and global ischemia. Indeed, profound hypothermia is often used for up to 1 h of total circulatory arrest. Unlike anesthetic agents, hypothermia decreases both basal and electrical metabolic requirements throughout the brain; metabolic requirements continue to decrease even after complete electrical silence. Additionally, hypothermia reduces free radicals and other mediators of ischemic injury. Induced hypothermia has shown benefit following cardiac arrest and is a routine part of most post-arrest protocols for comatose patients.

Anesthetic Agents
Barbiturates, etomidate, propofol, isoflurane, desflurane, and sevoflurane can produce burst suppression, and all but desflurane and sevoflurane can produce complete electrical silence of the brain and eliminate the metabolic cost of electrical activity. Unfortunately, these agents have no effect on basal energy requirements. Furthermore, with the exception of barbiturates, their effects are nonuniform, affecting different parts of the brain to variable extents.

Ketamine may also have a protective effect because of its ability to block the actions of glutamate at the NMDA receptor.

No anesthetic agent has consistently been shown to be protective against global ischemia. Studies highlighting the potential neurotoxicity of anesthetics (especially in infants) also question the role of volatile anesthetics in neuroprotection.

**Specific Adjuncts**

Nimodipine plays a role in the treatment of vasospasm associated with subarachnoid hemorrhage.

**General Measures**

*General patient management techniques are the neuroanesthesia interventions most likely to improve patient outcomes.*

Maintenance of a satisfactory CPP is critical. Hypotension, increases in venous pressure, and increases in ICP should be avoided. Oxygen-carrying capacity should be maintained and normal arterial oxygen tension preserved. Hyperglycemia aggravates neurological injuries following either focal or global ischemia, and blood glucose should be maintained at less than 180 mg/dL. Normocarbia should be maintained, as both hypercarbia and hypocarbia have no beneficial effect on cerebral ischemia; hypocarbia-induced cerebral vasoconstriction may aggravate the ischemia, whereas hypercarbia may induce a steal phenomenon (with focal ischemia) or worsen intracellular acidosis.

**EFFECT OF ANESTHESIA ON ELECTROPHYSIOLOGICAL MONITORING**

Electrophysiological monitors are used to assess the functional integrity of the CNS. The most commonly used monitor during neurosurgical procedures is evoked potentials. EEG is less commonly used. Proper application of these
monitoring modalities is critically dependent on recognizing anesthetic-induced changes. Both monitoring modalities are described in Chapter 6.

The effects of anesthetic agents on the EEG are summarized in Table 26–2.

**ELECTROENCEPHALOGRAPHY**

EEG monitoring is useful for assessing the adequacy of cerebral perfusion during carotid endarterectomy (CEA), as well as anesthetic depth (most often with processed EEG). EEG changes can be simplistically described as either activation or depression. EEG activation (a shift to predominantly high-frequency and low-voltage activity) is seen with light anesthesia and surgical stimulation, whereas EEG depression (a shift to predominantly low-frequency and high-voltage activity) occurs with deep anesthesia or cerebral compromise. Most anesthetics produce activation (at subanesthetic doses) followed by dose-dependent depression of the EEG.

**Inhalation Anesthetics**
Isoflurane, desflurane, and sevoflurane produce a burst suppression pattern at high doses (>1.2–1.5 MAC). Nitrous oxide is unusual in that it increases both frequency and amplitude (high-amplitude activation).

**Intravenous Agents**

Benzodiazepines can produce both activation and depression of the EEG. Barbiturates, etomidate, and propofol produce a similar pattern and are the only commonly used intravenous agents capable of producing burst suppression and electrical silence at high doses. Opioids characteristically produce only dose-dependent depression of the EEG. Lastly, ketamine produces an unusual activation consisting of rhythmic high-amplitude theta activity followed by very high-amplitude gamma and low-amplitude beta activities.

**EVOKED POTENTIALS**

Somatosensory evoked potentials test the integrity of the spinal dorsal columns and the sensory cortex and may be useful during resection of spinal tumors, instrumentation of the spine, and carotid artery and aortic surgery. The adequacy of perfusion of the spinal cord during aortic surgery is better assessed with motor evoked potentials (which assess the anterior part of the spinal cord). Brainstem auditory evoked potentials test the integrity of the eighth cranial nerve and the auditory pathways above the pons and are used for surgery in the posterior fossa. Visual evoked potentials may be used to monitor the optic nerve and occipital cortex during resections of large pituitary tumors.

Interpretation of evoked potentials is more complicated than that of the EEG. Evoked potentials have poststimulus latencies that are described as short, intermediate, and long. Short-latency evoked potentials arise from the nerve stimulated or the brainstem. Intermediate- and long-latency evoked potentials are primarily of cortical origin. In general, short-latency potentials are least affected by anesthetic agents, whereas long-latency potentials are affected by even subanesthetic levels of most agents. Visual evoked potentials are most affected by anesthetics, whereas brainstem auditory evoked potentials are least affected.

Intravenous agents in clinical doses generally have less marked effects on evoked potentials than do volatile agents, but, in high doses, can also decrease amplitude and increase latencies (see Chapter 6). Ketamine generally increases the amplitude of short-latency signals.
**Postoperative Hemiplegia**

A 62-year-old man has undergone a right carotid endarterectomy (CEA). Immediately following surgery, in the recovery room, he is noted to be weak on the contralateral side.

*How is a patient undergoing CEA evaluated preoperatively?*

Patients with carotid stenosis are at very increased risk of coronary artery and peripheral arterial disease. It would be unusual for a patient to have carotid stenosis who did not have evidence of atherosclerosis elsewhere. Patients undergoing CEA, therefore, require a preoperative cardiac evaluation, according to American College of Cardiology/American Heart Association guidelines.

With respect to patient risk factors, the guidelines provide algorithms for how patients should be evaluated and managed intraoperatively. As part of this patient’s preoperative evaluation, a thorough neurological examination should have been performed with special attention paid to motor function. This patient may well have been weak on the left side prior to surgery, in which case the hemiparesis might be due to a preexisting condition. If this is a new finding, it requires aggressive management.

*Is general or regional anesthesia the optimal anesthetic technique for managing patients undergoing CEA?*

For the past several decades, the majority of patients undergoing CEAs in the United States have had general anesthesia. General anesthesia was chosen because many surgeons operating in the neck area felt more comfortable if the airway was controlled, and the patient was completely anesthetized should evidence of cerebral ischemia develop.

More recently, regional anesthesia has been advocated as providing an adequate surgical field, a comfortable and relaxed patient (if done with monitored anesthesia care), stable hemodynamics, and ideal monitoring of cerebral function during crossclamping because an awake patient provides the best evidence of adequate cerebral perfusion. The patient can indicate or be observed for evidence of aphasia, facial droop, or hemiparesis. Regional anesthesia is usually performed with superficial cervical plexus blocks.
How should cerebral function be monitored intraoperatively in this patient?

When the carotid is cross-clamped, the ability to identify inadequate cerebral circulation in the ipsilateral hemisphere is critical, as there is a window of opportunity for immediate intervention and correction of any deficit.

Global and focal neurological status can continuously be assessed in awake patients if they are mildly sedated when undergoing regional anesthesia. In such a situation, practical assessment consists of frequent (every 2–5 min) examination of strength using the contralateral handgrip and maintenance of constant verbal contact (“cocktail conversation”) with the patient to assess level of consciousness.

In patients undergoing general anesthesia, indirect cerebral monitoring techniques have been used to assess the adequacy of the cerebral circulation. These techniques include stump bleeding, stump pressure, jugular venous oxygen saturation, EEG, and transcranial Doppler (TCD). Back bleeding of the distal carotid artery following crossclamp and incision of the artery suggests reasonable collateral circulation above the clamp. It is very subjective and nonquantitative.

To better qualify and quantify the adequacy of collateral perfusion (Figure 26–9), stump pressure measurements can be used. Some surgeons believe that a shunt should be used in all patients with a previous cerebrovascular accident, independent of stump pressure, and for any patient whose stump pressure is less than 25 mm Hg. However, this is controversial, as many neurosurgeons and vascular surgeons use 50 mm Hg as a cutoff. The reliability of stump pressure to predict the need for selective shunting has also been questioned. Some surgeons routinely shunt all patients, some shunt no patients, and others use selective shunting. Outcome data have not identified the best surgical approach.
The EEG is sometimes used for monitoring patients undergoing CEA under general anesthesia. In such a circumstance, inhalation or intravenous
anesthesia can influence the EEG, but gross changes associated with carotid clamping can be detected. However, analyzing subtleties of the EEG is labor and technology intensive.

Evoked potentials have also been employed during CEA. Should neurophysiological studies identify cerebral ischemia, the surgeon can place a vascular shunt during the surgical repair to provide for ipsilateral cerebral perfusion.

**How should hemodynamics be controlled intraoperatively?**

During carotid clamping and immediately afterward in the recovery room, patients are often hemodynamically labile. **Bradycardia can develop during surgical manipulation of the carotid sinus because of the direct stimulation of the vagus nerve.** Tachycardia may develop as a result of stress or pain or as a direct result of manipulation of the carotid sinus with release of catecholamines into the circulation.

Hypotension is also observed because of the direct vasodilating and negative ionotropic effects of anesthetic agents. Hypotension following carotid unclamping is common, particularly in patients with more severe carotid stenosis. This could be due to a cerebral protective process. Cerebral autoregulation protects the brain from reperfusion by reducing production of renin, vasopressin, and norepinephrine, which results in hypotension. Hypertension is also a frequent finding in patients undergoing CEA. Many patients have hypertension as a comorbid condition, which is often further exacerbated by the surgical stress and manipulation of the carotid body, which causes release of catecholamines and sympathetic stimulation.

Invasive arterial pressure monitoring and suitable venous access to infuse vasoactive medications are necessary during carotid surgery.

**What is the most likely etiology of this patient’s findings?**

This patient most likely has had a cerebrovascular accident due to an arterio-to-arterial embolus; more than 95% of such patients will fit into this category. Weakness can also develop as a result of a hyperperfusion syndrome, which occurs in patients with severe carotid stenosis who have now reestablished flow to the affected cerebral hemisphere. Such patients usually have a greater than 95% carotid stenosis with a less than 1-mm channel in the affected carotid artery. Typically, the syndrome does not develop in the postoperative anesthesia care unit (PACU), but several hours afterward when the patient begins complaining of a headache, and, in
severe cases, develops hemiparesis. Because a cerebrovascular accident is most likely, when the anesthesiologist is called to see such a patient in the PACU, a thorough neurological examination quantifying any cranial nerve involvement and the degree of weakness on the contralateral side should be performed. Any hemodynamic changes need to be treated immediately, with assurance of adequate hemoglobin and oxygenation levels. The surgeon needs to be notified at once, and ultrasonic evaluation of the carotid artery is frequently required to determine whether there might be problems with the intimal suture line. It may be necessary to return to the operating room to explore the carotid artery.

**SUGGESTED READINGS**

Regardless of the cause, intracranial masses present symptoms and signs according to growth rate, location, and intracranial pressure. Slowly growing masses are frequently asymptomatic for long periods (despite relatively large size), whereas rapidly growing ones may present when the mass remains relatively small.

Computed tomography and magnetic resonance imaging scans should be reviewed for evidence of brain edema, midline shift greater than 0.5 cm, or ventricular displacement or compression.

Operations in the posterior fossa can injure vital circulatory and respiratory brainstem centers, as well as cranial nerves or their nuclei.

Venous air embolism can occur when the pressure within an open vein is subatmospheric. These conditions may exist in any position and during any procedure whenever the wound is above the level of the heart.

Optimal recovery of air following venous air embolism is provided by a multiorificed catheter positioned at the junction between the right atrium and the superior vena cava. Confirmation of correct catheter positioning can be accomplished by intravascular electrocardiography, radiography, or transesophageal echocardiography.

In a patient with head trauma, correction of hypotension and control of any bleeding take precedence over radiographic studies and definitive neurosurgical treatment because systolic arterial blood pressures of less than 80 mm Hg predict a poor outcome.

Sudden, massive blood loss from injury to the great vessels can occur intraoperatively with adjacent thoracic or lumbar spine procedures.
Anesthetic techniques must be modified in the presence of intracranial hypertension and marginal cerebral perfusion. In addition, many neurosurgical procedures require patient positions (eg, sitting, prone) that further complicate management. This chapter applies the principles developed in Chapter 26 to the anesthetic care of neurosurgical patients.

**Intracranial Hypertension**

Intracranial hypertension is defined as a sustained increase in intracranial pressure (ICP) above 15 mm Hg. Intracranial hypertension may result from an expanding tissue or fluid mass, a depressed skull fracture if it compresses a venous sinus, inadequate absorption of cerebrospinal fluid (CSF), excessive cerebral blood volume (CBV), or systemic disturbances promoting brain edema (see next section). Multiple factors may be present. For example, tumors in the posterior fossa usually not only are associated with some degree of brain edema and mass effect, but also readily obstruct CSF outflow by compressing the fourth ventricle (obstructive hydrocephalus).

Although many patients with increased ICP are initially asymptomatic, they typically develop characteristic symptoms and signs, including headache, nausea, vomiting, papilledema, focal neurological deficits, and altered consciousness. When ICP exceeds 30 mm Hg, cerebral blood flow (CBF) progressively decreases, and a vicious circle is established: ischemia causes brain edema, which in turn, increases ICP, resulting in more ischemia. If left unchecked, this cycle continues until the patient dies of progressive neurological damage or catastrophic herniation. Periodic increases in arterial blood pressure with reflex slowing of the heart rate (Cushing response) can be correlated with abrupt increases in ICP (plateau waves) lasting 1 to 15 min. This phenomenon is the result of autoregulatory mechanisms periodically decreasing cerebral vascular resistance and increasing arterial blood pressure in response to cerebral ischemia. Eventually, severe ischemia and acidosis completely abolish autoregulation (vasomotor paralysis).

**CEREBRAL EDEMA**

An increase in brain water content can be produced by several mechanisms. Disruption of the blood–brain barrier (vasogenic edema) is most common and allows the entry of plasma-like fluid into the brain. Increases in blood pressure enhance the formation of this type of edema. Common causes of vasogenic
edema include mechanical trauma, high altitudes, inflammatory lesions, brain tumors, hypertension, and infarction. Cerebral edema following metabolic insults (cytotoxic edema), such as hypoxemia or ischemia, results from failure of brain cells to actively extrude sodium, causing progressive cellular swelling. Interstitial cerebral edema is the result of obstructive hydrocephalus and entry of CSF into brain interstitium. Cerebral edema can also be the result of intracellular movement of water secondary to acute decreases in serum osmolality (water intoxication).

**TREATMENT**

Treatment of intracranial hypertension, cerebral edema, or both, is ideally directed at the underlying cause. Metabolic disturbances are corrected, and operative intervention is undertaken whenever appropriate. Vasogenic edema—particularly that associated with tumors—often responds to corticosteroids (dexamethasone). Vasogenic edema from trauma typically does not respond to corticosteroids. Blood glucose should be monitored frequently and controlled with insulin infusions (if indicated) when steroids are used. Osmotic agents are usually effective in temporarily decreasing brain edema and ICP until more definitive measures can be undertaken. Diuresis lowers ICP chiefly by removing intracellular water from normal brain tissue. Moderate hyperventilation (Paco₂ of 30–33 mm Hg) is often very helpful in reducing CBF, CBV, and ICP acutely, but may aggravate ischemia in patients with focal ischemia.

Mannitol, in doses of 0.25 to 1 g/kg, is particularly effective in rapidly decreasing intracranial fluid volume and ICP. Its efficacy is primarily related to its effect on serum osmolality. A serum osmolality of 300 to 315 mOsm/L is generally considered desirable. Mannitol can transiently decrease blood pressure by virtue of its weak vasodilating properties, but its principal disadvantage is a transient increase in intravascular volume, which can precipitate pulmonary edema in patients with borderline cardiac or renal function. Mannitol should generally not be used in patients with intracranial aneurysms, arteriovenous malformations (AVMs), or intracranial hemorrhage until the cranium is opened. Osmotic diuresis in such instances can expand a hematoma as the volume of the normal brain tissue around it decreases. Rapid osmotic diuresis in elderly patients can also occasionally cause a subdural hematoma due to rupture of fragile bridging veins entering the sagittal sinus. Rebound cerebral edema may follow the use of osmotic agents.

Hypertonic saline (3% NaCl) is sometimes used to reduce cerebral edema and
ICP. Hypertonic saline should be administered with care to avoid central pontine myelinolysis or osmotic demyelination syndrome in hyponatremic patients (see Chapter 49). Serum sodium concentration and osmolality should be frequently monitored. In patients with traumatic brain injury, interventions in addition to mannitol to lower intracranial pressure include head elevation, CSF drainage via ventriculostomy, moderate hypocapnia, and metabolic suppression with barbiturates. Decompressive craniectomy has been shown to decrease mortality in patients with sustained increases in ICP (> 25 mm Hg) following traumatic brain injury.

**Anesthesia & Craniotomy for Patients with Mass Lesions**

Intracranial masses may be congenital, neoplastic (benign or malignant), infectious (abscess or cyst), or vascular (hematoma or arteriovenous malformation). Craniotomy is commonly undertaken for neoplasms of the brain. Primary tumors usually arise from glial cells (astrocytoma, oligodendroglioma, or glioblastoma), ependymal cells (ependymoma), or supporting tissues (meningioma, schwannoma, or choroidal papilloma). Childhood tumors include medulloblastoma, neuroblastoma, and astrocytoma.

Regardless of the cause, intracranial masses present symptoms and signs according to growth rate, location, and ICP. Slowly growing masses are frequently asymptomatic for long periods (despite relatively large size), whereas rapidly growing ones may present when the mass remains relatively small. Common presentations include headache, seizures, a general decline in cognitive or specific neurological functions, and focal neurological deficits. Symptoms typical to supratentorial masses include seizures, hemiplegia, or aphasia, whereas symptoms typical of infratentorial masses may include cerebellar dysfunction (ataxia, nystagmus, and dysarthria) or brainstem compression (cranial nerve palsies, altered consciousness, or abnormal respiration).

**PREOPERATIVE MANAGEMENT**

The preoperative evaluation for patients undergoing craniotomy should attempt to establish the presence or absence of intracranial hypertension. Computed tomography (CT) and magnetic resonance imaging (MRI) scans should be reviewed for evidence of brain edema, midline shift greater than 0.5 cm, or ventricular displacement or compression. Imaging studies typically will be
performed before the patient receives dexamethasone, so the mass effect may be less acute when patients who have already received dexamethasone present in the operating room. The neurological examination should document mental status and any sensory or motor deficits. Medications should be reviewed with special reference to corticosteroid, diuretic, and anticonvulsant therapy. Laboratory evaluation should rule out corticosteroid-induced hyperglycemia, electrolyte disturbances due to diuretics, or abnormal secretion of antidiuretic hormone. Anticonvulsant blood concentrations may be measured, particularly when seizures are not well controlled.

**Premedication**

Sedative or opioid premedication is best avoided, particularly when intracranial hypertension is suspected. Hypercapnia secondary to respiratory depression increases ICP. Corticosteroids and anticonvulsant therapy should be continued until the time of surgery.

**INTRAOPERATIVE MANAGEMENT**

**Monitoring**

In addition to standard monitors, direct intraarterial pressure monitoring and bladder catheterization are used for most patients undergoing craniotomy. Rapid changes in blood pressure during anesthetic procedures, positioning, and surgical manipulation are best managed with guidance from continuous invasive monitoring of blood pressure. Moreover, arterial blood gas analyses are necessary to closely regulate \( \text{PaCO}_2 \). We zero the arterial pressure transducer at the level of the head (external auditory meatus)—instead of the right atrium—to facilitate calculation of cerebral perfusion pressure (CPP), and we document this practice in the anesthetic record. End-tidal \( \text{CO}_2 \) measurements alone cannot be relied upon for precise regulation of ventilation; the arterial to end-tidal \( \text{CO}_2 \) gradient must be determined. Central venous access and pressure monitoring may be considered for patients requiring vasoactive drugs. Use of the internal jugular vein for access is theoretically problematic because of concern that the catheter might interfere with venous drainage from the brain. The external jugular, subclavian, or other peripheral veins may be suitable insertion sites for central venous catheters. A bladder catheter is necessary because of the use of diuretics, the long duration of most neurosurgical procedures, and the utility of
bladder catheterization in guiding fluid therapy and measuring core body temperature. Neuromuscular function should be monitored on the unaffected side in patients with hemiparesis because the twitch response is often abnormally resistant on the affected side. Monitoring visual evoked potentials may be useful in preventing optic nerve damage during resections of large pituitary tumors. Additional monitors for surgery in the posterior fossa are described later in this discussion.

Management of patients with intracranial hypertension may be guided by monitoring ICP perioperatively. Various ventricular, intraparenchymal, and subdural devices can be placed by neurosurgeons to provide measurements of ICP. The transducer should be zeroed to the same reference level as the arterial pressure transducer (usually the external auditory meatus, as previously noted). A ventriculostomy catheter provides the added advantage of allowing removal of CSF to decrease ICP.

**Induction**

Induction of anesthesia and tracheal intubation are critical periods for patients with compromised intracranial pressure to volume relationships, particularly if there is an elevated ICP. Intracranial elastance can be improved by osmotic diuresis or removal of small volumes of CSF via a ventriculostomy drain. The goal of any technique should be to induce anesthesia and intubate the trachea without increasing ICP or compromising CBF. Arterial hypertension during induction increases CBV and promotes cerebral edema. Sustained hypertension can lead to marked increases in ICP, decreasing CPP and risking herniation. Excessive decreases in arterial blood pressure can be equally detrimental by compromising CPP.

The most common induction technique employs propofol together with modest hyperventilation to reduce ICP and blunt the noxious effects of laryngoscopy and intubation. All patients receive controlled ventilation once the propofol has been injected. A neuromuscular blocker (NMB) is given to facilitate ventilation and prevent straining or coughing, both of which can abruptly increase ICP. An intravenous opioid given with propofol blunts the sympathetic response, particularly in young patients. Esmolol (0.5–1.0 mcg/kg) is effective in preventing tachycardia associated with intubation in lightly anesthetized patients.

The actual induction technique can be varied according to individual patient responses and coexisting diseases. Succinylcholine may theoretically increase
ICP, particularly if intubation is attempted before deep anesthesia is established. Succinylcholine, however, remains the agent of choice for rapid sequence induction or when there are concerns about a potentially difficult airway, as hypoxemia and hypercarbia are much more detrimental than any effect of succinylcholine to the patient with intracranial hypertension.

Hypertension during induction can be treated with $\beta_1$-blockers or by deepening the anesthetic with additional propofol. Modest concentrations of volatile agents (eg, sevoflurane) may also be used, provided that hyperventilation is also used. Sevoflurane best preserves autoregulation of CBF and produces limited vasodilation; it may be the preferred volatile agent in patients with elevated ICP. Because of their potentially deleterious effect on CBV and ICP, vasodilators (eg, nicardipine, nitroprusside, nitroglycerin, and hydralazine) are avoided until the dura is opened. Hypotension is generally treated with incremental doses of vasopressors (eg, phenylephrine).

**Positioning**

Frontal, temporal, and parietooccipital craniotomies are performed in the supine position. The head is elevated 15° to 30° to facilitate venous and CSF drainage. The head may also be turned to the side to facilitate exposure. Excessive flexion or rotation of the neck impedes jugular venous drainage and can increase ICP. Before and after positioning, the tracheal tube should be secured and position verified, and all breathing circuit connections checked. The risk of unrecognized disconnections is increased because the patient’s airway cannot be easily assessed after surgical draping; moreover, the operating table is usually turned 90° or 180° away from the anesthesia provider.

**Maintenance of Anesthesia**

Anesthesia can be maintained with inhalation anesthesia, total intravenous anesthesia techniques (TIVA), or a combination of an opioid and intravenous hypnotic (most often propofol) with a low-dose inhalation agent. Even though periods of stimulation are few, neuromuscular blockade is recommended—unless neurophysiological monitoring contradicts its use—to prevent straining, bucking, or other movement. Increased anesthetic requirements can be expected during the most stimulating periods: laryngoscopy–intubation, skin incision, dural opening, periosteal manipulations, including Mayfield pin placement and closure. TIVA with remifentanil and propofol facilitates rapid emergence and
immediate neurological assessment. Likewise, the $\alpha_2$-agonist dexmedetomidine can be employed during both asleep and awake craniotomies to similar effect.

Hyperventilation should be continued intraoperatively to maintain $\text{PaCO}_2$ at roughly 30 to 35 mm Hg. Lower $\text{PaCO}_2$ tensions provide little additional benefit and may be associated with cerebral ischemia and impaired oxygen dissociation from hemoglobin. Ventilatory patterns resulting in high mean airway pressures (a low rate with large tidal volumes) should be avoided because of a potentially adverse effect on ICP by increasing central venous pressure and the potential for lung injury. Hypoxic patients may require positive end-expiratory pressure (PEEP) and increased mean airway pressure; in such patients, the effect of PEEP on ICP is variable.

Intravenous fluid replacement should be limited to glucose-free isotonic crystalloid. Hyperglycemia is common in neurosurgical patients and has been implicated in increasing ischemic brain injury. Hyperglycemia should be corrected preoperatively. Neurosurgical procedures are often associated with occult blood loss (underneath surgical drapes or on the floor). Hypotension and hypertension should both be expeditiously corrected.

**Emergence**

Most patients undergoing elective craniotomy can be extubated at the end of the procedure. Patients who will remain intubated should be sedated to prevent agitation. Extubation in the operating room requires special handling during emergence. Straining or “bucking” on the tracheal tube may precipitate intracranial hemorrhage or worsen cerebral edema. As the skin is being closed, the patient may resume breathing spontaneously. Should the patient’s head be secured in a Mayfield pin apparatus, care must be taken to avoid any patient motions (eg, bucking on the tube), which could promote neck or cranial injuries. After the head dressing is applied and full access to the patient is regained (the table is turned back to its original position as at induction), any anesthetic agents are discontinued and the neuromuscular blockade is reversed. Rapid awakening facilitates immediate neurological assessment and is generally expected. Delayed awakening may be seen following opioid or sedative overdose, when the end-tidal concentration of the volatile agent remains greater than 0.2 minimum alveolar concentration (MAC), or when there is a metabolic derangement or a perioperative neurological injury. Patients may need to be transported to the CT scanner directly from the operating room for evaluation when they do not respond as predicted. Immediate reexploration may be
required. Most patients are taken to the intensive care unit postoperatively for close monitoring of neurological function.

### Anesthesia for Surgery in the Posterior Fossa

Craniotomy for a mass in the posterior fossa presents a unique set of potential problems: obstructive hydrocephalus, possible injury to vital brainstem centers, pneumocephalus, and, when these procedures are performed with the patient in the sitting position, an increased risk of postural hypotension and venous air embolism.

### Obstructive Hydrocephalus

Infratentorial masses can obstruct CSF flow through the fourth ventricle or the cerebral aqueduct of Sylvius. Small but critically located lesions can markedly increase ICP. In such cases, a ventriculostomy is often performed under local anesthesia to decrease ICP prior to induction of general anesthesia.

### Brainstem Injury

Operations in the posterior fossa can injure vital circulatory and respiratory brainstem centers, as well as cranial nerves or their nuclei. Such injuries may occur as a result of direct surgical trauma or ischemia from retraction or other interruptions of the blood supply. Damage to respiratory centers is said to nearly always produce circulatory changes; therefore, abrupt changes in blood pressure, heart rate, or cardiac rhythm should alert the anesthesia provider to the possibility of such an injury. Such changes should be communicated to the surgeon. Isolated damage to respiratory centers may rarely occur without premonitory circulatory signs during operations in the floor of the fourth ventricle. Historically, some clinicians have employed spontaneous ventilation during these procedures as an additional monitor of brain function. At completion of the surgery, brainstem injuries may present as an abnormal respiratory pattern or an inability to maintain a patent airway following extubation. Monitoring brainstem auditory evoked potentials may be useful in preventing eighth nerve damage during resections of acoustic neuromas. Electromyography is also used to avoid injury to the facial nerve but requires incomplete neuromuscular blockade intraoperatively.
Positioning

Although most explorations of the posterior fossa can be performed with the patient in either a modified lateral or prone position, the sitting position may be preferred by some surgeons.

The patient is actually semirecumbent in the standard sitting position (Figure 27–1); the back is elevated to 60°, and the legs are elevated with the knees flexed. The head is fixed in a three-point holder with the neck flexed; the arms remain at the sides with the hands resting on the lap.

Figure 27–1 The sitting position for craniotomy.

Careful positioning and padding help avoid injuries. Pressure points, such as the elbows, ischial spines, heels, and forehead, must be protected. Excessive neck flexion has been associated with swelling of the upper airway (due to venous obstruction), and, rarely, quadriplegia (due to compression of the cervical spinal cord). Preexisting cervical spinal stenosis probably predisposes patients to the latter injury.

Pneumocephalus

The sitting position increases the likelihood of pneumocephalus. In this position,
air readily enters the subarachnoid space as CSF is lost during surgery. In patients with cerebral atrophy, drainage of CSF is marked; air can replace CSF on the surface of the brain and in the lateral ventricles. Expansion of a pneumocephalus following dural closure can compress the brain. Postoperative pneumocephalus can cause delayed awakening and continued impairment of neurological function. Because of these and other concerns, nitrous oxide is rarely used for sitting craniotomies (see further discussion that follows).

**Venous Air Embolism**

Venous air embolism can occur when the pressure within an open vein is subatmospheric. These conditions may exist in any position and during any procedure whenever the wound is above the level of the heart. The incidence of venous air embolism is greater during sitting craniotomies (20–40%) than in craniotomies in any other position. Entry into large cerebral venous sinuses increases the risk.

The physiological consequences of venous air embolism depend on the volume and the rate of air entry and whether the patient has a right-to-left intracardiac shunt (eg, patent foramen ovale [10–25% incidence]). The latter are important because they can facilitate passage of air into the arterial circulation (paradoxical air embolism). Modest quantities of air bubbles entering the venous system ordinarily lodge in the pulmonary circulation, where they are eventually absorbed. Small quantities of embolized air are well tolerated by most patients. When the amount entrained exceeds the rate of pulmonary clearance, pulmonary artery pressure rises progressively. Eventually, cardiac output decreases in response to increases in right ventricular afterload. Preexisting cardiac or pulmonary disease enhances the adverse effects of venous air embolism; relatively small amounts of air may produce marked hemodynamic changes. Nitrous oxide, by diffusing into air bubbles and increasing their volume, can markedly accentuate the effects of even small amounts of entrained air. The lethal volume of venous air in experimental animals receiving nitrous oxide anesthesia is reduced to one-third to one-half that of control animals not receiving nitrous oxide.

In the absence of echocardiography, definitive signs of venous air embolism are often not apparent until large volumes of air have been entrained. A decrease in end-tidal CO₂ or arterial oxygen saturation may be noticed prior to hemodynamic changes. Arterial blood gas values may show only slight increases in PaCO₂ as a result of increased dead space ventilation (areas with normal
ventilation but decreased perfusion). Conversely, major hemodynamic manifestations, such as sudden hypotension, can occur well before hypoxemia is noted. Moreover, large amounts of intracardiac air impair tricuspid and pulmonic valve function and can produce sudden circulatory arrest by obstructing right ventricular outflow.

Paradoxic air embolism can result in a stroke or coronary occlusion, which may be apparent only postoperatively. Paradoxic air emboli are more likely to occur in patients with right-to-left intracardiac shunts, particularly when the normal transatrial (left > right) pressure gradient is consistently reversed.

A. Central Venous Catheterization
A properly positioned central venous catheter can be used to aspirate entrained air, but there is only limited evidence that this influences outcomes after venous air embolism. Some clinicians have considered right atrial catheterization mandatory for sitting craniotomies, but this is a minority viewpoint. Optimal recovery of air following venous air embolism is provided by a multiorificed catheter positioned at the junction between the right atrium and the superior vena cava. Confirmation of correct catheter positioning can be accomplished by intravascular electrocardiography, radiography, or transesophageal echocardiography (TEE), with the latter being simplest and easiest. Intravascular electrocardiography is accomplished by using the saline-filled catheter as a “V” lead. Correct positioning near the cavoatrial junction is indicated by the appearance of a maximally biphasic P wave. If the catheter is advanced farther into the heart, the P wave changes from a biphasic to a unidirectional deflection. A right ventricular or pulmonary artery waveform may also be observed when the catheter is connected to a pressure transducer and advanced too far, but pressure waveforms do not identify the cavoatrial junction.

B. Monitoring for Venous Air Embolism
The most sensitive detectors available should be used. Detecting even small amounts of venous air emboli is important because it allows surgical control of the entry site before additional air is entrained. Currently, the devices capable of detecting the smallest volumes of air are TEE and precordial Doppler sonography. These monitors can detect air bubbles as small as 0.25 mL. TEE has the added benefit of detecting the volume of the bubbles and any transatrial passage through a patent foramen ovale, as well as evaluating any effect venous air embolism may have on cardiac function. Doppler methods employ a probe over the right atrium (usually to the right of the sternum and between the third
and sixth ribs). Interruption of the regular swishing of the Doppler signal by sporadic roaring sounds indicates venous air embolism. Changes in end-tidal respiratory gas concentrations are less sensitive but are important monitors that can also detect venous air embolism before overt clinical signs are present. Venous air embolism causes a sudden decrease in end-tidal $\text{CO}_2$ tension in proportion to the increase in pulmonary dead space; however, decreases can also be seen with hemodynamic changes unrelated to venous air embolism, such as decreased cardiac output. A reappearance (or increase) of nitrogen in expired gases may also be seen with venous air embolism. Changes in blood pressure and heart sounds (“mill wheel” murmur) are late manifestations of venous air embolism.

C. Treatment of Venous Air Embolism

1. The surgeon should be notified so that he or she can flood the surgical field with saline or pack it with wet gauzes and apply bone wax to the skull edges until the entry site is identified and occluded.

2. Nitrous oxide (if used) should be discontinued, and the patient ventilated with 100% oxygen.

3. If a central venous catheter is present, it should be aspirated in an attempt to retrieve the entrained air.

4. Intravascular volume infusion should be given to increase central venous pressure.

5. Vasopressors should be given to treat hypotension.

6. Bilateral jugular vein compression, by increasing intracranial venous pressure, may slow air entrainment and cause back bleeding, which might help the surgeon identify the entry point of the embolus.

7. Some clinicians advocate PEEP to increase cerebral venous pressure; however, reversal of the normal transatrial pressure gradient may promote paradoxical embolism in a patient with incomplete closure of the foramen ovale.

8. If the previously listed measures fail, the patient should be placed in a head-down position, and the wound should be closed quickly.

9. Persistent circulatory arrest necessitates the supine position and institution of resuscitation efforts using advanced cardiac life support algorithms.
Anesthesia for Stereotactic Surgery

Stereotaxis can be employed in treating involuntary movement disorders, intractable pain, and epilepsy and can also be used when diagnosing and treating tumors that are located deep within the brain.

These procedures are often performed under local anesthesia to allow evaluation of the patient. Propofol or dexmedetomidine infusions are often used for sedation and amnesia. Sedation should be omitted, however, if the patient already has increased ICP. The ability to rapidly provide controlled ventilation and general anesthesia for emergency craniotomy is mandatory but is complicated by the platform and localizing frame that is attached to the patient’s head for the procedure. Although mask ventilation or ventilation through a laryngeal mask airway (LMA) or orotracheal intubation might be readily accomplished in an emergency, awake intubation with a fiberoptic bronchoscope or videolaryngoscope prior to positioning and surgery may be the safest approach when intubation is necessary for a patient whose head is already in a stereotactic head frame.

Functional neurosurgery is increasingly performed for removal of lesions adjacent to speech and other vital brain centers. Sometimes patients are managed with an asleep–awake–asleep technique, with or without instrumentation of the airway. Such operations require the patient to be awake to participate in cortical mapping to identify key speech centers, such as Broca’s area. Patients sleep during the painful periods of surgery (ie, during opening and closure). LMAs are often employed to assist airway management during the asleep portions of these surgeries. Local anesthetic infiltration of the scalp facilitates awake craniotomy.

Patients undergo deep brain stimulator insertion for control of movement and other disorders. A stimulator electrode is placed via a burr hole using radiological guidance to establish coordinates for electrode placement. A microelectrode recording (MER) is obtained to determine the correct placement of the stimulator in brain structures. The effect of stimulation upon the patient is noted. Sedative medications can adversely affect MER potentials, complicating the location of the correct depth of stimulator placement. Dexmedetomidine has been used to provide sedation to these patients; however, during MER and stimulation testing, sedative infusions should be discontinued to facilitate patient participation in determining correct electrode placement (Table 27–1).

**TABLE 27–1** Advantages and disadvantages of drugs used for conscious sedation.¹²
Anesthesia for Head Trauma

Head injuries are a contributory factor in up to 50% of deaths due to trauma. Most patients with head trauma are young, and many (10–40%) have associated intraabdominal or intrathoracic injuries, long bone fractures, or spinal injuries. The outcome from a head injury is dependent not only on the extent of the neuronal damage at the time of injury, but also on the occurrence of any secondary insults or sequelae from other injuries or complications (see Chapter 39). These secondary insults include (1) systemic factors such as hypoxemia, hypercapnia, or hypotension; (2) formation and expansion of an epidural, subdural, or intracerebral hematoma; and (3) sustained intracranial hypertension. Head-injured patients may have a wide variety of other injuries, may arrive at hospital in an intoxicated state, and are subject to the usual range of complications encountered in critical care (sepsis, acute respiratory distress syndrome [ARDS], etc). Surgical and anesthetic management of these patients is directed at immediate treatment of the primary injuries and avoiding these secondary insults. The Glasgow Coma Scale (GCS) score (Table 27–2) generally correlates well with the severity of injury and outcome. A GCS score of 8 or less on admission is associated with approximately 35% mortality. Evidence of greater than a 5-mm midline shift (on imaging) and ventricular compression on imaging are associated with substantially worse outcomes.
Specific lesions include skull fractures, subdural and epidural hematomas, brain contusions (including intracerebral hemorrhages), penetrating head injuries, and traumatic vascular occlusions and dissections. The presence of a skull fracture greatly increases the likelihood of an intracranial lesion. Linear skull fractures are commonly associated with subdural or epidural hematomas. Basilar skull fractures may be associated with CSF rhinorrhea, pneumocephalus, cranial nerve palsies, or even a cavernous sinus–carotid artery fistula. Depressed skull fractures often present with an underlying brain contusion. Contusions may be limited to the surface of the brain or may involve hemorrhage in deeper hemispheric structures or the brainstem. Rapid deceleration injuries often produce both coup (frontal) and contrecoup (occipital) lesions. Epidural and subdural hematomas can occur as isolated lesions, as well as in association with cerebral contusions (more commonly with subdural than epidural lesions).
Operative treatment is usually elected for depressed skull fractures; evacuation of epidural, subdural, and some intracerebral hematomas; and debridement of penetrating injuries. Decompressive craniectomy is used to provide room for cerebral swelling. The cranium is subsequently reconstructed following resolution of cerebral edema.

ICP monitoring is usually indicated in patients with lesions associated with intracranial hypertension: large contusions, mass lesions, intracerebral hemorrhage, or evidence of edema on imaging studies. ICP monitoring should also be considered in patients with signs of intracranial hypertension who are undergoing nonneurological procedures. Acute intracranial hypertension leading to herniation should be treated with hyperventilation, osmolar therapy, and barbiturates. Immediate neurosurgical intervention is mandated. Multiple studies have found that sustained increases in ICP of greater than 60 mm Hg result in severe disability or death. Randomized trials have failed to detect the efficacy of early use of large doses of glucocorticoids in patients with head trauma. Hypothermia has likewise failed to improve survival following traumatic brain injury.

PREOPERATIVE MANAGEMENT

Anesthetic care of patients with severe head trauma begins in the emergency department. Measures to ensure patency of the airway, adequacy of ventilation and oxygenation, stabilization of the cervical spine, and correction of systemic hypotension should proceed simultaneously with neurological and trauma surgical evaluation. Airway obstruction and hypoventilation are common. Up to 70% of such patients have hypoxemia, which may be complicated by pulmonary contusion, fat emboli, or neurogenic pulmonary edema. The latter is attributed to marked systemic and pulmonary hypertension secondary to intense sympathetic nervous system activity. Supplemental oxygen should be given to all patients while the airway and ventilation are evaluated. Many patients will have substance intoxication. All patients must be assumed to have a cervical spine injury (up to 10% incidence) until the contrary is proven radiographically. Patients with obvious hypoventilation, an absent gag reflex, or a persistent score below 8 on the GCS (Table 27–2) require tracheal intubation. All other patients should be carefully observed for deterioration.

**Intubation**

All patients should be regarded as having a full stomach and should have cricoid
pressure (Sellick maneuver) applied during ventilation and tracheal intubation. Nevertheless, the effectiveness of this maneuver in preventing aspiration is questionable. In-line stabilization should be used during airway manipulation to maintain the head in a neutral position, unless radiographs confirm that there is no cervical spine injury. Following preoxygenation, the adverse effects of intubation on ICP are blunted by prior administration of propofol, 1.5 to 3.0 mg/kg, and a rapid-onset NMB. Succinylcholine may produce mild and transient increases in ICP in patients with closed head injury; however, the necessity for expeditious airway management trumps these theoretical concerns. Rocuronium is often used to facilitate intubation. The presence of a hard collar for cervical spine stabilization will increase intubation difficulty. Video laryngoscopy performed with in-line stabilization generally permits neutral position intubation of the trauma patient. An intubating bougie should be available to facilitate tube placement. If a difficult intubation is encountered with video laryngoscopy, fiberoptic or other techniques (eg, intubating LMA) can be attempted. If airway attempts are unsuccessful, a surgical airway should be obtained. Blind nasal intubation or blind passage of a nasogastric tube should be avoided in the presence of a basilar skull fracture due to the possibility of passing tubes directly through the fracture into the brain. The diagnosis of basilar skull fracture is suggested by CSF rhinorrhea or otorrhea, hemotympanum, or ecchymosis into periorbital tissues (raccoon sign) or behind the ear (Battle sign).

**Hypotension**

Hypotension in the setting of head trauma is nearly always related to other associated injuries (often intraabdominal). Profuse bleeding from scalp lacerations may cause hypovolemic hypotension in children. Hypotension may be seen with spinal cord injuries because of the sympathectomy associated with spinal shock. In a patient with head trauma, correction of hypotension and control of any bleeding take precedence over radiographic studies and definitive neurosurgical treatment because systolic arterial blood pressures of less than 80 mm Hg predict a poor outcome. Glucose-containing or hypotonic solutions should not be used (see earlier discussion). Otherwise, crystalloids and blood products can be administered as necessary. Massive blood loss in the patient with multiple injuries should result in activation of a massive transfusion protocol to provide a steady supply of platelets, fresh frozen plasma, and packed red blood cells. Invasive monitoring of arterial pressure, central venous pressure, and ICP are valuable, but should not delay diagnosis and treatment. Arrhythmias and electrocardiographic abnormalities in the T wave, U wave, ST segment, and QT
interval are common following head injuries, but are not necessarily associated with cardiac injury; they likely represent altered autonomic function.

**Diagnostic Studies**

The choice between operative and medical management of head trauma is based on radiographic and clinical findings. Patients should be stabilized prior to any CT or other imaging studies. Critically ill patients must be closely monitored during such studies. Restless or uncooperative patients may require general anesthesia for imaging. Sedation in such cases without control of the airway should be avoided because of the risk of further increases in ICP from hypercapnia or hypoxemia and because of the risk of aspiration.

**INTRAOPERATIVE MANAGEMENT**

Anesthetic management is generally similar to that for other mass lesions associated with intracranial hypertension. Invasive monitoring should be established, if not already present, but should not delay surgical decompression in a rapidly deteriorating patient.

Anesthetic techniques are designed to preserve cerebral perfusion and mitigate increases in ICP. Hypotension may occur after induction of anesthesia as a result of the combined effects of vasodilation and hypovolemia and should be treated with an α-adrenergic agonist and volume infusion if necessary. Subsequent hypertension is common with surgical stimulation, but may also occur in response to acute elevations in ICP. Hypertension associated with elevated ICP and bradycardia is termed the Cushing reflex.

Hypertension can be treated with additional doses of the induction agent, with increased concentrations of an inhalation anesthetic (provided modest hyperventilation has been established) or with antihypertensives. β-Adrenergic blockers are usually effective in controlling hypertension associated with tachycardia. CPP should be maintained between 70 and 110 mm Hg. Vasodilators should be avoided until the dura is opened. Excessive hyperventilation (Paco₂ < 35 mm Hg) should be avoided in trauma patients (unless the patient manifests signs of impending herniation) to prevent excessive decreases in oxygen delivery.

Disseminated intravascular coagulation occasionally may be seen with severe head injuries. Such injuries cause the release of large amounts of brain thromboplastin and may also be associated with ARDS. Pulmonary aspiration
and neurogenic pulmonary edema may also be responsible for deteriorating lung function. When PEEP is used, ICP monitoring can be useful to confirm an adequate CPP. Diabetes insipidus, characterized by inappropriately dilute polyuria, is frequently seen following brain trauma, especially with injuries to the pituitary. Other likely causes of polyuria should be excluded and the diagnosis confirmed by measurement of urine and serum osmolality prior to treatment with fluid restriction and vasopressin (see Chapter 49). Gastrointestinal bleeding from stress ulceration is common in patients not receiving prophylaxis.

The decision whether to extubate the trachea at the conclusion of the surgical procedure depends on the severity of the injury, the presence of concomitant abdominal or thoracic injuries, preexisting illnesses, and the preoperative level of consciousness. Young patients who were conscious preoperatively may be extubated following the removal of a localized lesion, whereas patients with diffuse brain injury should remain intubated. Moreover, persistent intracranial hypertension requires continued paralysis, sedation, CSF drainage, and elevated head position. Protracted hyperventilation may be employed should other interventions fail to correct ICP; however, cerebral blood flow may be deleteriously affected, leading to brain ischemia.

---

### Anesthesia for Intracranial Aneurysms & Arteriovenous Malformations

Saccular aneurysms and AVMs are common causes of nontraumatic intracranial hemorrhages. Surgical or interventional neuroradiological treatment may be undertaken either electively to prevent hemorrhage or emergently to prevent further complications once hemorrhage has taken place. Other nontraumatic hemorrhages (eg, from hypertension, sickle cell disease, or vasculitis) are usually treated medically.

### CEREBRAL ANEURYSMS

#### Preoperative Considerations

Cerebral aneurysms typically occur at the bifurcation of the large arteries at the base of the brain; most are located in the anterior circle of Willis. Approximately 10% to 30% of patients have more than one aneurysm. The general incidence of
saccular aneurysms in some estimates is reported to be 5%, but only a minority of those with aneurysms will have complications. Rupture of a saccular aneurysm is the most common cause of subarachnoid hemorrhage (SAH). The acute mortality following rupture is approximately 10%. Of those who survive the initial hemorrhage, about 25% die within 3 months from delayed complications. Moreover, up to 50% of survivors are left with neurological deficits. As a result, the emphasis in management is on prevention of rupture. Unfortunately, most patients present only after rupture has already occurred.

Unruptured Aneurysms

Patients may present with prodromal symptoms and signs suggesting progressive enlargement. The most common symptom is headache, and the most common physical sign is a third-nerve palsy. Other manifestations could include brainstem dysfunction, visual field defects, trigeminal nerve dysfunction, cavernous sinus syndrome, seizures, and hypothalamic–pituitary dysfunction. The most commonly used techniques to diagnose an aneurysm are MRI, angiography, and helical CT angiography. Following diagnosis, patients are brought to the operating room, or more likely the “hybrid” suite, for coiling or clipping of the aneurysm. Most patients are in the 40- to 60-year-old age group and in otherwise good health.

Ruptured Aneurysms

Ruptured aneurysms usually present acutely as SAH. Patients typically complain of a sudden severe headache without focal neurological deficits, but often associated with nausea and vomiting. Transient loss of consciousness may occur and may result from a sudden rise in ICP and precipitous drop in CPP. If ICP does not decrease rapidly after the initial sudden increase, death usually follows. Large blood clots can cause focal neurological signs in some patients. Minor bleeding may cause only a mild headache, vomiting, and nuchal rigidity. The severity of SAH is graded according to the Hunt and Hess scale (Table 27–3), as well as the World Federation of Neurological Surgeons grading scale of SAH (Table 27–4). The Fisher grading scale, which uses CT to assess the amount of blood detected, gives the best indication of the likelihood of the development of cerebral vasospasm and patient outcome (Table 27–5).

2GCS, Glasgow Coma Scale.
3Excludes cranial neuropathies, but includes dysphasia.

**TABLE 27–5**  Fisher grading scale of cranial computerized tomography (CCT).1
Delayed complications include delayed cerebral ischemia (DCI), rerupture, and hydrocephalus. DCI occurs in 30% of patients (usually after 4–14 days) and is a major cause of morbidity and mortality. Previously, cerebral arterial vasospasm was considered the primary cause of DCI following SAH. While cerebral artery vasospasm does occur it often does not correlate with areas of cerebral infarction. Consequently, other mechanisms are considered as also contributing to DCI. These include cortical spreading depolarizations and microthrombosis. Cortical spreading depolarizations (CSDs) are progressive neuronal depolarizations of grey matter following brain injury such as SAH. CSDs can both increase and decrease cerebral blood flow. Cerebral ischemia results secondary to inadequate perfusion following CSDs in injured brains. *N*-methyl-D-aspartate (NMDA) receptor antagonists such as ketamine may modulate CSDs. SAH is also thought to contribute to platelet activation and formation of microthrombi, which likewise produce cerebral ischemia. Manifestations of DCI are due to cerebral ischemia and infarction and depend on the severity and distribution of the involved vessels. The Ca$^{2+}$ channel antagonist nimodipine is used following SAH to mitigate the effects of DCI. Both transcranial Doppler and brain tissue oxygen monitoring can be used to guide vasospasm therapy. Increased velocity of flow greater than 200 cm/s is indicative of severe spasm. The Lindegaard ratio compares the blood velocity of the cervical carotid artery with that of the middle cerebral artery. A ratio greater than 3 is likewise indicative of severe spasm. Brain tissue oxygen tension less than 20 mm Hg is also worrisome. In patients with symptomatic vasospasm with an inadequate response to nimodipine, intravascular volume expansion and induced hypertension (“triple H” therapy: hypervolemia, hemodilution, and hypertension) are added as part of the therapeutic regimen. Recent
reviews have questioned the role for hypervolemia, recommending maintenance of euvolemia while acknowledging that hypertension may be most beneficial in the management of DCI. Refractory vasospasm may be treated with catheter-delivered vasodilators, angioplasty, or both. However, radiological improvement in the vessel diameter does not necessarily correlate with an improvement in clinical status.

PREOPERATIVE MANAGEMENT

In addition to assessing and documenting neurological findings, the preoperative evaluation should include a search for coexisting diseases, such as hypertension and renal, cardiac, or ischemic cerebrovascular disease. Electrocardiographic abnormalities are commonly seen in patients with SAH, but do not necessarily reflect underlying heart disease. However, increases of cardiac troponin during SAH are associated with myocardial injury and may herald a poor outcome. Stress-induced cardiomyopathy may also be present. Most conscious patients with normal ICP are sedated following rupture to prevent rebleeding; such sedation should be continued until induction of anesthesia. Patients with persistent elevation in ICP should receive little or no premedication to avoid hypercapnia.

INTRAOPERATIVE MANAGEMENT

Aneurysm surgery can result in exsanguinating hemorrhage as a consequence of rupture or rebleeding. Blood should be available prior to the start of these operations.

Regardless of the anesthetic technique employed, anesthetic management should focus on preventing rupture (or rebleeding) and avoiding factors that promote cerebral ischemia or vasospasm. Intraarterial pressure monitoring is useful. Sudden increases in blood pressure with tracheal intubation or surgical stimulation should be avoided. Judicious intravascular volume loading permits surgical levels of anesthesia without excessive decreases in blood pressure. Because calcium channel blockers, angiotensin receptor blockers, and angiotensin-converting enzyme inhibitors cause systemic vasodilation and reduce systemic vascular resistance, patients receiving these agents preoperatively may be particularly prone to hypotension.

The great majority of cerebral aneurysms are addressed via an endovascular approach. The anesthetic concerns of patients taken for coiling in the neurointerventional suite are similar to those of patients undergoing craniotomy.
General anesthesia is often employed. Patients require heparin anticoagulation and radiological contrast. Communication with the surgeon or neurointerventionalist as to the desired activated clotting time and need for protamine reversal is essential. Moreover, anesthesia staff in the neuroradiology suite must be prepared to manipulate and monitor the blood pressure, as with an open surgical procedure.

For the less common situation in which open craniotomy is required, once the dura is opened, mannitol is often given to facilitate surgical exposure and reduce the need for surgical retraction. Rapid decreases in ICP prior to dural opening are avoided as they may promote rebleeding by removing a tamponading effect on the aneurysm.

Elective (controlled) hypotension has been used in aneurysm surgery. Decreasing mean arterial blood pressure reduces the transmural tension across the aneurysm, making rupture (or rebleeding) less likely and facilitating surgical clipping. Controlled hypotension can also decrease blood loss and improve surgical visualization in the event of bleeding. The combination of a slightly head-up position with a volatile anesthetic enhances the effects of any of the commonly used hypotensive agents. Should accidental rupture of the aneurysm occur, the surgeon may request transient hypotension to facilitate control of the bleeding. Neurophysiological monitoring may be employed during aneurysm surgery to identify potential ischemia during clip application. Rarely, hypothermic circulatory arrest is used for large basilar artery aneurysms.

Depending on neurological condition, most patients should be extubated at the end of surgery. Extubation should be handled similarly to other craniotomies (see earlier discussion). A rapid awakening allows neurological evaluation in the operating room, prior to transfer to the intensive care unit.

**ARTERIOVENOUS MALFORMATIONS**

AVMs cause intracerebral hemorrhage more often than SAH. These lesions are developmental abnormalities that result in arteriovenous fistulas; they typically grow in size with time. AVMs may present at any age, but bleeding is most common between 10 and 30 years of age. Other common presentations include headache and seizures. The combination of high blood flow with low vascular resistance can rarely result in high-output cardiac failure. In most cases an endovascular approach to occlude the vessels feeding the AVM will be attempted in the “hybrid” operating room or neurointerventional suite. This may provide definitive therapy or may render the AVM more amenable to surgical excision.
Neuroradiological embolization employs various coils, glues, and balloons to obliterate the AVM. Risks include embolization into cerebral arteries feeding the normal brain, as well as systemic or pulmonary embolism.

Anesthetic management of patients undergoing resection of AVMs may be complicated by extensive blood loss. Venous access with multiple large-bore cannulas is necessary. Hyperventilation and mannitol may be used to facilitate surgical access. Hyperemia and swelling can develop following resection, possibly because of altered autoregulation in the remaining normal brain. Emergence hypertension is typically controlled with agents that do not induce increases in CBF, such as β-blockers and clevidipine.

**Acute Ischemic Stroke**

Acute ischemic strokes are treated with thrombolysis (with tissue plasminogen activator [tPA]), or endovascular clot removal and stenting, or both. Multiple well-performed randomized clinical trials reported in 2015 have confirmed that immediate endovascular intervention greatly improves outcomes relative to tPA alone in patients with occlusions of proximal large cerebral arteries. The mantra in neurology and neurosurgery is “time is brain.” The goal is to have the patient revascularized as soon as possible. Endovascular treatment should not be delayed for placement of arterial lines, etc. These patients are at immediate risk of death and disability without treatment and certainly meet the criteria for an American Society of Anesthesiologists physical status of 5E! The benefit from endovascular treatment of acute ischemic stroke is even greater (a smaller number of patients need to be treated to have a patient with outcome benefit) than that for immediate revascularization for myocardial infarctions with elevated ST segments (STEMIs). However, the only patients who will benefit from endovascular treatment will have a significant amount of the ischemic brain tissue that remains “recoverable” as assessed in imaging studies by measures of CBF, CBV, and tissue transit time. In infarcted brain, all are abnormal. In recoverable brain tissue, at a minimum the CBV may be maintained or even increased.

Several post hoc analyses of the original clinical trials have suggested an association between the use of general anesthesia (versus sedation and monitoring) and worse outcomes in patients undergoing endovascular embolectomy. Nevertheless, general anesthesia remains the preference in many centers and will be required for many patients. We have observed that patients with acute left middle cerebral artery occlusion and aphasia may not hold still no matter how loudly they are asked!
The goals of anesthesia for endovascular treatment of acute ischemic stroke are to maintain the blood pressure less than 180 mm Hg if tPA has been given. If tPA has not been given, relative hypertension may be preferable to maintain cerebral perfusion pending clot retrieval and stenting. Once the occluded vessel has been reopened, we recommend tight control of blood pressure, in most cases keeping it at 140/90 mm Hg or less.

**Anesthesia for Surgery on the Spine**

Spinal surgery is most often performed for symptomatic nerve root or cord compression secondary to trauma or degenerative disorders. Compression may occur from protrusion of an intervertebral disk or osteophytic bone (spondylosis) into the spinal canal or an intervertebral foramen. Prolapse of an intervertebral disk often occurs at either the fourth or fifth lumbar or the fifth or sixth cervical levels in adults. Spondylosis tends to affect the lower cervical spine more than the lumbar spine and typically afflicts older patients. Operations on the spinal column can help correct deformities (eg, scoliosis), decompress the cord, and fuse the spine if disrupted by trauma or degenerative conditions. Spinal surgery may also be performed to resect a tumor or vascular malformation or to drain an abscess or hematoma.

**PREOPERATIVE MANAGEMENT**

Preoperative evaluation should focus on any anatomic abnormalities and limited neck movements (from disease, traction, “collars,” or other devices) that might complicate airway management. Neurological deficits should be documented. Neck mobility should be assessed. Patients with unstable cervical spines can be managed with either awake fiberoptic intubation or intubation after induction with in-line stabilization.

**INTRAOPERATIVE MANAGEMENT**

Spinal operations involving multiple levels, fusion, and instrumentation are also complicated by the potential for large intraoperative blood loss; a red cell salvage device is often used. Excessive distraction during spinal instrumentation (Harrington rod or pedicle screw fixation) can injure the spinal cord. Transthoracic approaches to the spine require one-lung ventilation. Anterior/posterior approaches require the patient to be repositioned in the middle
Positioning

Most spine surgical procedures are carried out in the prone position. The supine position may be used for an anterior approach to the cervical spine, making anesthetic management easier, but increasing the risk of injury to the trachea, esophagus, recurrent laryngeal nerve, sympathetic chain, carotid artery, or jugular vein. A sitting (for cervical spine procedures) or lateral decubitus (for lumbar spine procedures) position may occasionally be used.

Following induction of anesthesia and tracheal intubation in the supine position, the patient is turned to the prone position. Care must be taken to maintain the neck in a neutral position. Once in the prone position, the head may be turned to the side (not exceeding the patient’s normal range of motion) or (more commonly) can remain face down on a cushioned holder or secured by pins or tongs. Caution is necessary to avoid corneal abrasions or retinal ischemia from pressure on either globe, or pressure injuries of the nose, ears, forehead, chin, breasts, or genitalia. The chest should rest on parallel rolls (“chest rolls” of foam, gel, or other padding) or special supports—if a frame is used—to facilitate ventilation. The arms may be tucked by the sides in a comfortable position or extended with the elbows flexed (avoiding excessive abduction at the shoulder).

Turning the patient prone is a critical maneuver, sometimes complicated by hypotension. Abdominal compression, particularly in obese patients, may impede venous return and contribute to excessive intraoperative blood loss from engorgement of epidural veins. Prone positioning with chest rolls that permits the abdomen to hang freely can mitigate this increase in venous pressure. Deliberate hypotension has been advocated in the past to reduce bleeding associated with spine surgery. However, this should only be undertaken with a full understanding that controlled hypotension may increase the risk of perioperative vision loss (POVL).

POVL occurs secondary to:

- Ischemic optic neuropathy
- Perioperative glaucoma
- Cortical hypotension and embolism

Prolonged surgery in a head-down position, major blood loss, relative hypotension, diabetes, obesity, and smoking all put patients at greater risk of POVL following spine surgery.
Airway and facial edema can likewise develop after prolonged “head-down” positioning. Reintubation, if required, will likely present more difficulty than the intubation at the start of surgery.

Specialized head positioning pillows (eg, Covidien, ProneView) are often used when patients are placed in the prone position, and the face must be checked periodically to verify that the eyes, nose, and ears are free of pressure. Even foam cushions can exert pressure over time on the chin, orbit, and maxilla. Turning the head is not easily accomplished when the head is positioned on a cushion; therefore, if prolonged procedures are planned, the head can be secured with pins keeping the face free from any pressure.

**Monitoring**

When major blood loss is anticipated or the patient has preexisting cardiac disease, intraarterial pressure monitors should be considered prior to “positioning” or “turning.” Sudden, massive blood loss from injury to the great vessels can occur intraoperatively with adjacent thoracic or lumbar spine procedures.

Instrumentation of the spine requires the ability to intraoperatively detect spinal cord injury. Intraoperative wake-up techniques employing nitrous oxide-narcotic or total intravenous anesthesia allow the testing of motor function following distraction. Once preservation of motor function is established, the patient’s anesthetic can be deepened. Continuous monitoring of somatosensory evoked potentials and motor evoked potentials provides alternatives that avoid the need for intraoperative awakening. These monitoring techniques require substitution of propofol, opioid, or ketamine infusions for deep levels of inhalation anesthetics and avoidance of neuromuscular paralysis.

**CASE DISCUSSION**

**Resection of a Pituitary Tumor**

A 41-year-old woman presents to the operating room for resection of a 10-mm pituitary tumor. She complains of amenorrhea and galactorrhea, and had recently noticed a decrease in her visual acuity, with bitemporal hemianopsia.
What hormones does the pituitary gland normally secrete?

Functionally and anatomically, the pituitary is divided into two parts: anterior and posterior. The latter is part of the neurohypophysis, which also includes the pituitary stalk and the median eminence.

The anterior pituitary is composed of several cell types, each secreting a specific hormone. Anterior pituitary hormones include adrenocorticotropic hormone (ACTH), thyroid-stimulating hormone (TSH), growth hormone (GH), the gonadotropins (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]), and prolactin (PRL). Secretion of each of these hormones is regulated by hypothalamic peptides (releasing hormones) that are transported to the adenohypophysis by a capillary portal system. The secretion of FSH, LH, ACTH, TSH, and their respective releasing hormones is also under negative feedback control by the products of their target organs. For example, an increase in circulating thyroid hormone inhibits the secretion of TSH-releasing factor and TSH.

The posterior pituitary secretes antidiuretic hormone (ADH, also called vasopressin) and oxytocin. These hormones are actually formed in supraoptic and paraventricular neurons, respectively, and are transported down axons that terminate in the posterior pituitary. Hypothalamic osmoreceptors, and, to a lesser extent, peripheral vascular stretch receptors, regulate secretion of ADH.

What is the function of these hormones?

ACTH stimulates the adrenal cortex to secrete glucocorticoids. Unlike production of mineralocorticoids, production of glucocorticoids is dependent on ACTH secretion. TSH accelerates the synthesis and release of thyroid hormone (thyroxine). Normal thyroid function is dependent on production of TSH. The gonadotropins FSH and LH are necessary for normal production of testosterone and spermatogenesis and cyclic ovarian function. GH promotes tissue growth and increases protein synthesis as well as fatty acid mobilization. Its effects on carbohydrate metabolism are to decrease cellular glucose uptake and utilization and increase insulin secretion. PRL functions to support breast development during pregnancy. Dopamine receptor antagonists are known to increase secretion of PRL.

Through its effect on water permeability in renal collecting ducts, ADH regulates extracellular osmolarity and blood volume. Oxytocin acts on areolar myoepithelial cells as part of the milk letdown reflex during suckling and enhances uterine activity during labor.
What factors determine the surgical approach in this patient?

The pituitary gland is attached to the brain by a stalk and extends downward to lie in the sella turcica of the sphenoid bone. Anteriorly, posteriorly, and inferiorly, it is bordered by bone. Laterally, it is bordered by the cavernous sinus, which contains cranial nerves III, IV, V₁, and VI, as well as the cavernous portion of the carotid artery. Superiorly, the diaphragma sella, a thick dural reflection, usually tightly encircles the stalk and forms the roof of the sella turcica. In close proximity to the stalk lie the optic nerves and chiasm. The hypothalamus lies contiguous and superior to the stalk.

Tumors less than 10 mm in diameter are usually approached via the transsphenoidal route, whereas larger tumors and those with significant suprasellar extension are approached via a bifrontal craniotomy. With the use of prophylactic antibiotics, morbidity and mortality rates are significantly less with the transsphenoidal approach; the operation is carried out with the aid of a microscope through an incision in the gingival mucosa beneath the upper lip. The surgeon enters the nasal cavity, dissects through the nasal septum, and finally penetrates the roof of the sphenoid sinus to enter the floor of the sella turcica.

What are the major problems associated with the transsphenoidal approach?

Problems include (1) the need for mucosal injections of epinephrine-containing solution to reduce bleeding, (2) the accumulation of blood and tissue debris in the pharynx and stomach, (3) the risk of hemorrhage from accidental entry into the cavernous sinus or the internal carotid artery, (4) cranial nerve damage, and (5) pituitary hypofunction. Prophylactic administration of glucocorticoids is routinely used in most centers. Diabetes insipidus develops postoperatively in up to 40% of patients but is usually transient. Less commonly, the diabetes insipidus presents intraoperatively. The supine and slightly head-up position used for this procedure may also predispose to venous air embolism.

What type of tumor does this patient have?

Tumors in or around the sella turcica account for 10% to 15% of intracranial neoplasms. Pituitary adenomas are most common, followed by craniopharyngiomas and then parasellar meningiomas. Primary malignant
pituitary and metastatic tumors are rare. Pituitary tumors that secrete hormones (functional tumors) usually present early, when they are still relatively small (<10 mm). Other tumors present late, with signs of increased ICP (headache, nausea, and vomiting) or compression of contiguous structures (visual disturbances or pituitary hypofunction). Compression of the optic chiasm classically results in bitemporal hemianopia. Compression of normal pituitary tissue produces progressive endocrine dysfunction. Failure of hormonal secretion usually progresses in the order of gonadotropins, GH, ACTH, and TSH. Diabetes insipidus can also be seen preoperatively. Rarely, hemorrhage into the pituitary results in acute panhypopituitarism (pituitary apoplexy) with signs of a rapidly expanding mass, hemodynamic instability, and hypoglycemia. This patient has the most common type of secretory adenoma, producing hyperprolactinemia.

What other types of secretory hormones are seen?

Adenomas secreting ACTH (Cushing disease) produce classic manifestations of Cushing syndrome: truncal obesity, moon facies, abdominal striae, proximal muscle weakness, hypertension, and osteoporosis. Glucose tolerance is typically impaired, but frank diabetes is less common (<20%). Hirsutism, acne, and amenorrhea are also commonly seen in women.

Adenomas that secrete GH are often large and result in either gigantism (prepubertal patients) or acromegaly (adults). Excessive growth prior to epiphyseal fusion results in massive growth of the entire skeleton. After epiphyseal closure, the abnormal growth is limited to soft tissues and acral parts: hands, feet, nose, and mandible. Patients develop osteoarthritis, which often affects the temporomandibular joint and spine. Diabetes, myopathies, and neuropathies are common. Cardiovascular complications include hypertension, premature coronary disease, and cardiomyopathy in some patients. The most serious anesthetic problem encountered in these patients is difficulty in intubating the trachea.

Are any special monitors required for transsphenoidal surgery?

Monitoring should be carried out in somewhat the same way as for craniotomies. Visual evoked potentials may be employed with large tumors that involve the optic nerves. Precordial Doppler sonography may be used for detecting venous air embolism. Venous access with large-bore catheters
is desirable in the event of massive hemorrhage

**What modifications, if any, are necessary in the anesthetic technique?**

The same principles discussed for craniotomies apply; however, patients rarely have evidence of increased ICP. Intravenous antibiotic prophylaxis and glucocorticoid coverage (hydrocortisone, 100 mg) are usually given prior to induction. Many clinicians avoid nitrous oxide to prevent problems with a postoperative pneumocephalus (see earlier discussion). Effective neuromuscular blockade is important to prevent movement while the surgeon is using the microscope. A lumbar drain is often placed to reduce ICP, facilitate surgical exposure, and reduce the likelihood of CSF leaks after closure of the dura.

**SUGGESTED READINGS**

Huh J, Raghupathi R. New concepts in treatment of pediatric traumatic brain

Anesthesia for Patients with Neurological & Psychiatric Diseases

KEY CONCEPTS

1. Induction of anesthesia in patients receiving long-term levodopa therapy may result in either marked hypotension or hypertension.
2. In patients with multiple sclerosis, increases in body temperature cause exacerbation of symptoms.
3. The major risk of anesthesia in patients with autonomic dysfunction is severe hypotension, compromising cerebral and coronary blood flow.
4. Autonomic hyperreflexia should be expected in patients with spinal cord lesions above T6 and can be precipitated by surgical manipulations.
5. The most important interaction between anesthetic agents and tricyclic antidepressants is an exaggerated response to both indirect-acting vasopressors and sympathetic stimulation.

Patients with vascular and nonvascular neurological diseases or psychiatric disorders are frequently encountered by anesthesia providers. Anesthesiologists must have a basic understanding of the major neurological and psychiatric disorders and their drug therapy. Failure to recognize potential adverse anesthetic interactions may result in avoidable perioperative morbidity.

Cerebrovascular Disease

Preoperative Considerations
Patients with diagnosed cerebrovascular disease typically have a history of transient ischemic attacks (TIAs) or stroke. Patients with TIAs undergoing surgery for other indications have an increased risk of perioperative stroke. Asymptomatic carotid bruises occur in up to 4% of patients older than age 40 years, but do not necessarily indicate significant carotid artery obstruction. Fewer than 10% of patients with completely asymptomatic bruises have hemodynamically significant carotid artery lesions. An asymptomatic carotid bruit may not increase the risk of stroke following surgery, but it increases the likelihood of coexisting coronary artery disease. Moreover, the absence of a bruit does not exclude significant carotid obstruction.

The risk of perioperative stroke increases with patient age and varies with the type of surgery. Although the overall risk of stroke associated with surgery is low, it is greater in patients undergoing cardiovascular or cerebrovascular surgery. Rates of stroke after general anesthesia and surgery range from 0.08% to 0.4%. Even in patients with known cerebrovascular disease, the risk is only 0.4% to 3.3%. Patients at greatest risk of postoperative stroke are those undergoing open heart procedures for valvular disease, coronary artery disease with ascending aortic atherosclerosis, and diseases of the thoracic aorta. Stroke following open heart surgery is usually attributed to embolism of air, clots, or atheromatous debris. In one study, 6% of patients experienced an adverse neurological outcome following cardiac surgery. Stroke following thoracic aortic surgery may be due to emboli or ischemia secondary to prolonged circulatory arrest or a clamp placed close to the origin of the carotid artery.

The pathophysiology of postoperative strokes following noncardiovascular surgery is less clear but may involve severe sustained hypotension or hypertension. Hypotension with severe hypoperfusion can result in so-called “watershed” zone infarctions or thrombosis of cerebral arteries, whereas hypertension can result in intracerebral hemorrhage (hemorrhagic stroke). Sustained hypertension can disrupt the blood–brain barrier and promote cerebral edema. Perioperative atrial fibrillation can likewise lead to atrial clot formation and cerebral embolism. The period of time during which anesthesia and surgery should best be avoided following a stroke is not clear. Abnormalities in regional blood flow and metabolic rate usually resolve after 2 weeks, whereas alterations in CO₂ responsiveness and the blood–brain barrier may require more than 4 weeks. However, urgent surgery is performed for acute intracranial hemorrhage, symptomatic carotid disease, and cardiac sources of emboli.

Patients with TIAs have a history of transient (<24 h) impairment, and, by definition, no residual neurological impairment. These attacks are thought to
result from emboli of fibrin-platelet aggregates that form on plaques in extracranial vessels. Unilateral visual impairment, numbness or weakness of an extremity, or aphasia is suggestive of carotid disease, whereas bilateral visual impairment, dizziness, ataxia, dysarthria, bilateral weakness, or amnesia is suggestive of vertebral–basilar disease. Patients with TIAs have a 30% to 40% chance of developing a frank stroke within 5 years; 50% of these strokes occur within the first year. Patients with TIAs should not undergo any elective surgical procedure without an adequate medical evaluation that generally includes at least noninvasive (Doppler) flow and imaging studies. The presence of an ulcerated plaque of greater than 60% occlusion is generally an indication for endovascular intervention or less commonly an open carotid thromboendarterectomy.

**PREOPERATIVE MANAGEMENT**

Preoperative assessment requires neurological and cardiovascular evaluations. The type of stroke, the presence of neurological deficits, and the extent of residual impairment should be determined. Thromboembolic strokes usually occur in patients with generalized atherosclerosis. Most patients are elderly and have comorbid conditions, such as hypertension, hyperlipidemia, and diabetes. Coexisting coronary artery disease and renal impairment are common. Following nonhemorrhagic strokes or TIAs, many patients are placed on long-term anticoagulant or antiplatelet therapy, or both. Management of antiplatelet therapy and antithrombotic therapy should be reviewed by the anesthesia and surgical teams, often guided by the physician who prescribed the therapy, to determine the risks and benefits of discontinuation or maintenance of such therapy perioperatively. Other systemic diseases, such as diabetes, hypertension, coronary artery disease, heart failure, and chronic obstructive lung disease, frequently manifest in the patient with cerebrovascular disease.

**INTRAOPERATIVE MANAGEMENT**

Patients may present for surgery following embolic, thrombotic, and hemorrhagic strokes.

Management of the patient following acute embolic stroke is directed toward the embolic source. Cardiac surgery is performed to remove atrial myxomas. Systemic emboli can also be produced from endocarditic vegetations, as well as from degenerated heart valves and intracardiac thrombus.

Patients with acute strokes secondary to carotid and intracranial occlusive arterial disease present for carotid endarterectomy and endovascular procedures.
When an awake procedure is undertaken, the patient serves as a monitor of the adequacy of cerebral blood flow during application of vessel clamps or placement of a stent. When general anesthesia is used, electroencephalography, evoked potentials, carotid stump pressure, near-infrared cerebral oximetry, or transcranial Doppler may be used to estimate the adequacy of cerebral oxygen delivery. During open carotid thromboendarterectomy the surgeon may place a shunt to deliver blood to the brain around the cross-clamped vessel. Despite adequate cerebral blood flow, perioperative stroke can occur during carotid surgery secondary to emboli.

Management of patients following thrombotic or hemorrhagic stroke for nonneurological surgery must be individualized. Cerebral autoregulation of blood flow may fail, leaving flow directly dependent upon cerebral perfusion pressure (Figure 28–1). The penumbra of potentially salvageable neurological tissue may therefore be very sensitive to injury from the effects of both hypotension and hypertension (Figure 28–2). We advocate tight control of blood pressure in these patients.

![Cerebral autoregulation in a normal person, cerebral ischemia, and chronic hypertension.](image)

*Figure 28–1 Cerebral autoregulation in a normal person, cerebral ischemia, and chronic hypertension. (Reproduced with permission from Shaikh S. Anesthesia considerations for the patient with acute ischemic stroke. *Semin Cardiothorac Vasc Anesth*. 2010 Mar;14(1):62-63.)*
Patients taken to surgery following administration of thrombolytic therapy are at increased risk of cerebral hemorrhage, and tight blood pressure control may reduce the likelihood of cerebral bleeding.

Patients with major intracerebral hemorrhage or epidural or subdural hematomas after trauma typically undergo craniotomy and evacuation of hematoma. In these patients invasive arterial pressure monitoring is helpful given that cerebral autoregulation is deranged (see Figure 28–1). Hypertension is frequently treated with intravenous vasodilators and β-blockers. Subarachnoid hemorrhage is discussed in Chapter 27.

**INTRACRANIAL TUMORS**

Patients with intracranial mass lesions frequently present to their primary care physicians with complaints of headache, visual disturbances, or seizures. Families may have noticed behavioral changes in patients with frontal lobe masses. Imaging studies confirm the presence of a mass, and initial treatment with dexamethasone is aimed at decreasing cerebral edema. Electrolytes should be reviewed perioperatively in all patients undergoing cranial surgery, as both hyponatremia and hypernatremia can develop secondary to cerebral salt wasting, inappropriate antidiuretic hormone secretion, or central diabetes insipidus (Table 28–1; see also Chapter 49). Patients with altered mentation preoperatively may
likewise be dehydrated. Hyperglycemia secondary to steroid use is frequently seen.

Seizure Disorders

Preoperative Considerations

Seizures represent abnormal synchronized electrical activity in the brain. They may be a manifestation of an underlying central nervous system disease, a systemic disorder, or idiopathic. Up to 2% of the population may experience a seizure in their lifetime. Epilepsy is a disorder characterized by recurrent paroxysmal seizure activity. Healthy individuals who experience an isolated nonrecurrent seizure are not considered to have epilepsy.

Seizure activity may be localized to a specific area in the brain or may be generalized. Moreover, initially localized (focal) seizures can subsequently spread, becoming generalized. A simple classification scheme is presented in Table 28–2. Partial seizures (also called focal) are clinically manifested by motor, sensory, autonomic, or psychiatric symptoms, depending on the brain region affected. Focal seizures associated with impairment in consciousness are termed “complex partial” (psychomotor or temporal lobe) seizures. Generalized seizures characteristically produce bilaterally symmetric electrical activity without local onset. They may result in abnormal motor activity, loss of consciousness, or both. Absence (petit mal) seizures produce generalized activity resulting in isolated, transient lapses in consciousness. Other generalized seizures are usually classified according to the type of motor activity. Tonic–clonic (grand mal) seizures are most common and are characterized by a loss of consciousness followed by clonic and then tonic motor activity.

**PREOPERATIVE MANAGEMENT**

Anesthetic evaluation should focus primarily on the cause and type of seizure activity and the drugs with which the patient is being treated. Seizures in adults are most commonly due to structural brain lesions (head trauma, tumor, degeneration, or stroke) or metabolic abnormalities (uremia, hepatic failure, hypoglycemia, hypocalcemia, drug toxicity, or drug/alcohol withdrawal). Idiopathic seizures occur more often in children than in adults. Grand mal seizures are serious complicating factors in surgical patients and should be treated promptly to prevent musculoskeletal injury, hypoventilation, hypoxemia, and aspiration of gastrointestinal contents. If a seizure occurs, maintaining an open airway and adequate oxygenation are the first priorities. Propofol (50–100 mg) or a benzodiazepine such as diazepam (5–10 mg) or midazolam (1–5 mg) can be given intravenously to terminate the seizure.

Most patients with seizure disorders receive antiepileptic drugs preoperatively (Table 28–3). Antiseizure medications should be continued throughout the perioperative period to maintain therapeutic levels.

**TABLE 28–3** Commonly used antiepileptic drugs, mechanisms of action, and common side effects.¹,²
Intraoperative Management

In selecting general anesthetic agents, we avoid those few drugs with consistent propensity to induce seizures, (eg, enflurane) when there are reasonable alternatives. Theoretically, ketamine and methohexital (in small doses) could precipitate seizure activity. Hypothetically, large doses of atracurium, cisatracurium, or meperidine may be relatively contraindicated because of the reported epileptogenic potential of their respective metabolites, laudanosine, and normeperidine. Hepatic microsomal enzyme induction should be expected from chronic antiseizure therapy. Enzyme induction may increase the dose requirement and frequency of intravenous anesthetics and nondepolarizing neuromuscular blockers (NMBs) and may increase the risk for hepatotoxicity from halothane.

Degenerative & Demyelinating Diseases
PARKINSON DISEASE

Preoperative Considerations

Parkinson disease (PD) is a common movement disorder that typically afflicts individuals aged 50 to 70 years; it has a prevalence of 3% in the United States and Canada. This neurodegenerative disease is characterized by bradykinesia, rigidity, postural instability, and resting (pill-rolling) tremor. Additional frequently occurring findings include facial masking, hypophonia, dysphagia, and gait disturbances. Increasing problems with freezing, rigidity, and tremor eventually result in physical incapacitation. Early in the course of the disease, intellectual function is usually preserved, but the disease may progress to Lewy body dementia. PD is caused by a progressive loss of dopamine in the nigrostriatal pathway. Concurrent with the loss of dopamine, the activity of the γ-aminobutyric acid (GABA) nuclei in the basal ganglia increases, leading to an inhibition of thalamic and brainstem nuclei. Thalamic inhibition, in turn, suppresses the motor system in the cortex, resulting in the characteristic signs and symptoms.

Medical treatment is directed at controlling the symptoms. A variety of drugs may be used for mild disease, including levodopa, dopamine receptor agonists, monoamine oxidase (MAO) B inhibitors, anticholinergic agents, amantadine, and catechol-O-methyltransferase (COMT) inhibitors.

Moderate to severe disease is typically treated pharmacologically with dopaminergic agents, either levodopa (a precursor of dopamine) or a dopamine-receptor agonist. COMT inhibitors are also used to prevent the decarboxylation of levodopa. Levodopa side effects include nausea, vomiting, dyskinesias, sudden sleepiness, cardiac irritability, and orthostatic hypotension. Dopamine receptor agonists include both ergot derivatives (bromocriptine, cabergoline, lisuride, and apomorphine) and nonergot derivatives (pramipexole and ropinirole). The nonergot derivatives have been shown to be beneficial when used as monotherapy in early PD; all dopamine receptor agonists are effective when given as combination therapy with levodopa in the treatment of moderate to severe PD. Side effects are similar to those found with the use of levodopa alone, and, in addition, include headache, confusion, and hallucinations. Pulmonary, cardiac, and retroperitoneal fibrosis; pleural effusion and thickening; Raynaud syndrome; and erythromelalgia are more common side effects with the use of ergot derivatives than with nonergot derivatives.

The surgical treatment of PD formerly included ablative procedures (thalamotomy and pallidotomy), but implantation of electrodes for deep brain
stimulation is currently the most common approach. Stimulation of the subthalamic nucleus improves all of the primary symptoms of PD and results in a greater decrease in the amount of medication required for symptom relief, when compared with stimulation of the globus pallidus pars internus. However, globus pallidus pars internus stimulation may produce greater improvement in dyskinesia as compared with stimulation of the subthalamic nucleus.

**Anesthetic Considerations**

Medications for PD should be continued perioperatively, including the morning of surgery, because the half-life of levodopa is short. Abrupt withdrawal of levodopa can cause worsening of muscle rigidity and may interfere with ventilation. Phenothiazines, butyrophenones (droperidol), and metoclopramide can exacerbate symptoms as a consequence of their antidopaminergic activity and should be avoided. Anticholinergics (atropine) or antihistamines (diphenhydramine) may be used for acute exacerbation of symptoms. Diphenhydramine may be used for intraoperative sedation in patients with tremor. Induction of anesthesia in patients receiving long-term levodopa therapy may result in either marked hypotension or hypertension. Relative hypovolemia, catecholamine depletion, autonomic instability, and sensitization to catecholamines are probably contributory. Hypotension should be treated with small doses of a direct-acting vasopressor, such as phenylephrine, rather than ephedrine. The response to NMBs is generally normal. As mentioned previously, patients who fail medical treatment are candidates for surgical intervention—for example, implantation of a deep brain stimulator of the subthalamic nucleus, the ventral intermediate nucleus, or the globus pallidus internus. Because general anesthesia alters the threshold for stimulation, correct placement of the electrodes can be affected. Awake craniotomy has been the norm for epilepsy surgery and is being used increasingly for deep brain stimulation procedures. Two techniques are advocated: (1) a true awake craniotomy with heavy sedation (we recommend dexmedetomidine), and (2) an approach in which the patient receives a general anesthetic, usually a total intravenous anesthetic with propofol and remifentanil and a laryngeal mask airway for control of the airway. Following appropriate surgical exposure, the intravenous infusions are discontinued and the laryngeal mask airway is removed. The patient can be reanesthetized once the implantation of leads is complete.
DEMENTIAS

Preoperative Considerations

Neurodegenerative diseases often lead to dementia. The incidence of dementia varies by population but seems to double every decade of life, starting at age 60. Alzheimer disease (AD) is the most common neurodegenerative disease, causing more than half of all cases of dementia; dementia with Lewy bodies (most often associated with PD) and vascular dementia comprise most of the rest. Slow, progressive impairment of memory, judgment, and decision making, as well as emotional lability, are hallmarks of AD. Late in the course of the disease, severe extrapyramidal signs, apraxias, and aphasia are often present. Patients with AD usually show marked cortical atrophy with ventricular enlargement; the pathological hallmarks of AD seen at necropsy include neurofibrillary tangles that contain the phosphorylated microtubular protein tau, neuritic plaques, and excessive brain concentrations of amyloid β-peptides.

Anesthetic Considerations

Anesthetic management of patients with moderate to severe dementia is often complicated by disorientation and uncooperativeness. New onset of temporary cognitive impairment is frequent in elderly patients and often persists for 1 to 3 days following surgery. Such patients require repeated reassurance and explanation. Legally incompetent patients cannot provide informed consent for anesthesia or surgery. We avoid premedication if at all possible. Centrally acting anticholinergics, such as atropine and scopolamine, may contribute to postoperative confusion. Glycopyrrolate, which does not cross the blood–brain barrier, may be the preferred agent when an anticholinergic is required. Patients having dementia with Lewy bodies often will have PD and thus the anesthetic issues with PD that were addressed earlier in the chapter would apply.

Animal studies have shown that conventional general anesthetic agents are associated with neuronal injury and cell death. The outcome implications of general anesthesia in both the elderly and small children are currently the subject of much investigation and debate. Apoptotic neurodegeneration has been linked to the use of GABA receptor modulators and N-methyl-D-aspartic acid receptor antagonists, mechanisms by which common general anesthetics produce their effects. Moreover, increased β-amyloid production is associated with anesthetic exposure; tau protein phosphorylation increases after general anesthesia; and hypothermia transiently increases tau protein phosphorylation. Despite concerns
about anesthetic exposure in patients with or at risk for AD, current studies do not support avoiding needed surgery in this group.

**MULTIPLE SCLEROSIS**

**Preoperative Considerations**

Multiple sclerosis (MS) is characterized by demyelination at multiple sites in the brain and spinal cord; chronic inflammation eventually produces scarring (gliosis). Most investigators believe that the disease is an autoimmune disorder; however, the definitive cause has not been identified. MS primarily affects patients between 20 and 40 years of age, with a 2:1 female predominance, and typically follows an unpredictable course of attacks and remissions. With time, remissions become less complete, and the disease progresses to incapacitation; almost 50% of patients will require help with walking within 15 years of diagnosis. Clinical manifestations depend on the sites affected but frequently include sensory disturbances (paresthesias), visual problems (optic neuritis and diplopia), and motor weakness. Symptoms develop over the course of days and remit over weeks to months. Early diagnosis of exacerbations can often be confirmed by analysis of cerebrospinal fluid and magnetic resonance imaging. Remyelination is limited and often fails to occur. Moreover, axonal loss can develop. Changes in neurological function seem to be related to changes in axonal conduction. Conduction can occur across demyelinated axons, but seems to be affected by multiple factors, particularly temperature. In patients with MS, increases in body temperature cause exacerbation of symptoms.

The treatments of MS focus separately on symptoms and attempts to arrest the disease process. Diazepam, dantrolene, or baclofen, and, in refractory cases, an intrathecal delivery system for baclofen are used to control spasticity; bethanechol and other anticholinergics are useful for urinary retention. Painful dysesthesia may respond to carbamazepine, phenytoin, or antidepressants. Glucocorticoids may decrease the severity and duration of acute attacks. Corticosteroid-resistant relapses may respond to five to seven courses of plasma exchange offered on alternate days. Interferon has also been used to treat MS. Immunomodulation with a variety of drugs has been used in an attempt to halt disease progression, and ocrelizumab has received regulatory approval for this indication. The systemic effects of these therapies on coagulation, immunological, hepatic, and cardiac function should be reviewed preoperatively.
Anesthetic Considerations

The effect of stress, anesthesia, and surgery on the course of MS is controversial. Overall, the effect of anesthesia is unpredictable. Elective surgery should be avoided during relapse, regardless of the anesthetic technique employed. The preoperative consent record should document counseling of the patient to the effect that the stress of surgery and anesthesia might worsen symptoms. Spinal anesthesia has been associated with exacerbation of the disease; however, the entire surgery/delivery/anesthetic process may likewise lead to exacerbations. Peripheral nerve blocks are less of a concern because MS is a disease of the central nervous system; however, patients may have preexisting peripheral neuropathies. Epidural and other regional techniques seem to have no adverse effect on the course of the disease. No specific interactions with general anesthetics are recognized. Patients with advanced disease may have a labile cardiovascular system due to autonomic dysfunction. In the setting of paresis or paralysis, succinylcholine should be avoided because of possible hyperkalemia. Increases in body temperature should be avoided. Irrespective of anesthetic technique, patients may experience a worsening of symptoms perioperatively and should be counseled accordingly.

AMYOTROPHIC LATERAL SCLEROSIS

Motor neuron disease is another common neurodegenerative disease, with amyotrophic lateral sclerosis (ALS) being the most prevalent. The cause of ALS is unknown, although small numbers of patients with the familial form of the disease have a defect in the superoxide dismutase-1 gene. ALS is a rapidly progressive disorder of both upper and lower motor neurons. Patients often present in the fifth or sixth decade of life with muscular weakness, atrophy, fasciculation, and spasticity. The disease may initially be asymmetric, but over the course of 2 to 3 years becomes generalized, involving all skeletal and bulbar muscles. Progressive respiratory muscle weakness makes the patient susceptible to aspiration and eventually leads to death from ventilatory failure. Although the heart is unaffected, autonomic dysfunction can be seen. There is no specific treatment for ALS.

The primary emphasis in management is judicious respiratory care. As with other patients with lower motor neuron disease, succinylcholine is contraindicated because of the risk of hyperkalemia. Adequacy of ventilation should be carefully assessed both intraoperatively and postoperatively; an awake extubation is desirable. Difficulty in weaning patients from mechanical
ventilation postoperatively may be anticipated in patients with advanced disease.

**GUILLAIN–BARRÉ SYNDROME**

Guillain–Barré syndrome (GBS), a relatively common disorder affecting 1 to 4 individuals per 100,000 population, is characterized by a sudden onset of ascending motor paralysis, areflexia, and variable paresthesias. Subtypes of GBS include acute inflammatory demyelinating polyneuropathy (about 75% of cases), acute motor axonal neuropathy (with antibodies against gangliosides), and acute motor sensory axonal neuropathy. Bulbar involvement, including respiratory muscle paralysis, is a frequent complication. Pathologically, the disease seems to be an immunological reaction against the myelin sheath of peripheral nerves, particularly lower motor neurons. In most instances, the syndrome seems to follow an infection; the disorder can also present as a paraneoplastic syndrome associated with Hodgkin disease or as a complication of human immunodeficiency virus infection. Some patients respond to plasmapheresis. The prognosis is relatively good, with most patients recovering completely; however, approximately 10% of patients die of complications, and another 10% are left with long-term neurological sequelae.

Anesthetic management is complicated by lability of the autonomic nervous system in addition to concerns about respiratory insufficiency. Exaggerated hypotensive and hypertensive responses during anesthesia may be seen. As with other lower motor neuron disorders, succinylcholine should not be used because of the risk of hyperkalemia. The use of regional anesthesia in these patients remains controversial, as it might worsen symptoms. As with all decisions, the risks and benefits of regional versus general anesthesia must be weighed on an individual basis. As damaged nerves are more susceptible to a second injury (the “double crush” effect), performance of regional techniques in patients with preexistent neurological dysfunction should be carefully considered.

**AUTONOMIC DYSFUNCTIONS**

**Preoperative Considerations**

Autonomic dysfunction, or dysautonomia, may be due to generalized or segmental disorders of the central or peripheral nervous system. Symptoms can be generalized, segmental, or focal. These disorders may be congenital, familial, or acquired. Common manifestations include impotence; bladder and gastrointestinal dysfunction; abnormal regulation of body fluids; decreased
sweating, lacrimation, and salivation; and orthostatic hypotension. The latter can be the most serious manifestation of the disorder.

Acquired autonomic dysfunction can be isolated (pure autonomic failure), part of a more generalized degenerative process (Shy–Drager syndrome, PD, olivopontocerebellar atrophy), part of a segmental neurological process (MS, syringomyelia, reflex sympathetic dystrophy, or spinal cord injury), or a manifestation of disorders affecting peripheral nerves (GBS, diabetes, chronic alcoholism, amyloidosis, or porphyria).

There are at least three forms of hereditary sensory and autonomic neuropathies, each with its own underlying genetic mutation(s). Autonomic dysfunction is prominent and is associated with generalized diminished sensation and emotional lability. Moreover, patients are predisposed to dysautonomic crises triggered by stress and characterized by marked hypertension, tachycardia, abdominal pain, diaphoresis, vomiting, and the risk of dehydration.

**Anesthetic Considerations**

- The major risk of anesthesia in patients with autonomic dysfunction is severe hypotension, compromising cerebral and coronary blood flow. Marked hypertension can be equally deleterious. Most patients are chronically hypovolemic, and if volume deficits are not corrected the vasodilatory effects of spinal and epidural anesthesia are poorly tolerated. The vasodilatory and cardiac depressant effects of most general anesthetic agents combined with positive airway pressure can be equally problematic. Continuous intraarterial blood pressure monitoring is useful. Hypotension should be treated with fluids and direct-acting vasopressors (in preference to indirect-acting agents). The dose–response relationship for vasopressors may be abnormal due to denervation. Blood loss also is usually poorly tolerated. Body temperature should be monitored closely. Patients with anhidrosis are particularly susceptible to hyperpyrexia.

**SYRINGOMYELIA**

Syringomyelia results in progressive cavitation of the spinal cord. In many cases, obstruction of cerebrospinal fluid outflow from the fourth ventricle seems to be contributory. Many patients have craniovertebral abnormalities, particularly the Arnold–Chiari malformation. Increased pressure in the central canal of the spinal cord produces enlargement or diverticulation to the point of cavitation.
Syringomyelia typically affects the cervical spine, producing sensory and motor deficits in the upper extremities, and, frequently, thoracic scoliosis. Extension upward into the medulla (syringobulbia) leads to cranial nerve deficits. Syringoperitoneal shunting and other decompressive procedures have variable success in arresting the disease.

Anesthetic evaluation should focus on defining existing neurological deficits and any pulmonary impairment due to scoliosis. Autonomic instability should be expected in patients with extensive lesions. Succinylcholine should be avoided when muscle wasting is present because of the risk of hyperkalemia. As always, adequacy of ventilation and reversal of nondepolarizing NMBs should be achieved prior to extubation. Spinal puncture is contraindicated with intracranial hypertension. Epidural anesthetics have been used successfully for labor analgesia in patients with Arnold–Chiari malformations, with and without syringomyelia. Risks of cerebral herniation, worsening nerve injury, and infection must be weighed against potential benefits.

**Spinal Cord Injury**

**Preoperative Considerations**

Spinal cord injuries are most often traumatic and may arise from partial or complete transection. The majority of injuries are due to fracture and dislocation of the vertebral column. The mechanism is usually either compression and flexion at the thoracic spine or extension at the cervical spine. Clinical manifestations depend on the level of the injury. Injuries above C3–5 (diaphragmatic innervation) require patients to receive ventilatory support to stay alive. Transections above T1 result in quadriplegia, whereas those above L4 result in paraplegia. The most common sites of injury are C5–6 and T12–L1. Acute spinal cord transection produces loss of sensation, flaccid paralysis, and loss of spinal reflexes below the level of injury. These findings characterize a period of spinal shock that typically lasts 1 to 3 weeks.

Over the course of the next few weeks, spinal reflexes gradually return, together with muscle spasms and signs of sympathetic overactivity. Injury in the low thoracic or lumbar spine may result in cauda equina (conus medullaris) syndrome. The latter usually consists of incomplete injury to nerve roots rather than the spinal cord.

Overactivity of the sympathetic nervous system is common with transections at T5 or above, but is unusual with injuries below T10. Interruption of normal
descending inhibitory impulses in the cord results in autonomic hyperreflexia. Cutaneous or visceral stimulation below the level of injury can induce intense autonomic reflexes: sympathetic discharge produces hypertension and vasoconstriction below the transection and a baroreceptor-mediated reflex bradycardia and vasodilation above the transection. Cardiac arrhythmias are common.

Emergent surgical management is undertaken whenever there is reversible compression of the spinal cord due to dislocation of a vertebral body or bony fragment. Operative treatment is also indicated for spinal instability to prevent further injury.

Anesthetic Considerations

A. Acute Transection
Anesthetic management depends on the age of the injury. In the early care of acute injuries, the emphasis should be on preventing further spinal cord damage during patient movement, airway manipulation, and positioning. High-dose corticosteroid therapy (methylprednisolone) has been traditionally given for the first 24 h following injury to possibly improve neurological outcome. Airway management of the patient with an unstable cervical spine is discussed in Chapter 19. Patients with high transections often have impaired airway reflexes and are further predisposed to hypoxemia because of a decrease in functional residual capacity and atelectasis. Spinal shock can lead to hypotension and bradycardia prior to any anesthetic administration. Direct arterial pressure monitoring is helpful. An intravenous fluid bolus and the use of ketamine for anesthesia may help to prevent further decreases in blood pressure; vasopressors may also be required. Succinylcholine can be used safely in the first 24 h but should not be used thereafter because of the risk of hyperkalemia. The latter can occur within the first week following injury and is due to excessive release of potassium secondary to the proliferation of acetylcholine receptors beyond the neuromuscular synaptic cleft.

B. Chronic Transection
Anesthetic management of patients with nonacute transections is complicated by the possibility of autonomic hyperreflexia and the risk of hyperkalemia. Autonomic hyperreflexia should be expected in patients with spinal cord lesions above T6 and can be precipitated by surgical manipulations. Regional anesthesia and deep general anesthesia are effective in preventing
**hyperreflexia.** Many clinicians, however, are reluctant to administer spinal and epidural anesthesia in these patients because of the difficulties encountered in determining anesthetic level, exaggerated hypotension, and technical problems resulting from deformities. Severe hypertension can result in pulmonary edema, myocardial ischemia, or cerebral hemorrhage and should be treated promptly. Direct arterial vasodilators should be readily available. Nondepolarizing muscle relaxants may be used. Body temperature should be monitored carefully, particularly in patients with transections above T1, because chronic vasodilation and loss of normal reflex cutaneous vasoconstriction predispose to hypothermia. Many patients with a long-standing spinal cord injury have a long history of undergoing surgery without hyperreflexia. These patients can often be managed with monitoring and sedation.

---

**Encephalitis**

Various forms of encephalitis can present secondary to infectious or autoimmune mechanisms. Patients with encephalitis are managed with the normal care given any patient with potentially increased intracranial pressure at risk of cerebral hypoperfusion.

---

**Psychiatric Disorders**

**DEPRESSION**

Depression is a very common mood disorder characterized by sadness and pessimism. Its cause is multifactorial, but pharmacological treatment is based on the presumption that its manifestations are due to a brain deficiency of dopamine, norepinephrine, and serotonin or altered receptor activities. Up to 50% of patients with major depression hypersecrete cortisol and have abnormal circadian secretion. Current pharmacological therapy utilizes drugs that increase brain levels of these neurotransmitters: tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), MAO inhibitors, and atypical antidepressants. The mechanisms of action of these drugs result in some potentially serious anesthetic interactions. Electroconvulsive therapy (ECT) is increasingly used for refractory severe cases and may be continued prophylactically after the patient’s mood recovers. The use of general anesthesia for ECT is largely responsible for its safety and widespread acceptance.
Selective Serotonin Reuptake Inhibitors

SSRIs include fluoxetine, sertraline, and paroxetine, which some clinicians consider first-line agents of choice for depression. A surprisingly large fraction of patients undergoing elective surgery will be receiving one of these agents. These agents have little or no anticholinergic activity and do not generally affect cardiac conduction. Their principal side effects are headache, agitation, and insomnia. Other agents include the norepinephrine–dopamine reuptake inhibitors and the serotonin–norepinephrine reuptake inhibitors.

Tricyclic Antidepressants

Tricyclic antidepressants are used for the treatment of depression and chronic pain syndromes. All tricyclic antidepressants work at nerve synapses by blocking neuronal reuptake of catecholamines, serotonin, or both. Desipramine and nortriptyline are used because they are less sedating and tend to have fewer side effects. Other agents are generally more sedating and include amitriptyline, imipramine, protriptyline, amoxapine, doxepin, and trimipramine. Clomipramine is used in the treatment of obsessive–compulsive disorders. Most tricyclic antidepressants also have significant anticholinergic (antimuscarinic) actions: dry mouth, blurred vision, prolonged gastric emptying, and urinary retention. Quinidine-like cardiac effects include tachycardia, T-wave flattening or inversion, and prolongation of the PR, QRS, and QT intervals. Amitriptyline has the most marked anticholinergic effects, whereas doxepin has the fewest cardiac effects.

Herbal Approaches

St. John’s wort is being used with increased frequency as an over-the-counter therapy for depression. Because it induces hepatic enzymes, blood levels of other drugs may decrease, sometimes with serious complications. During the preoperative evaluation, the use of all over-the-counter medications should be reviewed.

Perioperative Management

Antidepressant drugs are generally continued perioperatively. Increased anesthetic requirements, presumably from enhanced brain catecholamine activity, have been reported with these agents. Potentiation of centrally acting
anticholinergic agents (atropine and scopolamine) may increase the likelihood of postoperative sedation, confusion, delirium, blurred vision, and urinary retention. The most important interaction between anesthetic agents and tricyclic antidepressants is an exaggerated response to both indirect-acting vasopressors and sympathetic stimulation. Chronic therapy with tricyclic antidepressants is reported to deplete cardiac catecholamines, theoretically potentiating the cardiac depressant effects of anesthetics. If hypotension occurs, small doses of a direct-acting vasopressor should be used instead of an indirect-acting agent. Amitriptyline’s anticholinergic action may occasionally contribute to postoperative delirium.

**Monoamine Oxidase Inhibitors**

MAO inhibitors were the first medications shown to be effective for depression. They are no longer considered first- or second-line agents due to their side effects. MAO inhibitors block the oxidative deamination of naturally occurring amines. At least two MAO isoenzymes (types A and B) with differential substrate selectivities have been identified. MAO-A is selective for serotonin, dopamine, and norepinephrine, whereas MAO-B is selective for dopamine and phenylethylamine. Nonselective MAO inhibitors include phenelzine, isocarboxazid, and tranylcypromine. Selective MAO-B inhibitors are useful in the treatment of PD. Additionally, unlike older nonreversible MAO inhibitors, reversible MAO-A inhibitors have been developed. Side effects include orthostatic hypotension, agitation, tremor, seizures, muscle spasms, urinary retention, paresthesias, and jaundice. The most serious sequela is a hypertensive crisis that occurs following ingestion of tyramine-containing foods (cheeses and red wines), because tyramine is used to generate norepinephrine.

Phenelzine can decrease plasma cholinesterase activity and prolong the duration of succinylcholine. Opioids should generally be used with caution in patients receiving MAO inhibitors, as rare but serious reactions to opioids have been reported. Most serious reactions are associated with meperidine, resulting in hyperthermia, seizures, and coma. Meperidine should not be administered to patients receiving MAO inhibitors. As with tricyclic antidepressants, exaggerated responses to vasopressors and sympathetic stimulation should be expected. If a vasopressor is necessary, a direct-acting agent in small doses should be employed. MAO inhibitors are used today infrequently.

Patients taking St. John’s wort are at increased risk of serotonin syndrome, as are those taking drugs with similar effects (eg, MAO inhibitors, meperidine). Serotonin syndrome manifestations include agitation, hypertension,
hyperthermia, tremor, acidosis, and autonomic instability. Treatment is supportive, along with the administration of a 5-HT antagonist (eg, cyproheptadine).

**BIPOLAR DISEASE**

Mania is a mood disorder characterized by elation, hyperactivity, and flight of ideas. Manic episodes may alternate with depression in patients with a bipolar (formerly manic–depressive) disorder. Mania is thought to be related to excessive norepinephrine activity in the brain. The most common agents used for maintenance therapy for this condition are lithium, valproate, quetiapine, and lamotrigine. Aripiprazole, olanzapine, and risperidone are used if the first group fails.

The mechanism of action of lithium is poorly understood. It has a narrow therapeutic range, with a desirable blood concentration between 0.8 and 1.0 mEq/L. Side effects include reversible T-wave changes, mild leukocytosis, and, on rare occasions, hypothyroidism or a vasopressin-resistant diabetes insipidus-like syndrome. Toxic blood concentrations produce confusion, sedation, muscle weakness, tremor, and slurred speech. Still higher concentrations result in widening of the QRS complex, atrioventricular block, hypotension, and seizures.

Although lithium is reported to decrease minimum alveolar concentration and prolong the duration of some NMBs, clinically these effects seem to be minor. Blood levels should be checked perioperatively. Sodium depletion (secondary to loop or thiazide diuretics) decreases renal excretion of lithium and can lead to lithium toxicity. Fluid restriction and overdiuresis should be avoided. Lithium dilution cardiac output measurements are contraindicated in patients on lithium therapy.

**SCHIZOPHRENIA**

Patients with schizophrenia display delusions, hallucinations, disorganized or withdrawn behavior, disorganized speech, and severe emotional withdrawal. The diagnoses of schizoaffective disorder, bipolar disorder, and severe depression will need to be excluded. Schizophrenia is thought to result from an excess of dopaminergic activity in the brain.

The most commonly used antipsychotics include phenothiazines, thioxanthenes, phenylbutylpiperidines, dihydroindolones, dibenzapines, benzisoxazoles, and butyrophenones. There are numerous trade names for these drugs. First-generation antipsychotic medications had strong dopamine
antagonistic effects, leading to extrapyramidal side effects (eg, muscle rigidity and progression to tardive dyskinesia). Second-generation agents have less dopamine antagonism and reduced extrapyramidal effects. The antipsychotic effect of these agents seems to be due to dopamine antagonist activity. Most cause weight gain and sedation and are mildly anxiolytic. Mild α-adrenergic blockade and anticholinergic activity are also observed. Side effects include orthostatic hypotension, acute dystonic reactions, and parkinsonism-like manifestations. Risperidone and clozapine have little extrapyramidal activity, but the latter is associated with a significant incidence of granulocytopenia. T-wave flattening, ST segment depression, and prolongation of the PR and QT intervals may be seen, increasing the risk of les torsades des pointes.

Continuing antipsychotic medication perioperatively is desirable. Reduced anesthetic requirements may be observed in some patients, and some patients may experience perioperative hypotension.

**NEUROLEPTIC MALIGNANT SYNDROME**

Neuroleptic malignant syndrome is a rare and life-threatening complication of antipsychotic therapy that may occur hours or weeks after drug administration. It has also accompanied abrupt withdrawal of medication for PD. Meperidine and metoclopramide can also precipitate the disorder. The mechanism is related to dopamine blockade in the basal ganglia and hypothalamus and impairment of thermoregulation. In its most severe form, the presentation is similar to that of malignant hyperthermia. Muscle rigidity, hyperthermia, rhabdomyolysis, autonomic instability, and altered consciousness are seen. Creatine kinase levels are often high. The mortality rate approaches 20% to 30%, with deaths occurring primarily as a result of kidney failure or arrhythmias. Treatment begins with stopping the offending agent and initiating supportive care. Dantrolene and bromocriptine have been used, but there is no strong evidence for consistent efficacy. Differential diagnoses include serotonin syndrome, malignant hyperthermia, malignant catatonia, and some other acute intoxications (eg, cocaine).

**SUBSTANCE ABUSE**

Behavioral disorders from abuse of psychotropic (mind-altering) substances may involve a socially acceptable drug (alcohol), a medically prescribed drug (eg, an opioid or diazepam), or an illegal substance (eg, cocaine or “ecstasy”). With chronic abuse, patients develop tolerance to the drug and varying degrees of
psychological and physical dependence. Physical dependence is most often seen with opioids, barbiturates, alcohol, and benzodiazepines. Life-threatening complications primarily due to sympathetic overactivity can develop during abstention.

Knowledge of a patient’s substance abuse preoperatively may prevent adverse drug interactions, predict tolerance to anesthetic agents, and facilitate the recognition of drug withdrawal. The history of substance abuse may be volunteered by the patient (usually only on direct questioning) or deliberately hidden.

Anesthetic requirements for substance abusers vary, depending on whether the drug exposure is acute or chronic (Table 28–4). Elective procedures should be postponed for acutely intoxicated patients and those with signs of withdrawal. When surgery is deemed necessary in patients with physical dependence, perioperative doses of the abused substance should be provided, or specific agents should be given to prevent withdrawal. In the case of opioid dependence, any opioid can be used, whereas for alcohol, a benzodiazepine is usually substituted due to the reluctance of hospital pharmacies to dispense alcohol-containing beverages to patients. Alcoholic patients should receive B vitamin/folate supplementation to prevent Korsakoff syndrome. Tolerance to most anesthetic agents is often seen but is not always predictable. For general anesthesia, a technique primarily relying on a volatile inhalation agent may be preferable so that anesthetic depth can be readily adjusted according to individual need. Awareness monitoring should be likewise considered. Opioids with mixed agonist–antagonist activity can precipitate acute withdrawal. Nevertheless, buprenorphine is often used to manage substance disorders. Clonidine is a useful adjuvant in the treatment of postoperative withdrawal syndromes.

TABLE 28–4  Effect of acute and chronic substance abuse on anesthetic requirements.¹
Patients routinely present acutely intoxicated for emergency surgery following trauma related to substance abuse. Patients may have consumed more than one intoxicating agent. Acute cocaine intoxication may produce hypertension secondary to the increase in central neurotransmitters, such as norepinephrine and dopamine. Hypertension and arrhythmias can occur perioperatively. Chronic abusers deplete their sympathomimetic neurotransmitters, potentially developing hypotension. Amphetamine abusers have similar anesthetic concerns, as amphetamines also affect the sympathetic nervous system.

Patients on chronic, prescribed opioid therapy, or those taking medications illicitly, have substantially increased postoperative opioid requirements. We strongly advocate for multimodal approaches to pain control perioperatively. Whenever possible patients should remain on their maintenance methadone or buprenorphine.

Consultation with pain management and addiction specialists is often indicated.

CASE DISCUSSION
Anesthesia for Electroconvulsive Therapy

A 64-year-old man with depression refractory to drug therapy is scheduled for electroconvulsive therapy (ECT).

**How is ECT administered?**

The electroconvulsive shock is applied to one or both cerebral hemispheres to induce a seizure. Variables include stimulus pattern, amplitude, and duration. The goal is to produce a therapeutic generalized seizure 30 to 60 s in duration. Electrical stimuli are usually administered until a therapeutic seizure is induced. A good therapeutic effect is generally not achieved until a total of 400 to 700 seizure seconds have been induced. Because only one treatment is given per day, patients are usually scheduled for a series of treatments, generally two or three a week. Progressive memory loss often occurs with an increasing number of treatments, particularly when electrodes are applied bilaterally.

**Why is anesthesia necessary?**

When the efficacy of ECT was discovered, enthusiasm was tempered in the medical community because drugs were not used to control the violent seizures caused by the procedure, thus engendering a relatively high incidence of musculoskeletal injuries. Moreover, when an NMB was used alone, patients sometimes recalled being paralyzed and awake just prior to the shock. The routine use of general anesthesia to ensure amnesia and neuromuscular blockade to prevent injuries has renewed interest in ECT. The current mortality rate for ECT is estimated to be one death per 10,000 treatments.

**What are the physiological effects of ECT-induced seizures?**

Seizure activity is characteristically associated with an initial parasympathetic discharge followed by a more sustained sympathetic discharge. The initial phase is characterized by bradycardia and increased secretions. Marked bradycardia (<30 beats/min) including transient asystole, is occasionally seen. The hypertension and tachycardia that follow are typically sustained for several minutes. Transient autonomic imbalance can produce arrhythmias and T-wave abnormalities on the electrocardiogram. Cerebral blood flow and ICP, intragastric pressure, and
intraocular pressure all transiently increase.

**Are there any contraindications to ECT?**

Contraindications are a recent myocardial infarction (usually <3 months), a recent stroke (usually <1 month), an intracranial mass or aneurysm, or increased ICP from any cause. More relative contraindications include angina, poorly controlled heart failure, significant pulmonary disease, bone fractures, severe osteoporosis, pregnancy, glaucoma, and retinal detachment.

**What are the important considerations in selecting anesthetic agents?**

Amnesia is required only for the brief period (1–5 min) from when the NMB is given to when a therapeutic seizure has been successfully induced. The seizure itself usually results in a brief period of anterograde amnesia, somnolence, and often confusion. Consequently, only a short-acting induction agent is necessary. Moreover, because most induction agents (barbiturates, etomidate, benzodiazepines, and propofol) have anticonvulsant properties, small doses must be used. Seizure threshold is increased and seizure duration is decreased by all of these agents.

Following adequate preoxygenation, methohexital (0.5–1 mg/kg) is most commonly employed. Propofol (1–1.5 mg/kg) may be used, but higher doses reduce seizure duration. Benzodiazepines raise the seizure threshold and decrease duration. Ketamine increases seizure duration but is generally not used because it also increases the incidence of delayed awakening, nausea, and ataxia and is also associated with hallucinations during emergence. Use of etomidate also prolongs recovery. Short-acting opioids, such as alfentanil, are not given alone because they do not consistently produce amnesia. However, alfentanil can be a useful adjunct when very small doses of methohexital (10–20 mg) are required in patients with a high seizure threshold. In very small doses, methohexital may actually enhance seizure activity. Increases in seizure threshold are often observed with each subsequent ECT.

Neuromuscular blockade is required from the time of electrical stimulation until the end of the seizure. A short-acting agent, such as succinylcholine (0.25–0.5 mg/kg), is most often selected. Controlled mask ventilation, using a self-inflating bag device or an anesthesia circle system, is required until spontaneous respirations resume.
**Can seizure duration be increased without increasing the electrical stimulus?**

Hyperventilation can increase seizure duration and is routinely employed in some centers. Intravenous caffeine (125–250 mg), given slowly, has also been reported to increase seizure duration.

**What monitors should be used during ECT?**

Monitoring should be similar to what is appropriate with the use of any other general anesthetic. Seizure activity is sometimes monitored by an unprocessed electroencephalogram. It can also be monitored in an isolated limb: a tourniquet is inflated around one arm prior to injection of succinylcholine, preventing entry of the NMB and allowing observation of convulsive motor activity in that arm.

**How can the adverse hemodynamic effects of the seizure be controlled in patients with limited cardiovascular reserve?**

Exaggerated parasympathetic effects should be treated with atropine. In fact, premedication with glycopyrrolate is desirable both to prevent the profuse secretions associated with seizures and to attenuate bradycardia. Nitroglycerin, nifedipine, and α- and β-adrenergic blockers have all been employed successfully to control sympathetic manifestations. High doses of β-adrenergic blockers (esmolol, 200 mg), however, are reported to decrease seizure duration.

**What if the patient has a pacemaker?**

Patients with pacemakers may safely undergo electroconvulsive treatments, but a magnet should be readily available to convert the pacemaker to a fixed mode, if necessary.

**SUGGESTED READINGS**

Anesthesia for Patients with Neuromuscular Disease

KEY CONCEPTS

1. Weakness associated with myasthenia gravis is due to autoimmune destruction or inactivation of postsynaptic acetylcholine receptors at the neuromuscular junction, leading to reduced numbers of receptors and degradation of their function, and to complement-mediated damage to the postsynaptic membrane.

2. Patients who have myasthenia gravis with respiratory muscle or bulbar involvement are at increased risk for pulmonary aspiration.

3. Many patients with myasthenia gravis are exquisitely sensitive to nondepolarizing neuromuscular blockers (NMBs).

4. Patients who have myasthenia gravis are at risk for postoperative respiratory failure. Disease duration of more than 6 years, concomitant pulmonary disease, a peak inspiratory pressure of less than –25 cm H₂O (ie, –20 cm H₂O), a vital capacity less than 4 mL/kg, and a pyridostigmine dose greater than 750 mg/d are predictive of the need for postoperative ventilation following thymectomy.

5. Patients with Lambert–Eaton myasthenic syndrome and other paraneoplastic neuromuscular syndromes are very sensitive to both depolarizing and nondepolarizing NMBs.

6. Respiratory muscle degeneration in patients with muscular dystrophy interferes with an effective cough mechanism and leads to retention of secretions and frequent pulmonary infections.

7. Degeneration of cardiac muscle in patients with muscular dystrophy is also common, but results in dilated or hypertrophic cardiomyopathy in only 10% of patients.
Succinylcholine should be avoided in patients with Duchenne or Becker muscular dystrophies because of unpredictable response and the risk of inducing severe hyperkalemia or triggering malignant hyperthermia.

Anesthetic management in patients with periodic paralysis is directed toward preventing attacks. Perioperative management must include frequent determinations of plasma potassium concentration and correction of abnormal values, with careful electrocardiographic monitoring to detect arrhythmias.

In patients with periodic paralysis, the response to NMBs is unpredictable, and neuromuscular function should be carefully monitored during their use. Increased sensitivity to nondepolarizing NMBs is particularly apt to be encountered in patients with hypokalemic periodic paralysis.

Neuromuscular diseases are disorders that adversely affect muscle function either primarily or via nerve or neuromuscular junction abnormalities. They include myasthenia gravis; Lambert–Eaton syndrome; amyotrophic lateral sclerosis (ALS, or Lou Gehrig disease); Becker, Duchenne, facioscapulohumeral, and myotonic muscular dystrophies; Charcot–Marie–Tooth disease; polymyositis; and a large number of other pathological conditions.

Although relatively uncommon, patients with these diseases will present to the operating room and to non–operating room procedure areas for diagnostic studies, treatment of complications, or procedural management of related or unrelated disorders, and may also be evaluated and managed by anesthesia providers in the emergency department, intensive care unit, and on hospital wards. Overall debility, with diminished respiratory muscle strength and increased sensitivity to neuromuscular blockers (NMBs), predisposes these patients to postoperative ventilatory failure and pulmonary aspiration, and may slow their post-procedure recovery because of difficulty with ambulation and increased risk of falling. Cardiac involvement may include cardiomyopathy or dysrhythmias. A basic understanding of the major disorders and their potential interaction with anesthetic agents is necessary to minimize the risk of perioperative morbidity. In addition, inherited or acquired neuromuscular pathology must be considered in the differential diagnosis of any patient with unexplained acute respiratory failure (Table 29–1).

TABLE 29–1 Differential diagnosis of acute neuromuscular respiratory failure.¹
Myasthenia gravis is an autoimmune disorder characterized by weakness and easy fatigability of skeletal muscle. It is classified according to disease distribution and severity (Table 29–2). The prevalence is estimated at 50 to 200 per million population. The incidence is highest in women during their third decade, and men exhibit two peaks, one in the third decade and another in the sixth decade.

Weakness associated with myasthenia gravis is due to autoimmune destruction or inactivation of postsynaptic acetylcholine receptors at the neuromuscular junction, leading to reduced numbers of receptors and degradation of their function, and to complement-mediated damage to the postsynaptic end-plate. IgG antibodies against the nicotinic acetylcholine receptor in neuromuscular junctions are found in 85% to 90% of patients with generalized myasthenia gravis and up to 50% to 70% of patients with ocular myasthenia. Among patients
with myasthenia, 10% to 15% percent develop thymoma, whereas approximately 70% exhibit histologic evidence of thymic lymphoid follicular hyperplasia. Other autoimmune-related disorders (hypothyroidism, hyperthyroidism, rheumatoid arthritis, and systemic lupus erythematosus) are also present in up to 10% of patients. In addition, acute seronegative myasthenia gravis has been associated with infusion of immune checkpoint inhibitor cancer chemotherapeutic agents, including nivolumab, pembrolizumab, and ipilimumab. The differential diagnosis of myasthenia gravis includes a number of other clinical conditions that may mimic its signs and symptoms (Table 29–3). Myasthenia gravis crisis is an exacerbation requiring mechanical ventilation and should be included in the differential diagnosis of any patient with respiratory failure of unclear etiology.

**TABLE 29–3** Differential diagnosis of myasthenia gravis.¹
The course of myasthenia gravis is marked by exacerbations and remissions, which may be partial or complete. The weakness can be asymmetric, confined to one group of muscles, or generalized. Ocular muscles are most commonly affected, resulting in fluctuating ptosis and diplopia. With bulbar involvement, laryngeal and pharyngeal muscle weakness can result in dysarthria, difficulty in chewing and swallowing, problems clearing secretions, or pulmonary aspiration. Severe disease is usually also associated with proximal muscle weakness (primarily in the neck and shoulders) and involvement of respiratory muscles. As with other neuromuscular diseases, active management of potential respiratory complications is a critical element of disease therapy (Table 29–4). Muscle strength characteristically improves with rest but deteriorates rapidly with
exertion. Infection, stress, surgery, and pregnancy have unpredictable effects on the disease but often lead to exacerbations. A number of medications may exacerbate the signs and symptoms of myasthenia gravis (Table 29–5).

Anticholinesterase drugs are used most commonly to treat the muscle weakness of this disorder. These drugs increase the amount of acetylcholine at the neuromuscular junction through inhibition of end-plate acetylcholinesterase. Pyridostigmine is prescribed most often; when given orally, it has an effective duration of 2 to 4 h. Excessive administration of an anticholinesterase may precipitate cholinergic crisis, which is characterized by increased weakness and excessive muscarinic effects, including salivation, diarrhea, miosis, and bradycardia. An edrophonium (Tensilon) test may help differentiate a cholinergic from a myasthenic crisis. Increased weakness after administration of up to 10 mg of intravenous edrophonium indicates cholinergic crisis, whereas increasing strength implies myasthenic crisis. If this test is equivocal or if the patient clearly has manifestations of cholinergic hyperactivity, all cholinesterase drugs should be discontinued and the patient should be monitored in an intensive care unit or close-observation area. Anticholinesterase drugs are often the only agents used to treat patients with mild disease. Moderate to severe disease is treated with a combination of an anticholinesterase drug and immunomodulating therapy. Corticosteroids are usually tried first, followed by other agents (Table 29–6). Plasmapheresis is reserved for patients with dysphagia or respiratory failure, or to normalize muscle strength preoperatively in patients undergoing a surgical
procedure, including thymectomy. Up to 85% of patients younger than 55 years of age show clinical improvement following thymectomy even in the absence of a tumor, but improvement may be delayed up to several years.

**Anesthetic Considerations**

Patients with myasthenia gravis may present for thymectomy or for unrelated surgical or obstetric procedures, and medical management of their condition should be optimized prior to the intended procedure. Myasthenic patients with respiratory and oropharyngeal weakness should be treated preoperatively with intravenous immunoglobulin or plasmapheresis. If strength normalizes, the incidence of postoperative respiratory complications should be similar to that of a nonmyasthenic patient undergoing a similar surgical procedure. Patients scheduled for thymectomy may have deteriorating muscle strength, whereas those undergoing other elective procedures may be well controlled or in remission. Adjustments in anticholinesterase medication, immunosuppressants,
or steroid therapy in the perioperative period may be necessary. Patients with advanced generalized disease may deteriorate significantly when anticholinesterase agents are withheld. These medications should be restarted when the patient resumes oral intake postoperatively. When necessary, cholinesterase inhibitors can also be given parenterally at 1/30th the oral dose. Potential problems associated with management of anticholinesterase therapy in the postoperative period include altered patient requirements, increased vagal reflexes, and the possibility of disrupting bowel anastomoses secondary to hyperperistalsis. Moreover, because these agents also inhibit plasma cholinesterase, they could theoretically prolong the duration of ester-type local anesthetics and succinylcholine.

Preoperative evaluation should focus on the recent course of the disease, the muscle groups affected, drug therapy, and coexisting illnesses. Patients who have myasthenia gravis with respiratory muscle or bulbar involvement are at increased risk for pulmonary aspiration. Premedication with an H₂ blocker or proton pump inhibitor may decrease this risk. Because patients with myasthenia are often very sensitive to the respiratory depressant effect of opioids and benzodiazepines, premedication with these drugs should be done with caution, if at all.

With the exception of NMBs, standard anesthetic agents may be used in patients with myasthenia gravis. Marked respiratory depression, however, may be encountered following even moderate doses of propofol or opioids. When general anesthesia is required, a volatile agent–based anesthetic is frequently employed. Deep anesthesia with a volatile agent alone in patients with myasthenia may provide sufficient relaxation for tracheal intubation and most surgical procedures, and many clinicians routinely avoid NMBs entirely. The response to succinylcholine is said to be unpredictable, and patients may manifest a relative resistance or a moderately prolonged effect (see Chapter 11). The dose of succinylcholine may be increased to 2 mg/kg to overcome any resistance, expecting that the duration of paralysis could be increased by 5 to 10 min.

Many patients with myasthenia gravis are exquisitely sensitive to nondepolarizing NMBs. Even a defasciculating dose in some patients may result in nearly complete paralysis. If NMBs are necessary, small doses of a relatively short-acting nondepolarizing agent are preferred. We have not found nondepolarizing NMBs to be necessary during thymectomy with volatile anesthesia. Neuromuscular blockade should be monitored very closely with a nerve stimulator, and ventilatory function should be evaluated carefully prior to
extubation.

Patients who have myasthenia gravis are at risk for postoperative respiratory failure. Disease duration of more than 6 years, concomitant pulmonary disease, peak inspiratory pressure of less than −25 cm H₂O (ie, −20 cm H₂O), vital capacity less than 4 mL/kg, and pyridostigmine dose greater than 750 mg/d are predictive of the need for postoperative ventilation following thymectomy.

Women with myasthenia can experience increased weakness in the last trimester of pregnancy and in the early postpartum period. Epidural anesthesia is generally preferable for these patients because it avoids potential problems with respiratory depression and NMBs related to general anesthesia. Excessively high levels of motor blockade, however, can also result in hypoventilation. Infants of myasthenic mothers may show transient myasthenia for 1 to 3 weeks following birth, induced by transplacental transfer of acetylcholine receptor antibodies, which may necessitate intubation and mechanical ventilation.

PARANEOPLASTIC NEUROMUSCULAR SYNDROMES

Paraneoplastic syndromes are immune-mediated diseases associated with an underlying cancer in which organ or tissue dysfunction or damage occurs distant from the primary or metastatic tumor. Myasthenia gravis is often considered a paraneoplastic syndrome because it is an autoimmune disorder associated with thymic hyperplasia, including thymoma. Other neurological or neuromuscular paraneoplastic syndromes include Lambert–Eaton myasthenic syndrome, limbic encephalitis, neuromyotonia, stiff person syndrome, myotonic dystrophy, and polymyositis.

Lambert–Eaton Myasthenic Syndrome

The Lambert–Eaton myasthenic syndrome (LEMS) is a paraneoplastic syndrome characterized by proximal muscle weakness that typically begins in the lower extremities but may spread to involve upper limb, bulbar, and respiratory muscles. Dry mouth, male impotence, and other manifestations of autonomic dysfunction are also common. LEMS is usually associated with small cell carcinoma of the lung but may also be seen with other malignancies or as an idiopathic autoimmune disease. The disorder results from a presynaptic defect of neuromuscular transmission in which antibodies to voltage-gated calcium
channels on the nerve terminal markedly reduce the quantal release of acetylcholine at the motor end-plate. Small cell lung carcinoma cells express identical voltage-gated calcium channels, serving as a trigger for the autoimmune response in patients with paraneoplastic LEMS.

In contrast to myasthenia gravis, muscle weakness associated with LEMS improves with repeated effort and is improved less dramatically by anticholinesterase drugs. Guanidine hydrochloride and 3,4-diaminopyridine (3,4-DAP), which increase the presynaptic release of acetylcholine, often produce significant improvement in LEMS. Corticosteroid or other immunosuppressive medications, or plasmapheresis, may also be of benefit.

**Limbic Encephalitis**

Limbic encephalitis is a degenerative central nervous system disorder characterized by personality changes, hallucinations, seizures, autonomic dysfunction, varying degrees of dementia, and asymmetric loss of sensation in the extremities. It may involve the brain, brainstem, cerebellum, and spinal cord. In approximately 60% of cases, limbic encephalitis is paraneoplastic. There is a strong association with small cell lung carcinoma, and neurological dysfunction often precedes the cancer diagnosis. Therapy includes treatment of the underlying cancer, if present, and administration of immunosuppressive medications.

**Neuromyotonia**

Neuromyotonia is a condition of peripheral nerve hyperexcitability that is frequently associated with an underlying cancer but may also be inherited or associated with diabetic, drug- or toxin-induced, or other acquired neuropathies. Its features include *myokymia* (a continuous undulating movement of muscles described as being like a “bag of worms”), stiffness, impaired muscle relaxation, painful muscle cramping, hyperhidrosis, and muscle hypertrophy. Treatment includes immunoglobulin therapy, plasma exchange, and administration of anticonvulsants.

**Stiff Person Syndrome**

Stiff person syndrome is a progressive disorder characterized by axial stiffness and rigidity that may subsequently involve the proximal limb muscles. In advanced cases, paraspinal rigidity may cause marked spinal deformities, and the
patient may have difficulty with ambulation and a history of frequently falling. Although stiff person syndrome is rare, when it occurs it is frequently associated with cancer. Therapy includes treatment of the underlying cancer, if present, and administration of immunoglobulin and benzodiazepines.

**Myotonic Dystrophy**

See page 645 for details.

**Polymyositis**

Polymyositis is an inflammatory myopathy of skeletal musculature, especially proximal limb muscles, characterized by weakness and easy fatigability. Patients are prone to aspiration and frequent pneumonias because of thoracic muscle weakness and dysphagia secondary to oropharyngeal muscle involvement. They may also exhibit cardiac dysrhythmias due to conduction defects. Therapy includes treatment of the underlying neoplasm, if present; plasma exchange; and administration of immunoglobulin, corticosteroids, and immunomodulators such as methotrexate, cyclosporine, and tumor necrosis factor-α inhibitors.

**Anesthetic Considerations for Patients with Neuromuscular Paraneoplastic Syndromes**

Patients with LEMS and other neuromuscular paraneoplastic syndromes are very sensitive to both depolarizing and nondepolarizing NMBs. Volatile agents alone are often sufficient to provide muscle relaxation for both intubation and most surgical procedures. NMBs should be given only in small increments and with careful neuromuscular monitoring. Because these patients frequently exhibit marked debility, benzodiazepines, opioids, and other medications with sedative effects should be administered with caution, if at all.

**MUSCULAR DYSTROPHIES**

**Preoperative Considerations**

Muscular dystrophies are a heterogeneous group of hereditary disorders characterized by muscle fiber necrosis and regeneration, leading to muscle degeneration and progressive weakness. Anticipated anesthetic risk is increased
by the patient’s overall debilitated status, which may impede clearance of secretions and postoperative ambulation, as well as by increased risk of respiratory failure and pulmonary aspiration. Duchenne muscular dystrophy is the most common and most severe form of muscular dystrophy. Other muscular dystrophy variants include Becker, myotonic, facioscapulohumeral, and limb-girdle dystrophies.

**Duchenne Muscular Dystrophy**

An X-linked recessive disorder, Duchenne muscular dystrophy affects males almost exclusively. It has an incidence of approximately 1 to 3 cases per 10,000 live male births and most commonly presents between 3 and 5 years of age. Affected individuals produce abnormal dystrophin, a protein found on the sarcolemma of muscle fibers. Patients characteristically develop symmetric proximal muscle weakness that is manifested as a gait disturbance. Fatty infiltration typically causes enlargement (pseudohypertrophy) of muscles, particularly the calves. Progressive weakness and contractures eventually result in kyphoscoliosis. Many patients are confined to wheelchairs by age 12. Disease progression may be delayed by up to 2 to 3 years with glucocorticoid therapy in some patients. Intellectual impairment is common but generally nonprogressive. Plasma creatine kinase (CK) levels are 10 to 100 times normal even early in the disease and may reflect an abnormal increase in the permeability of muscle cell membranes. Female genetic carriers often also have high plasma CK levels, variable degrees of muscle weakness, and, rarely, cardiac involvement. Plasma myoglobin concentration may also be elevated. The diagnosis is confirmed by muscle biopsy.

Respiratory muscle degeneration in patients with muscular dystrophy interferes with an effective cough mechanism and leads to retention of secretions and frequent pulmonary infections. The combination of marked kyphoscoliosis and muscle wasting may produce a severe restrictive ventilatory defect. Pulmonary hypertension is common with disease progression. Degeneration of cardiac muscle in patients with muscular dystrophy is also common, but results in dilated or hypertrophic cardiomyopathy in only 10% of patients. Mitral regurgitation secondary to papillary muscle dysfunction is also found in up to 25% of patients. Electrocardiogram abnormalities include P–R interval prolongation, QRS and ST-segment abnormalities, and prominent R waves over the right precordium with deep Q waves over the left precordium. Atrial arrhythmias are common. Death at a relatively young age is usually due to recurrent pulmonary infections, respiratory failure, or cardiac failure.
**Becker Muscular Dystrophy**

Becker muscular dystrophy is, like Duchenne, an X-linked recessive disorder, but it is less common (1:30,000 male births). Manifestations are nearly identical to those of Duchenne muscular dystrophy except that they usually present later in life (adolescence) and progress more slowly. Mental retardation is less common. Patients often reach the fourth or fifth decade, although some may survive into their 80s. Death is usually from respiratory complications. Cardiomyopathy may occur in some cases and may precede severe skeletal weakness.

**Myotonic Dystrophy**

Myotonic dystrophy is a multisystem disorder that is the most common cause of myotonia, a slowing of relaxation after muscle contraction in response to electrical or percussive stimuli. The disease is autosomal dominant, with an incidence of 1:8000, and usually becomes clinically apparent in the second to third decade of life, but it has also been reported as a paraneoplastic disorder in association with thymoma. Myotonia is the principal early manifestation; muscle weakness and atrophy become more prominent as the disease progresses. This weakness and atrophy usually affect cranial muscles (orbicularis oculi and oris, masseter, and sternocleidomastoid), and in contrast to most myopathies, distal muscles more than proximal muscles. Plasma CK levels are normal or slightly elevated.

Multiple organ systems are involved in myotonic dystrophy, as evidenced by presenile cataracts, premature frontal baldness, hypersomnolence with sleep apnea, and endocrine dysfunction leading to pancreatic, adrenal, thyroid, and gonadal insufficiency. Respiratory involvement leads to decreased vital capacity, and chronic hypoxemia may cause cor pulmonale. Gastrointestinal hypomotility may predispose patients to pulmonary aspiration. Uterine atony can prolong labor and increase the incidence of retained placenta. Cardiac manifestations, which are often present before other clinical symptoms appear, may include cardiomyopathy, atrial arrhythmias, and varying degrees of heart block.

The myotonia is usually described by patients as a “stiffness” that may lessen with continued activity—the so-called “warm-up” phenomenon. Patients often report that cold temperatures worsen stiffness. Antimyotonic treatment may include mexiletine, phenytoin, baclofen, dantrolene, or carbamazepine. A cardiac pacemaker may be placed in patients with significant conduction defect, even if they are asymptomatic.
Facioscapulohumeral Dystrophy

Facioscapulohumeral dystrophy, an autosomal dominant disorder with an incidence of approximately 1 to 3 cases per 100,000, affects both sexes, although more females than males are asymptomatic. Patients usually present in the second or third decade of life with weakness that is confined primarily to the muscles of the face and the shoulder girdle. Muscles in the lower extremities are less commonly affected, and respiratory muscles are usually spared. The disease is slowly progressive with a variable course. Plasma CK levels are usually normal or only slightly elevated. Cardiac involvement is rare, but loss of atrial electrical activity with an inability to atrially pace the heart has been reported; ventricular pacing is still possible in these patients. Longevity is minimally affected.

Limb-Girdle Dystrophy

Limb-girdle muscular dystrophy is a heterogeneous group of genetic neuromuscular diseases. Limb-girdle syndromes include severe childhood autosomal recessive muscular dystrophy and other incompletely defined autosomal recessive syndromes such as Erb (scapulohumeral type) and Leyden–Mobius (pelvifemoral type) dystrophies. Most patients present between childhood and the second or third decade of life with slowly progressive muscle weakness that may involve the shoulder girdle, the hip girdle, or both. Plasma CK levels are usually elevated. Cardiac involvement is relatively uncommon but may present as frequent arrhythmias or congestive heart failure. Respiratory complications, such as hypoventilation and recurrent respiratory infections, may occur.

Anesthetic Considerations

A. Duchenne and Becker Muscular Dystrophies

The anesthetic management of these patients is complicated not only by muscle weakness but also by cardiac and pulmonary manifestations. An association with malignant hyperthermia has been suggested but is unproven. Preoperative premedication with sedatives or opioids should be avoided because of increased aspiration risk due to respiratory muscle weakness, gastric hypomotility, or both. Intraoperative positioning may be complicated by kyphoscoliosis or by flexion contractures of the extremities or neck. Succinylcholine should be avoided in
patients with Duchenne or Becker muscular dystrophies because of unpredictable response and the risk of inducing severe hyperkalemia or triggering malignant hyperthermia. Inhalational anesthetics have been associated with rhabdomyolysis and hyperkalemia in patients with Duchene muscular dystrophy in cases where no succinylcholine was employed. Although some patients exhibit a normal response to nondepolarizing NMBs, others may be very sensitive. Marked respiratory and circulatory depression may be seen with volatile anesthetics in patients with advanced disease, and regional or local anesthesia may be preferable in these patients. Perioperative morbidity is usually due to respiratory complications. Patients with vital capacities less than 30% of predicted are at greatest risk and often require temporary postoperative mechanical ventilation.

B. Myotonic Dystrophy

Patients with myotonic dystrophy are at increased risk for perioperative respiratory and cardiac complications. Most perioperative problems arise in patients with severe weakness and in those cases in which surgeons and anesthesiologists are unaware of the diagnosis. The diagnosis of myotonic dystrophy has been made in some patients in the course of investigating prolonged apnea following general anesthesia.

Patients with myotonic dystrophy are often sensitive to even small doses of opioids, sedatives, and inhalation and intravenous anesthetic agents, all of which may cause sudden and prolonged apnea. Premedication should therefore be avoided. Succinylcholine is relatively contraindicated because it may precipitate intense myotonic contraction of the diaphragm, chest wall, or laryngeal muscles, making ventilation difficult or impossible. Other drugs that act on the motor end-plate, such as neostigmine, and physostigmine, can aggravate myotonia. Regional anesthesia may be preferentially employed but does not always prevent myotonic contractions.

The response to nondepolarizing NMBs is reported to be normal; however, they do not consistently prevent or relieve myotonic contractions. As reversal of nondepolarizing NMBs can induce myotonic contractions, the use of short-acting nondepolarizing agents is recommended. Postoperative shivering may induce myotonic contractions in the recovery room, and doses of meperidine can often prevent such shivering and may preempt myotonic contractions.

Induction of anesthesia without complications has been reported with a number of agents including inhalation agents and propofol. Neuromuscular blockade, if needed, should employ short-acting nondepolarizing NMBs. An
association between myotonic dystrophy and malignant hyperthermia has been suggested but not established. Nitrous oxide and inhalation agents can be used as maintenance anesthesia. Reversal with anticholinesterases should be avoided, if possible.

The principal postoperative complications of myotonic dystrophy are prolonged hypoventilation, atelectasis, aspiration, and pneumonia. Patients undergoing upper abdominal surgery or those with severe proximal weakness are more likely to experience pulmonary complications. Close postoperative monitoring for arrhythmias should be accompanied by aggressive pulmonary hygiene with physical therapy and incentive spirometry. Aspiration prophylaxis is indicated.

C. Other Forms of Muscular Dystrophy

Patients with facioscapulohumeral and limb-girdle muscular dystrophy generally have normal responses to anesthetic agents. Nevertheless, because of the great variability and overlap among the various forms of muscular dystrophy, sedative-hypnotics, opioids, and nondepolarizing NMBs should be used cautiously, and succinylcholine should be avoided.

MYOTONIAS

Myotonia Congenita & Paramyotonia Congenita

Myotonia congenita is a disorder manifested early in life with generalized myotonia. Both autosomal dominant (Thomsen) and recessive (Becker) forms exist. The disease is confined to skeletal muscle, and weakness is minimal or absent. Many patients have very well-developed musculature due to near constant muscle contraction. Antimyotonic therapy includes phenytoin, mexiletine, quinine sulfate, or procainamide. Other medications that have been used include tocainide, dantrolene, prednisone, acetazolamide, and taurine. There is no cardiac involvement in myotonia congenita, and a normal life span is expected.

Paramyotonia congenita is a very rare autosomal dominant disorder characterized by transient stiffness (myotonia) and, occasionally, weakness after exposure to cold temperatures. The stiffness worsens with activity, in contrast to true myotonia, thus the term paramyotonia. Serum potassium concentration may rise following an attack similar to hyperkalemic periodic paralysis (discussed next). Medications that have been used to block the cold response include
mexiletine and tocaainide.

Anesthetic management of patients with myotonia congenita and paramyotonia is complicated by an abnormal response to succinylcholine, intraoperative myotonic contractions, and the need to avoid hypothermia. NMBs may paradoxically cause generalized muscle spasms, including trismus, leading to difficulty with intubation and ventilation.

Infiltration of muscles in the operative field with a dilute local anesthetic may alleviate refractory myotonic contraction. Among patients with these types of myotonia, none have been reported with positive in vitro tests for malignant hyperthermia. Excised muscle in these patients does, however, display a prolonged myotonic contraction when exposed to succinylcholine. Excessive muscle contraction during anesthesia, therefore, likely represents aggravation of myotonia and not malignant hyperthermia.

**PERIODIC PARALYSIS**

Periodic paralysis is a group of disorders characterized by spontaneous episodes of transient muscle weakness or paralysis. Symptoms usually begin in childhood, with episodes lasting a few hours and typically sparing respiratory muscle involvement. The weakness usually lasts less than 1 h but can last several days, and frequent attacks may lead to progressive, long-term weakness in some patients. Hypothermia exacerbates the frequency and severity of episodes. Muscle strength and serum potassium concentrations are usually normal between attacks. The episodes of weakness are due to a loss of muscle fiber excitability secondary to partial depolarization of the resting potential. This partial depolarization prevents the generation of action potentials and thereby precipitates weakness.

Periodic paralysis is classified into primary genetic channelopathies and secondary acquired forms. The genetic types are due to dominantly inherited mutations in the voltage-gated sodium, calcium, or potassium ion channels. Classifications have been based on clinical differences, but these have not been shown to relate to specific ion channels. Different defects in the same channel can cause different clinical pictures, whereas mutations in different channels may have similar clinical pictures. However, the clinical classifications remain useful as guides to prognosis and therapy.

*Hypokalemic periodic paralysis* is typically associated with low serum potassium levels, and *hyperkalemic periodic paralysis* with elevated serum potassium levels, during episodes of weakness. In these defects, muscle
membranes are inexcitable to both direct and indirect stimulation due to either decreased potassium conductance or increased sodium conductance, respectively. Both defects are associated with fluid and electrolyte shifts.

*Thyrotoxic periodic paralysis* occurs most commonly in Asian men and is characterized by episodes of marked weakness associated with increased thyroid hormones, low thyroid-stimulating hormone, and hypokalemia. Primary therapy is treatment of the underlying hyperthyroid state.

Secondary hypokalemic paralysis can also develop if there are marked losses of potassium through the kidneys or the gastrointestinal tract. The associated weakness is, at times, episodic, and potassium levels are much lower than in other variants of hypokalemic periodic paralysis. Management of the primary disease with potassium replacement and treatment of acidosis or alkalosis are is important in preventing attacks.

Patients who consume large amounts of barium salts, which block potassium channels, can also develop hypokalemic periodic paralysis. This condition is treated by stopping the barium salts and administering oral potassium.

Potassium levels that exceed 7 mEq/L between episodes of weakness suggest a secondary form of hyperkalemic periodic paralysis. Treatment is targeted toward the primary disease and involves restriction of potassium.

**Anesthetic Considerations**

- Anesthetic management of patients with periodic paralysis is directed toward preventing attacks. Perioperative management must include frequent determinations of plasma potassium concentration and correction of abnormal values, with careful electrocardiographic monitoring to detect arrhythmias. Because of the potential for glucose and alkalosis to lower the plasma potassium concentration, glucose-containing intravenous solutions and hyperventilation should be avoided in patients with hypokalemic paralysis, including thyrotoxic periodic paralysis, and use of drugs such as insulin and epinephrine that lower serum potassium should be minimized. Tachycardia associated with thyrotoxic periodic paralysis is treated with nonselective β-blockade. The response to NMBs is unpredictable, and neuromuscular function should be carefully monitored during their use. Increased sensitivity to nondepolarizing NMBs is particularly apt to be encountered in patients with hypokalemic periodic paralysis. Succinylcholine is contraindicated in hyperkalemic paralysis and perhaps other variants as well because of the risk of hyperkalemia. Intraoperative maintenance of core temperature is important because shivering and
hypothermia may trigger or exacerbate episodes of periodic paralysis.

CASE DISCUSSION

Anesthesia for Muscle Biopsy
A 16-year-old boy with progressive proximal muscle weakness is suspected of having a primary myopathy and is scheduled for biopsy of the quadriceps muscle.

What other potential abnormalities should concern the anesthesiologist?

The diagnosis of myopathy can be difficult to make, and the differential diagnosis may include any one of several hereditary, inflammatory, endocrine, metabolic, or toxic disorders. A muscle biopsy may be necessary to supplement clinical, laboratory, nerve conduction, and electromyographic findings and help establish the diagnosis. Although the cause of the myopathy in this case is not yet clear, the clinician must always consider potential problems that can be associated with primary myopathies.

Respiratory muscle involvement should always be suspected in patients with muscle weakness. Pulmonary reserve can be assessed clinically by asking about dyspnea and activity level. Pulmonary function tests are indicated if significant dyspnea on exertion is present. An increased risk of pulmonary aspiration is suggested by a history of dysphagia, regurgitation, recurrent pulmonary infections, or abdominal distention. Cardiac abnormalities may be manifested as arrhythmias, mitral valve prolapse, or cardiomyopathy. A 12-lead electrocardiogram is also helpful in excluding conduction abnormalities. A chest radiograph can evaluate inspiratory effort, the pulmonary parenchyma, and cardiac size; gastric distention secondary to smooth muscle or autonomic dysfunction may also be evident. Preoperative laboratory evaluation should have excluded a metabolic cause with measurement of serum sodium, potassium, magnesium, calcium, and phosphate concentrations. Similarly, thyroid, adrenal, and pituitary disorders should have been excluded. Plasma CK measurement may not be helpful, but very high levels (10 times normal) generally suggest a muscular dystrophy or polymyositis.
What anesthetic technique should be used?

The choice of anesthesia should be based on both patient and procedural requirements. Most muscle biopsies can be performed under local or regional anesthesia with supplemental intravenous sedation, using small doses of midazolam. Spinal or epidural anesthesia may be utilized. A femoral nerve block can provide excellent anesthesia for biopsy of the quadriceps muscle; a separate injection may be necessary for the lateral femoral cutaneous nerve to anesthetize the anterolateral thigh. General anesthesia should be reserved for uncooperative patients or for times when local or regional anesthesia is inadequate. The anesthesiologist must therefore always be prepared with a plan for general anesthesia.

What agents may be safely used for general anesthesia?

Major goals include preventing pulmonary aspiration, avoiding excessive respiratory or circulatory depression, avoiding NMBs if possible, and perhaps avoiding agents known to trigger malignant hyperthermia. A normal response to a previous general anesthetic in the patient or a family member may be reassuring but does not guarantee the same response subsequently. General anesthesia may be induced and maintained with a combination of a benzodiazepine, propofol, and a short-acting opioid with or without nitrous oxide. Patients at increased risk for aspiration should be intubated. When an NMB is necessary, a short-acting nondepolarizing agent should be used. Succinylcholine should generally be avoided because of the unknown risk of an unusual response (myotonic contractions, prolonged duration, or phase II block), of inducing severe hyperkalemia, or of triggering malignant hyperthermia.

SUGGESTED READINGS

KEY CONCEPTS

1. The combined blood flow through both kidneys normally accounts for 20% to 25% of total cardiac output.
2. Autoregulation of renal blood flow normally occurs between mean arterial blood pressures of 80 and 180 mm Hg and is principally due to intrinsic myogenic responses of the afferent glomerular arterioles to blood pressure changes.
3. Renal synthesis of vasodilating prostaglandins (PGD$_2$, PGE$_2$, and PGI$_2$) is an important protective mechanism during periods of systemic hypotension and kidney ischemia.
4. Dopamine and fenoldopam dilate afferent and efferent arterioles via D$_1$-receptor activation.
5. Reversible decreases in renal blood flow, glomerular filtration rate, urinary flow, and sodium excretion occur during both neuraxial and general anesthesia. Acute kidney injury is less likely to occur if adequate intravascular volume and normal blood pressure are maintained.
6. The endocrine response to surgery and anesthesia is at least partly responsible for the transient fluid retention often seen postoperatively.
7. Compound A, a breakdown product of sevoflurane, causes acute kidney injury in laboratory animals. Low fresh gas flow rates promote its accumulation in the anesthesia machine breathing circuit. No clinical study has detected significant kidney injury in humans as a consequence of sevoflurane anesthesia; nonetheless, some authorities recommend a fresh gas flow of at least 2 L/min with sevoflurane to minimize the risk of this theoretical problem.
8. Pneumoperitoneum produced during laparoscopy causes an abdominal
compartment syndrome–like state. The increase in intraabdominal pressure often produces oliguria or anuria that is generally proportional to insufflation pressure. Mechanisms include vena cava and renal vein compression; kidney parenchymal compression; decreased cardiac output; and increases in plasma levels of renin, aldosterone, and antidiuretic hormone.

The kidneys play a vital role in regulating the volume and composition of body fluids, eliminating toxins, and elaborating hormones, including renin, erythropoietin, and the active form of vitamin D. Factors directly and indirectly related to operative procedures and to anesthetic management frequently have a physiologically significant impact on kidney physiology and function, and may lead to perioperative fluid overload, hypovolemia, and acute kidney injury, which are major causes of perioperative morbidity and mortality.

Diuretics are frequently used in the perioperative period. They are commonly administered on a chronic basis to patients with hypertension or chronic heart failure, and to patients with liver or kidney disease. Diuretics may be used intraoperatively, typically during neurosurgical, cardiac, major vascular, ophthalmic, and urological procedures. Familiarity with the various types of diuretics and their mechanisms of action, side effects, and potential anesthetic interactions is therefore essential.

The Nephron

Each kidney is made up of approximately 1 million functional units called nephrons. Anatomically, a nephron consists of a tortuous tubule with at least six specialized segments. In the renal corpuscle, a structure at its proximal end composed of a glomerulus and a Bowman’s capsule, an ultrafiltrate of blood is formed which flows through the nephron’s tubules. During this process, the ultrafiltrate’s volume and composition are modified by both reabsorption and secretion of solutes, and the collected final product is eliminated as urine.

Nephrons are classified as cortical or juxtamedullary, and the renal corpuscles of all nephrons are located in the renal cortex. In addition to the renal corpuscle, the other major anatomical and functional divisions of the nephron are the proximal convoluted tubule, the loop of Henle, the distal renal tubule, the collecting tubule, and the juxtaglomerular apparatus (Figure 30–1 and Table 30–1).

**THE RENAL CORPUSCLE**

Each renal corpuscle contains a glomerulus, which is composed of tufts of capillaries that jut into Bowman’s capsule, providing a large surface area for blood filtration. Blood enters by a single afferent arteriole and departs by a single efferent arteriole. The glomerular endothelial cells are separated from the epithelial cells of Bowman’s capsule only by their fused basement membranes.
The endothelial cells are perforated with relatively large fenestrae (70–100 nm), but the epithelial cells interdigitate tightly with one another, leaving relatively small filtration slits (approximately 25 nm). The two cell types with their basement membranes provide an effective filtration barrier to cells and large-molecular-weight substances. This barrier has multiple anionic sites that give it a net negative charge, favoring filtration of cations relative to anions. A third cell type, called intraglomerular mesangial cells, is located between the basement membrane and epithelial cells near adjacent capillaries. These contractile cells regulate glomerular blood flow and also exhibit phagocytic activity. Mesangial cells contract, reducing glomerular filtration, in response to angiotensin II, vasopressin, norepinephrine, histamine, endothelins, thromboxane A₂, leukotrienes (C₄ and D₄), prostaglandin F₂, and platelet-activating factor. They relax, thereby increasing glomerular filtration, in response to atrial natriuretic peptide (ANP), prostaglandin E₂, and dopaminergic agonists.

Glomerular filtration pressure (approximately 60 mm Hg) is normally approximately 60% of mean arterial pressure and is opposed by both plasma oncotic pressure (approximately 25 mm Hg) and renal interstitial pressure (approximately 10 mm Hg). Afferent and efferent arteriolar tone are both important in determining glomerular filtration pressure: filtration pressure is directly proportional to efferent arteriolar tone but inversely proportional to afferent tone. Approximately 20% of plasma is normally filtered into the Bowman’s capsule as blood passes through the glomerulus.

**The Proximal Tubule**

Of the ultrafiltrate formed in Bowman’s capsule, 65% to 75% is normally reabsorbed isotonically (proportional amounts of water and sodium) in the proximal renal tubule (Figure 30–2). To be reabsorbed, most substances must first traverse the tubular (apical) side of the cell membrane, and then cross the basolateral cell membrane into the renal interstitium before entering peritubular capillaries. The major function of the proximal tubule is Na⁺ reabsorption. Sodium is actively transported out of proximal tubular epithelial cells at their capillary side by membrane-bound Na⁺–K⁺-adenosine triphosphatase (Na⁺–K⁺-ATPase) (Figure 30–3). The resulting low intracellular concentration of Na⁺ allows passive movement of Na⁺ down its gradient from tubular fluid into the tubular epithelial cells. Angiotensin II and norepinephrine enhance Na⁺ reabsorption in the early proximal tubule. In contrast, dopamine and fenoldopam decrease the proximal reabsorption of sodium via D₁-receptor activation.
FIGURE 30–2 Sodium reabsorption in the nephron. Numbers represent the percentage of the filtered sodium reabsorbed at each site. (Reproduced with permission from Cogan MG. Fluid and Electrolytes: Physiology and Pathophysiology. New York, NY: Appleton & Lange; 1991.)
Figure 30–3  Reabsorption of solutes in proximal tubules. Note that Na\(^+\)-K\(^+\)-ATPase supplies the energy for reabsorption of most solutes by maintaining a low intracellular concentration of sodium.

Sodium reabsorption is coupled with the reabsorption of other solutes and the secretion of H\(^+\) (Figure 30–3). Specific carrier proteins use the low concentration of Na\(^+\) inside cells to transport phosphate, glucose, and amino acids. The net loss of intracellular positive charges, the result of Na\(^+\)-K\(^+\)-ATPase activity (exchanging 3Na\(^+\) for 2K\(^+\)), favors the absorption of other cations (K\(^+\), Ca\(^{2+}\), and Mg\(^{2+}\)). Thus, the Na\(^+\)-K\(^+\)-ATPase at the basolateral side of the renal tubular epithelial cells provides the energy for the reabsorption of most solutes. Sodium reabsorption at the luminal membrane is also coupled with countertransport.
(secretion) of $H^+$. The latter mechanism is responsible for reabsorption of 90% of the filtered bicarbonate ions (see Figure 50–3). Unlike other solutes, chloride can traverse the tight junctions between adjacent tubular epithelial cells, and accordingly, is passively resorbed via its concentration gradient. Active chloride reabsorption may also take place as a result of a K$^+$–Cl$^-$ cotransporter that extrudes both ions at the capillary side of the cell membrane (Figure 30–3). Water moves passively out the proximal tubule along osmotic gradients. Apical membranes of epithelial cells contain specialized water channels, composed of a membrane protein called aquaporin-1, that facilitate water movement.

The proximal tubules are capable of secreting organic cations and anions. Creatinine excretion can be inhibited by other organic cations (eg, trimethoprim or pyrimethamine), leading to increases in serum creatinine concentration. Organic anions such as urates, ketoacids, penicillins, cephalosporins, diuretics, salicylates, and most radiocontrast dyes also share common secretory mechanisms and can compete with one another. Low-molecular-weight proteins, which are filtered by glomeruli, are normally reabsorbed by proximal tubular epithelial cells, to be metabolized intracellularly.

**The Loop of Henle**

The loop of Henle consists of *descending* and *ascending* portions. They are responsible for maintaining a hypertonic medullary interstitium and also indirectly for provide the collecting tubules with the ability to concentrate urine. The thin descending segment is a continuation of the proximal tubule and descends from the renal cortex into the renal medulla. In the medulla, the descending portion acutely turns back upon itself and rises back up toward the cortex as the ascending portion. The ascending portion consists of a functionally distinct thin ascending limb, a medullary thick ascending limb, and a cortical thick ascending limb (Figure 30–1). *Cortical* nephrons have relatively short loops of Henle that extend only into the more superficial regions of the renal medulla and often lack a thin ascending limb. *Juxtamedullary* nephrons, which have renal corpuscles located near the renal medulla, possess loops of Henle that project deeply into the renal medulla. Cortical nephrons outnumber juxtamedullary nephrons by approximately 7:1.

Only 25% to 35% of the ultrafiltrate formed in Bowman’s capsule normally reaches the loop of Henle, where 15% to 20% of the filtered sodium load is normally reabsorbed. With the notable exception of the ascending thick medullary and cortical segments, solute and water reabsorption in the loop of
Henle is passive and follows concentration and osmotic gradients. In the ascending thick segment, however, Na\(^+\) and Cl\(^-\) are reabsorbed in excess of water; Na\(^+\) reabsorption in this part of the nephron is directly coupled to both K\(^+\) and Cl\(^-\) reabsorption (Figure 30–4), and [Cl\(^-\)] in tubular fluid appears to be the rate-limiting factor. Active Na\(^+\) reabsorption still results from Na\(^+\)–K\(^+\)-ATPase activity on the capillary side of tubular epithelial cells.

**FIGURE 30–4** Sodium and chloride reabsorption in the thick ascending loop of Henle. All four sites on the luminal carrier protein must be occupied for transport to occur. The rate-limiting factor appears to be chloride concentration in tubular fluid.
Unlike the descending limb and the thin ascending limb of the loop of Henle, the thick parts of the ascending limb are impermeable to water. As a result, tubular fluid flowing out of the loop of Henle is hypotonic (100–200 mOsm/L) and the interstitium surrounding the loop of Henle is therefore hypertonic. A *countercurrent multiplier mechanism* is established such that both the tubular fluid and medullary interstitium become increasingly hypertonic with increasing depth into the medulla (Figure 30–5). Urea concentrations also increase within the medulla and contribute to the hypertonicity. The countercurrent mechanism includes the loop of Henle, the cortical and medullary collecting tubules, and adjacent capillaries (vasarecta).

**FIGURE 30–5** The countercurrent multiplier mechanism. This mechanism is dependent on differential permeability and transport characteristics between the descending and ascending limbs. The descending limb and the thin ascending limb are permeable to water, Na\(^+\), Cl\(^-\), and urea. The thick ascending limb is impermeable to water and urea, actively reabsorbs Na\(^+\) and Cl\(^-\), and therefore can generate an osmotic gradient. This figure depicts from “time zero,” a progressive 200-mOsm/kg gradient between the descending and ascending limbs. Note that as urine flows, the gradient remains unchanged but the osmolality progressively increases at the bottom of the loop. (Reproduced with permission from Pitts RF. *Physiology of the Kidney and Body Fluids.* 3rd ed. Philadelphia, PA: Year Book; 1974.)

The thick ascending loop of Henle is also an important site for calcium and
magnesium reabsorption, and parathyroid hormone augments calcium reabsorption at this location.

The Distal Tubule

The distal tubule receives hypotonic fluid from the loop of Henle and is normally responsible for only minor modifications of tubular fluid. In contrast to more proximal portions, the distal nephron has very tight junctions between tubular epithelial cells and is relatively impermeable to water and sodium and therefore maintains the gradients generated by the loop of Henle. Sodium reabsorption in the distal tubule normally accounts for only about 5% of the filtered sodium load. As in other parts of the nephron, the energy is derived from Na\(^+\)–K\(^+\)-ATPase activity on the capillary side, but on the luminal side Na\(^+\) is reabsorbed by an Na\(^+\)–Cl\(^-\) carrier. Sodium reabsorption in this segment is directly proportional to Na\(^+\) delivery. The distal tubule is the major site of parathyroid hormone– and vitamin D–mediated calcium reabsorption.

The latter portion of the distal tubule is referred to as the connecting segment. Although it is involved in hormone-mediated calcium reabsorption, unlike more proximal portions, it also participates in aldosterone-mediated Na\(^+\) reabsorption.

The Collecting Tubule

The collecting tubule can be divided into cortical and medullary portions, and together, they normally account for the reabsorption of 5% to 7% of the filtered sodium load.

A. Cortical Collecting Tubule

This part of the nephron consists of two cell types: (1) principal cells that primarily secrete potassium and participate in aldosterone-stimulated Na\(^+\) reabsorption, and (2) intercalated cells that are responsible for acid–base regulation. Because principal cells reabsorb Na\(^+\) via an electrogenic pump, either Cl\(^-\) must also be reabsorbed or K\(^+\) must be secreted to maintain electroneutrality. Increased intracellular [K\(^+\)] favors K\(^+\) secretion. Aldosterone enhances Na\(^+\)–K\(^+\)-ATPase activity in this part of the nephron by increasing the number of open K\(^+\) and Na\(^+\) channels in the luminal membrane. Aldosterone also enhances the H\(^+\)-secreting ATPase on the luminal border of I cells (Figure 30–6). Intercalated cells additionally have a luminal K\(^+\)–H\(^+\)-ATPase pump, which reabsorbs K\(^+\) and
secretes $H^+$, and are also capable of secreting bicarbonate ion in response to large alkaline loads.

**FIGURE 30–6** Secretion of hydrogen ions and reabsorption of bicarbonate and potassium in the cortical collecting tubule.

**B. Medullary Collecting Tubule**

The medullary collecting tubule courses down from the cortex through the hypertonic medulla before joining collecting tubules from other nephrons to form a single ureter in each kidney. This part of the collecting tubule is the principal site of action for antidiuretic hormone (ADH), also called vasopressin or arginine vasopressin (AVP). Vasopressin stimulates the expression of a water
channel protein, aquaporin-2, in the cell membrane. The permeability of the luminal membrane to water is entirely dependent on the presence of vasopressin (see Chapter 49). Dehydration increases vasopressin secretion, rendering the luminal membrane permeable to water. As a result, water is osmotically drawn out of the collecting tubule fluid passing through the medulla, resulting in production of concentrated urine (up to 1400 mOsm/L). Conversely, adequate hydration suppresses vasopressin secretion, allowing fluid in the collecting tubules to pass through the medulla relatively unchanged and to remain hypotonic (100–200 mOsm/L). This part of the nephron is responsible for acidifying urine; the hydrogen ions secreted are excreted in the form of titratable acids (phosphates) and ammonium ions (see Chapter 50).

C. Role of the Collecting Tubule in Maintaining a Hypertonic Medulla
Differences in permeability to urea in the cortical and medullary collecting tubules account for up to half the hypertonicity of the renal medulla. Cortical collecting tubules are freely permeable to urea, whereas medullary collecting tubules are normally impermeable. In the presence of vasopressin, the innermost part of the medullary collecting tubules becomes even more permeable to urea. Thus, when vasopressin is secreted, water moves out of the collecting tubules and the urea becomes highly concentrated. Urea can then diffuse out deeply into the medullary interstitium, increasing its tonicity.

The Juxtaglomerular Apparatus
This small organ within each nephron consists of a specialized segment of the afferent arteriole, containing juxtaglomerular cells within its wall, and the end of the thick, ascending cortical segment of the loop of Henle, the macula densa (Figure 30–7). Juxtaglomerular cells contain the enzyme renin and are innervated by the sympathetic nervous system. Release of renin depends on β1-adrenergic sympathetic stimulation, changes in afferent arteriolar wall pressure (see Chapter 49), and changes in chloride flow past the macula densa. Renin released into the bloodstream catalyzes the conversion of angiotensinogen, a protein synthesized by the liver, to angiotensin I. This inert decapeptide is then rapidly converted, primarily in the lungs, by angiotensin-converting enzyme (ACE) to form the octapeptide angiotensin II. Angiotensin II plays a major role in blood pressure regulation (see Chapter 15) and aldosterone secretion (see Chapter 49). Proximal renal tubular cells have ACE as well as angiotensin II
receptors. Moreover, intrarenal formation of angiotensin II enhances sodium reabsorption in proximal tubules. Extrarenal production of renin and angiotensin II also takes place in the vascular endothelium, the adrenal glands, and the brain.

![Figure 30–7 The juxtaglomerular apparatus.](image)

**The Renal Circulation**

Renal function is intimately related to renal blood flow (RBF). In fact, the kidneys are the only organs for which oxygen consumption is determined by blood flow; the reverse is true in other organs. The combined blood flow through both kidneys normally accounts for 20% to 25% of total cardiac output. Approximately 80% of RBF normally goes to cortical nephrons, and only 10% to 15% goes to juxtamedullary nephrons. The renal cortex extracts relatively little oxygen, having an oxygen tension of approximately 50 mm Hg, because the relatively high blood flow principally serves the filtration function. In contrast, the renal medulla maintains high metabolic activity because of solute reabsorption and requires low blood flow to maintain high osmotic gradients. It has an oxygen tension of approximately 15 mm Hg and is relatively vulnerable to ischemia.

Redistribution of RBF away from cortical nephrons with short loops of Henle to larger juxtamedullary nephrons with long loops occurs under conditions including sympathetic stimulation, increased levels of catecholamines and
angiotensin II, and heart failure, and this redistribution of RBF to the medulla is associated with sodium retention.

In most individuals, each kidney is supplied by a single renal artery arising from the aorta. The renal artery divides at the renal pelvis into interlobar arteries, which in turn give rise to arcuate arteries at the junction between the renal cortex and medulla (Figure 30–8). Arcuate arteries further divide into interlobular branches that eventually supply each nephron via a single afferent arteriole. Blood from each glomerular capillary tuft is drained via a single efferent arteriole and then travels alongside adjacent renal tubules in a second peritubular system of capillaries. In contrast to the glomerular capillaries, which favor filtration, peritubular capillaries are primarily “reabsorptive.” Venules draining this second capillary plexus return blood to the inferior vena cava via a single renal vein from each kidney.

FIGURE 30–8 The renal circulation. (Reproduced with permission from Leaf A, Cotran RS.)
KIDNEY BLOOD FLOW & GLOMERULAR FILTRATION

Clearance

The concept of *clearance* is frequently used in measurements of RBF and the glomerular filtration rate (GFR). The renal clearance of a substance is defined as the volume of blood that is completely cleared of that substance per unit of time (usually, per minute).

Renal Blood Flow

Renal plasma flow (RPF) is commonly measured by *p*-aminohippurate (PAH) clearance. PAH at low plasma concentrations can be assumed to be completely cleared from plasma by filtration and secretion in one passage through the kidneys. Consequently,

\[
RPF = \text{Clearance of PAH} = \left( \frac{[\text{PAH}]_U}{[\text{PAH}]_P} \right) \times \text{Urine flow}
\]

where \([\text{PAH}]_U\) is the urinary concentration of PAH and \([\text{PAH}]_P\) is the plasma PAH concentration.

If the hematocrit (measured as a decimal rather than as a percent) is known, then

\[
RBF = \frac{RPF}{(1 - \text{Hematocrit})}
\]

RPF and RBF are normally about 660 and 1200 mL/min, respectively.

Glomerular Filtration Rate

The GFR, the volume of fluid filtered from the glomerular capillaries into Bowman’s capsule per unit time, normally approximates 20% of RPF. Clearance of inulin, a fructose polysaccharide that is completely filtered but is neither secreted nor reabsorbed, is a good measure of GFR. Normal values for GFR are
approximately 120 ± 25 mL/min in men and 95 ± 20 mL/min in women. Although less accurate than measuring inulin clearance, creatinine clearance is a much more practical measurement of GFR. Creatinine clearance tends to overestimate GFR because some creatinine is normally secreted by renal tubules (see Chapter 30). Creatinine is a product of phosphocreatine breakdown in muscle. Creatinine clearance is calculated as follows:

\[
\text{Creatinine clearance} = \frac{([\text{Creatinine}]_U \times \text{Urinary flow rate})}{[\text{Creatinine}]_P}
\]

where \([\text{creatine}]_U\) is the creatinine concentration in urine and \([\text{creatinine}]_P\) is the creatinine concentration in plasma.

The ratio of GFR to RPF is called the filtration fraction (FF) and is normally 20%. GFR is dependent on the relative tones of both the afferent and efferent arterioles (discussed earlier). Afferent arteriolar dilation or efferent arteriolar vasoconstriction can increase the FF and maintain GFR, even when RPF decreases. Afferent arteriolar tone is responsible for maintaining a relatively constant GFR over a wide range of blood pressures.

**Control Mechanisms**

Regulation of RBF represents a complex interplay between intrinsic autoregulation, tubuloglomerular balance, and hormonal and neuronal influences on the kidney and on systemic blood pressure (Figure 30–9).

A. Intrinsic Regulation
Autoregulation of RBF normally occurs between mean arterial blood pressures of 80 and 180 mm Hg and is principally due to intrinsic smooth muscle response of afferent glomerular arterioles to blood pressure changes. Within these limits, RBF and GFR are kept relatively constant by afferent arteriolar vasoconstriction or vasodilation. Outside the autoregulation limits, RBF becomes pressure dependent. Glomerular filtration generally ceases when mean systemic arterial pressure is less than 40 to 50 mm Hg.

B. Tubuloglomerular Balance and Feedback

*Tubuloglomerular feedback* plays an important role in maintaining constant GFR over a wide range of perfusion pressures. Increased tubular flow tends to result in reduced GFR; conversely, decreased tubular flow tends to result in increased GFR. Although the mechanism is poorly understood, the macula densa appears to be responsible for tubuloglomerular feedback by inducing reflex changes in afferent arteriolar tone and possibly glomerular capillary permeability. Angiotensin II probably plays a permissive role in this mechanism. Local release of adenosine, which occurs in response to volume expansion, may inhibit renin release and dilate the afferent arteriole.

C. Hormonal Regulation

Decreases in afferent glomerular arteriolar pressure, increases in sympathetic nervous system activity, and decreases in distal tubule sodium load stimulate prorenin (the precursor to renin) and renin release, resulting in the subsequent formation of angiotensin II, which causes generalized arterial vasoconstriction and secondarily reduces RBF. Both afferent and efferent glomerular arterioles are constricted, but because the efferent arteriole is smaller, its resistance becomes relatively greater than that of the afferent arteriole; GFR therefore tends to be relatively preserved. Very high levels of angiotensin II constrict both arterioles and can markedly decrease GFR. Epinephrine and norepinephrine directly and preferentially increase afferent arteriolar tone but usually do not cause marked decreases in GFR because these agents also increase renin release and angiotensin II formation. Relative preservation of GFR during increased aldosterone or catecholamine secretion appears at least partly to be mediated by angiotensin-induced prostaglandin synthesis because it can be blocked by inhibitors of prostaglandin synthesis such as nonsteroidal antiinflammatory drugs (NSAIDs). Renal synthesis of vasodilating prostaglandins (PGD$_2$, PGE$_2$, and PGI$_2$) is an important protective mechanism during periods of systemic hypotension and kidney ischemia.
Atrial natriuretic protein (ANP) is released from atrial myocytes in response to atrial distention and is a direct smooth muscle dilator that antagonizes the vasoconstrictive action of norepinephrine and angiotensin II. It preferentially dilates the afferent glomerular arteriole, constricts the efferent glomerular arteriole, and relaxes mesangial cells, effectively increasing GFR (see Chapter 49). ANP also inhibits both the release of renin and angiotensin-induced secretion of aldosterone, and antagonizes the action of aldosterone in the distal and collecting tubules.

D. Neuronal and Paracrine Regulation

Sympathetic outflow from the spinal cord at the level of T4–L1 reaches the kidneys via the celiac and renal plexuses. Sympathetic nerves innervate the juxtaglomerular apparatus ($\beta_1$) as well as the renal vasculature ($\alpha_1$), and this innervation is largely responsible for sympathetic-mediated reductions in RBF (see later discussion). $\alpha_1$-Adrenergic receptors enhance sodium reabsorption in proximal tubules, whereas $\alpha_2$ receptors decrease sodium reabsorption and promote water excretion. Dopamine and fenoldopam dilate afferent and efferent arterioles via $D_1$-receptor activation. Unlike dopamine, fenoldopam is selective for the $D_1$-receptor. Although these agents are commonly administered for “renal preservation” during catecholamine infusions, there is no clinical evidence that they are effective. Activation of $D_2$-receptors on presynaptic postganglionic sympathetic neurons can also vasodilate arterioles through inhibition of norepinephrine secretion (negative feedback). Dopamine is formed extraneuronally in the proximal tubule cells from circulating L-3,4-dihydroxyphenylalanine (L-dopa) and is released into the tubule where it can bind dopaminergic receptors to reduce proximal reabsorption of Na$^+$. 

Effects of Anesthesia & Surgery on Renal Function

Acute kidney injury (AKI) is a common and underappreciated perioperative problem, occurring in 1% to 5% of all hospitalized patients, and it is a major contributor to increased hospital length of stay, markedly increasing morbidity, mortality, and cost of care. Patients may develop AKI and kidney failure secondary to intrinsic kidney disease (Table 30–2), and risk factors for AKI in the perioperative setting include preexisting renal impairment, diabetes mellitus, cardiovascular disease, hypovolemia, and use of potentially nephrotoxic medication by elderly patients. The risk index in Table 30–3 identifies
preoperative predictors of AKI following general surgery.

**TABLE 30–3** Acute kidney injury risk index for patients undergoing general surgery.\(^{1,2}\)
Clinical studies attempting to define the effects of anesthetic agents on renal function are complicated and difficult. However, several conclusions can be stated:

1. Reversible decreases in RBF, GFR, urinary flow, and sodium excretion occur during both neuraxial and general anesthesia.
2. Such changes are usually less pronounced during neuraxial anesthesia.
3. Most of these changes are indirect and are mediated by autonomic and hormonal responses to surgery and anesthesia.
4. AKI is less likely to occur when an adequate intravascular volume and a normal blood pressure are maintained.
5. There is no evidence that currently utilized vapor anesthetic agents cause AKI in humans. However, studies have reported that compound A, a breakdown product of sevoflurane, produces renal toxicity when sevoflurane is administered with reduced fresh gas flow rates in laboratory animals.

INDIRECT EFFECTS

Cardiovascular
Most inhalation and intravenous anesthetics produce concentration-dependent decreases in systemic blood pressure via cardiac depression and vasodilation. Depending on the level of sympathetic blockade, spinal or epidural anesthesia may cause a drop in systemic blood pressure secondary to decreased cardiac output as a result of decreased sympathetic tone. This leads to increased venous pooling of blood and decreased systemic vascular resistance, decreased heart rate and contractility, and decreased cardiac output. Decreases in blood pressure below the limits of autoregulation reduce RBF, GFR, urinary flow, and sodium excretion, and this adverse impact on renal function can be reversed by administration of pressor agents and intravenous fluids.

**Neurological**

Increased sympathetic tone commonly occurs in the perioperative period as a result of anxiety, pain, light anesthesia, and surgical stimulation. Heightened sympathetic activity increases renal vascular resistance and activates several hormonal systems, reducing RBF, GFR, and urine output.

**Endocrine**

Endocrine changes during sedation and general anesthesia are a component of the stress response induced by factors that may include anxiety, pain, surgical stimulation, circulatory depression, hypoxia, acidosis, and hypothermia. Increases in epinephrine and norepinephrine, renin, angiotensin II, aldosterone, ADH, adrenocorticotropic hormone, and cortisol are common. Catecholamines, ADH, and angiotensin II all reduce RBF by inducing renal arterial constriction. Aldosterone enhances sodium reabsorption in the distal tubule and collecting tubule, resulting in sodium retention and expansion of the extracellular fluid compartment. Nonosmotic release of ADH also favors water retention and may result in hyponatremia. The endocrine response to surgery and anesthesia is at least partly responsible for the transient fluid retention often seen postoperatively in many patients.

**DIRECT ANESTHETIC EFFECTS**

The direct effects of anesthetics on renal function are minor compared with the secondary effects described earlier.
**Volatile Agents**

Halothane, isoflurane, sevoflurane, and desflurane decrease renal vascular resistance. As previously noted, compound A, a breakdown product of sevoflurane, causes acute kidney injury in laboratory animals. Low fresh gas flow rates promote its accumulation in the anesthesia machine breathing circuit. No clinical study has detected kidney injury in humans as a consequence of sevoflurane anesthesia; nonetheless, some authorities recommend a fresh gas flow of at least 2 L/min with sevoflurane to minimize the risk of this theoretical problem, especially when anesthetizing laboratory rats!

**Intravenous Agents**

Opioids and propofol exhibit minor, if any, effects on the kidney when used alone. Ketamine minimally affects kidney function and may, relative to other anesthetic agents, preserve kidney function during hemorrhagic hypovolemia. Agents with α-adrenergic blocking activity may prevent catecholamine-induced redistribution of RBF. Drugs with antidopaminergic activity—such as metoclopramide, phenothiazines, and droperidol—may impair the renal response to dopamine. Inhibition of prostaglandin synthesis by NSAIDs such as ketorolac prevents renal production of vasodilatory prostaglandins in patients with high levels of angiotensin II and norepinephrine; attenuation of prostaglandin synthesis in this setting may promote AKI. ACE inhibitors block the protective effects of angiotensin II and may result in reductions in GFR during anesthesia. The effects of intravenous fluids on kidney function are reviewed in Chapter 31.

**Other Drugs**

Many medications, including radiocontrast agents, used in the perioperative period can adversely affect kidney function, especially in the setting of preexisting renal dysfunction (Table 30–4). Mechanisms of injury include vasoconstriction, direct tubular injury, drug-induced immunological and inflammatory responses, and renal microvascular or tubular obstruction. Radiocontrast agents are probably the most common cause of AKI in the acute care setting. In addition to intravenous hydration, pretreatment with N-acetylcysteine (600 mg orally every 12 h in four doses beginning prior to contrast administration) has been shown to decrease the risk of radiocontrast agent–induced AKI in patients with preexisting renal dysfunction. N-Acetylcysteine’s protective action may be due to free radical scavenging or
sulfhydryl donor reducing properties. Fenoldopam, mannitol, loop diuretics, and low-dose dopamine infusion do not help maintain renal function or confer protection against AKI, and N-acetylcysteine has not been shown to be protective in the perioperative setting except in patients who receive radiocontrast dyes.

**DIRECT SURGICAL EFFECTS**

In addition to the physiological changes associated with the neuroendocrine stress response to surgery, certain surgical procedures can significantly alter
kidney physiology. Pneumoperitoneum produced during laparoscopy creates an abdominal compartment syndrome–like state. The increase in intraabdominal pressure often produces oliguria or anuria that is proportional to insufflation pressure. Mechanisms include vena cava and renal vein compression; kidney parenchymal compression; decreased cardiac output; and increases in plasma levels of renin, aldosterone, and ADH. Abdominal compartment syndrome can also be produced by a number of comorbid problems, with similar adverse impact on kidney function via the same mechanisms (Table 30–5; see Chapters 31 and 39).

**TABLE 30–5 Risk factors for intraabdominal hypertension and abdominal compartment syndrome.**¹,²

| Diminished abdominal well compliance |  
|------------------------------------|---|
| Acute respiratory failure, especially mechanical ventilation with high mean airway pressure (ie, high positive end-expiratory pressure) |   |
| Abdominal surgery with primary fascial or tight closure |   |
| Major trauma/burns |   |
| Prone positioning or head of bed >30° |   |
| High BMI, central obesity |   |
| Abdominal wall edema |   |
| **Increased intraluminal visceral contents** |  
| Gastroparesis |   |
| Ileus |   |
| Colonic pseudo-obstruction |   |
| Bowel obstruction |   |
| **Increased abdominal cavity contents** |  
| Hemoperitoneum/pneumoperitoneum |   |
| Ascites (from any mechanism) |   |
| Space-occupying mass (ie, malignancy) |   |
| Intraabdominal abscess or other infection |   |
| Peritoneal dialysis |   |
Other surgical procedures that can impair kidney function and may also increase the risk of AKI include cardiopulmonary bypass (see Chapter 22), cross-clamping of the aorta (see Chapter 22), and dissection near the renal arteries (see Chapter 32). The potential effects of neurosurgical procedures on ADH physiology are discussed in Chapters 27 and 49.

**Diuretics**

Diuretics increase urinary output by decreasing reabsorption of Na⁺ and water. Although classified according to their mechanism of action, many diuretics have more than one such mechanism; hence this classification system is imperfect. Only major mechanisms will be reviewed here.

The majority of diuretics exert their action on the luminal cell membrane from within the renal tubules. Because nearly all diuretics are highly protein bound, relatively little of the free drug enters the tubules by filtration. Most diuretics must therefore be secreted by the proximal tubule (usually via the organic anion pump) to exert their action. Impaired delivery into the renal tubules accounts for resistance to diuretics in patients with decreased kidney function.

**OSMOTIC DIURETICS (MANNITOL)**
Osmotically active diuretics are filtered at the glomerulus and undergo limited or no reabsorption in the proximal tubule. Their presence in the proximal tubule limits passive water reabsorption that normally follows active sodium reabsorption. Although their major effect is to increase water excretion, in large doses, osmotically active diuretics also increase electrolyte excretion. The same mechanism also impairs water and solute reabsorption in the loop of Henle.

Mannitol is a six-carbon sugar that is the most commonly used osmotic diuretic. It also increases RBF in addition to its diuretic effect, which can promote washing out some of the medullary hypertonicity and thus interfere with renal concentrating ability. Mannitol activates intrarenal synthesis of vasodilating prostaglandins and may be a free radical scavenger.

**Uses**

**A. Prophylaxis Against Acute Kidney Injury in High-Risk Patients**

Many clinicians continue to administer mannitol for kidney protection and, less frequently, to convert oliguric acute kidney failure to nonoliguric kidney failure, with the goal of lowering associated morbidity and mortality. However, there is no clinical evidence that such use of mannitol provides kidney protection, lessens the severity of AKI, or lessens the morbidity or mortality associated with AKI when compared with correction of hypovolemia and preservation of adequate kidney perfusion alone. In addition, high-dose mannitol can be nephrotoxic, especially in patients with impaired kidney function.

**B. Evaluation of Acute Oliguria**

Mannitol will augment urinary output in the setting of hypovolemia but will have little effect in the presence of severe glomerular or tubular injury. The optimal initial approach to evaluation of acute oliguria is to correct hypovolemia and optimize cardiac output and kidney perfusion.

**C. Acute Reduction of Intracranial Pressure & Cerebral Edema**

See Chapter 27.

**D. Acute Reduction of Intraocular Pressure in the Perioperative Period**

See Chapter 36.
**Intravenous Dosage**

The intravenous dose for mannitol is 0.25 to 1 g/kg of ideal body weight.

**Side Effects**

Mannitol solutions are hypertonic and acutely raise plasma and extracellular osmolality. A rapid intracellular to extracellular shift of water can transiently increase intravascular volume and precipitate cardiac decompensation and pulmonary edema in patients with limited cardiac reserve. Transient hyponatremia and reductions in hemoglobin concentration are also common and represent acute hemodilution resulting from rapid movement of water out of cells; a small and transient increase in plasma potassium concentration may also be observed. It is also important to note that the initial hyponatremia does not represent hypoosmolality but reflects the presence of mannitol (see Chapter 49). If fluid and electrolyte losses are not replaced following diuresis, mannitol administration can result in hypovolemia, hypokalemia, and hypernatremia. The hypernatremia occurs because water is lost in excess of sodium. As previously noted, high-dose mannitol can be nephrotoxic, especially in patients with impaired kidney function.

**LOOP DIURETICS**

The loop diuretics include furosemide (Lasix), bumetanide (Bumex), ethacrynic acid (Edecrin), and torsemide (Demadex). All loop diuretics inhibit Na\(^+\) and Cl\(^-\) reabsorption in the thick ascending limb. Sodium reabsorption at that site requires that all four sites on the Na\(^+\)–K\(^+\)–2Cl\(^-\) luminal carrier protein be occupied. Loop diuretics compete with Cl\(^-\) for its binding site on the carrier protein (see Figure 30–4). With a maximal effect, they can promote excretion of 15% to 20% of the filtered sodium load. Both urinary concentrating and urinary diluting capacities are impaired. The large amounts of Na\(^+\) and Cl\(^-\) presented to the distal nephron overwhelm its limited reabsorptive capability. The resulting urine remains hypotonic due to rapid urinary flow rates that prevent equilibration with the hypertonic renal medulla and due to interference with the action of ADH on the collecting tubules. A marked increase in diuresis may occur when a loop diuretic is combined with a thiazide diuretic, especially metolazone (Mykrox, Zaroxolyn, Zytanix).

Loop diuretics also increase urinary calcium and magnesium excretion. Ethacrynic acid is the only loop diuretic that is not a sulfonamide derivative, and
thus may be the diuretic of choice in patients allergic to sulfonamide drugs. Torsemide may have an antihypertensive action independent of its diuretic effect.

### Uses

**A. Edematous States (Sodium Overload)**
These disorders include heart failure, cirrhosis, nephrotic syndrome, and renal insufficiency. When given intravenously, these loop diuretics can rapidly reverse cardiac and pulmonary manifestations of fluid overload.

**B. Hypertension**
Loop diuretics may be used as adjuncts to other hypotensive agents, particularly when thiazides alone are ineffective (see later discussion).

**C. Evaluation of Acute Oliguria**
The optimal initial approach to acute oliguria is to correct hypovolemia and optimize cardiac output and renal perfusion.

**D. Conversion of Oliguric Kidney Failure to Nonoliguric Failure**
As with mannitol, discussed earlier, many clinicians continue to administer loop diuretics for kidney protection and to convert oliguric acute kidney failure to nonoliguric kidney failure, despite lack of evidence that such use provides kidney protection, lessens the severity of AKI, or lessens the morbidity or mortality associated with AKI, when compared with correction of hypovolemia and preservation of adequate kidney perfusion alone.

**E. Treatment of Hypercalcemia**
See Chapter 49.

**F. Rapid Correction of Hyponatremia**
See Chapter 49.

### Intravenous Dosages
The intravenous doses are furosemide, 10 to 100 mg; bumetanide, 0.5 to 1 mg; ethacrynic acid, 50 to 100 mg; and torsemide 10 to 100 mg.
Side Effects

Increased delivery of Na\(^+\) to the distal and collecting tubules increases K\(^+\) and H\(^+\) secretion at those sites and thus produce hypokalemia and metabolic alkalosis. Marked Na\(^+\) losses will also lead to hypovolemia and prerenal azotemia; secondary hyperaldosteronism often accentuates the hypokalemia and metabolic alkalosis. Urinary calcium and magnesium loss promoted by loop diuretics may result in hypocalcemia or hypomagnesemia, or both. Hypercalciuria can promote urolithiasis. Hyperuricemia may result from increased urate reabsorption and from competitive inhibition of urate secretion in the proximal tubule. Reversible and irreversible hearing loss has been reported with loop diuretics, especially furosemide and ethacrynic acid.

THIAZIDE & THIAZIDE-LIKE DIURETICS

This group of agents includes thiazides, containing a benzothiadiazine molecular structure, and also thiazide-like drugs with similar actions but without the benzothiadiazine structure, including chlorthalidone (Thalitone), quinethazone (Hydromox), metolazone, and indapamide (Lozol). These diuretics act at the distal tubule, including the connecting segment, and inhibition of sodium reabsorption at this site impairs diluting but not concentrating ability. They compete for the Cl\(^-\) site on the luminal Na\(^+\)–Cl\(^-\) carrier protein. When given alone, thiazide and thiazide-like diuretics increase Na\(^+\) excretion to only 3% to 5% of the filtered load because of enhanced compensatory Na\(^+\) reabsorption in the collecting tubules. They also possess carbonic anhydrase–inhibiting activity in the proximal tubule, which is usually masked by sodium reabsorption in the loop of Henle and which is probably responsible for the marked diuresis often seen when they are combined with loop diuretics. In contrast to their effects on sodium excretion, thiazide and thiazide-like diuretics augment Ca\(^{2+}\) reabsorption in the distal tubule. Indapamide has some vasodilating properties and is the only thiazide or thiazide-like diuretic with significant hepatic excretion.

Uses

A. Hypertension

Thiazide and thiazide-like diuretics are often selected as first-line agents in the treatment of hypertension (see Chapter 21), and they have been shown to improve long-term outcomes in this disorder.
B. Edematous Disorders (Sodium Overload)
These drugs are used to treat mild to moderate edema and congestive heart failure related to mild to moderate sodium overload.

C. Hypercalciuria
Thiazide and thiazide-like diuretics are often used to decrease calcium excretion in patients who form calcium-containing kidney stones.

D. Nephrogenic Diabetes Insipidus
The efficacy of these agents in this disorder is based upon their ability to impair diluting capacity and increase urine osmolality (see Chapter 49).

Intravenous Dosages
These agents are only given orally.

Side Effects
Although thiazide and thiazide-like diuretics deliver less sodium to the collecting tubules than loop diuretics, the increase in sodium excretion is enough to enhance K$^+$ secretion and frequently results in hypokalemia. Enhanced H$^+$ secretion can also occur, resulting in metabolic alkalosis. Impairment of renal diluting capacity may produce hyponatremia. Hyperuricemia, hyperglycemia, hypercalcemia, and hyperlipidemia may also be seen.

POTASSIUM-SPARING DIURETICS
These are weak diuretic agents and characteristically do not increase potassium excretion. Potassium-sparing diuretics inhibit Na$^+$ reabsorption in the collecting tubules and therefore can maximally excrete only 1% to 2% of the filtered Na$^+$ load. They are usually used in conjunction with more potent diuretics for their potassium-sparing effect.

1. Aldosterone Antagonists (Spironolactone & Eplerenone)
Spironolactone (Aldactone) and eplerenone (Inspra) are direct antagonists of
collecting tubule aldosterone receptor. They inhibit aldosterone-mediated Na\(^+\) reabsorption and K\(^+\) secretion. Both agents have been shown to improve survival in patients with chronic heart failure.

**Uses**

These agents may be used as adjuvants in the treatment of refractory edematous states associated with secondary hyperaldosteronism (see Chapter 49). Spironolactone is particularly effective in patients with ascites related to advanced liver disease. Eplerenone is commonly used in the management of chronic heart failure, where it may improve outcomes.

**Intravenous Dosage**

These agents are only given orally.

**Side Effects**

These agents can result in hyperkalemia in patients with high potassium intake or renal insufficiency and in those receiving β-blockers or ACE inhibitors. Metabolic acidosis may also be seen. Eplerenone lacks spironolactone’s side effects of gynecomastia and sexual dysfunction.

2. **Noncompetitive Potassium-Sparing Diuretics**

Triamterene (Dyrenium) and amiloride (Midamor) inhibit Na\(^+\) reabsorption and K\(^+\) secretion by decreasing the number of open sodium channels in the luminal membrane of collecting tubules and are not dependent upon aldosterone activity. Amiloride may also inhibit Na\(^+\)–K\(^+\)-ATPase activity in the collecting tubule.

**Uses**

In patients with hypertension, these agents are often combined with a thiazide or similar diuretic to minimize hypokalemia produced by the other agent. They have been added to more potent loop diuretics in congestive heart failure patients with marked potassium wasting. These agents are only given orally.

**Side Effects**
Amiloride and triamterene can cause hyperkalemia and metabolic acidosis similar to that seen with spironolactone (see above). Both can also cause nausea, vomiting, and diarrhea. Amiloride is generally associated with fewer side effects, but paresthesias, depression, muscle weakness, and cramping may occasionally be seen. Triamterene on rare occasions has resulted in renal stones and is potentially nephrotoxic, particularly when combined with nonsteroidal antiinflammatory agents.

**CARBONIC ANHYDRASE INHIBITORS**

Carbonic anhydrase inhibitors such as acetazolamide (Diamox) interfere with $\text{Na}^+$ reabsorption and $\text{H}^+$ secretion in proximal tubules. They are weak diuretics because the former effect is limited by the reabsorptive capacities of more distal segments of nephrons. Nonetheless, these agents significantly interfere with $\text{H}^+$ secretion in the proximal tubule and impair $\text{HCO}_3^-$ reabsorption.

**Uses**

**A. Correction of Metabolic Alkalosis in Edematous Patients**
Carbonic anhydrase inhibitors often potentiate the effects of other diuretics.

**B. Alkalization of Urine**
Alkalization enhances urinary excretion of weakly acidic compounds such as uric acid.

**C. Reduction of Intraocular Pressure**
Inhibition of carbonic anhydrase in the ciliary processes reduces the formation of aqueous humor and, secondarily, intraocular pressure. Carbonic anhydrase inhibitors, including oral or intravenous acetazolamide, oral methazolamide (Neptazane), and ophthalmic topical brinzolamide (Azopt) and dorzolamide (Trusopt), are often used to treat glaucoma.

**Intravenous Dosage**
For acetazolamide, the intravenous dose is 250 to 500 mg.
Side Effects
Carbonic anhydrase inhibitors generally produce only a mild hyperchloremic metabolic acidosis because of an apparently limited effect on the distal nephron. Large doses of acetazolamide have been reported to cause drowsiness, paresthesias, and confusion. Alkalization of the urine can interfere with the excretion of amine drugs, such as quinidine. Acetazolamide is frequently used for prophylaxis against altitude sickness.

OTHER DRUGS WITH DIURETIC EFFECTS
These agents may increase GFR by elevating cardiac output or arterial blood pressure, thereby increasing RBF. Drugs in this category are not primarily classified as diuretics because of their other major actions. They include methylxanthines (theophylline), cardiac glycosides (digitalis), fenoldopam (Corlopam), inotropes (dopamine, dobutamine), and intravenous crystalloid and colloid infusions. Methylxanthines also appear to decrease sodium reabsorption in both the proximal and distal renal tubules.

CASE DISCUSSION

Intraoperative Oliguria
A 58-year-old woman is undergoing radical hysterectomy under general anesthesia. She was in good health prior to the diagnosis of uterine carcinoma. An indwelling urinary catheter is placed following induction of general anesthesia. Total urinary output was 60 mL for the first 2 h of surgery. After the third hour of surgery, only 5 mL of urine is noted in the drainage reservoir.

Should the anesthesia provider be concerned?
Decreases in urinary output during anesthesia are very common. Although decreases may be expected owing to the physiological effects of surgery and anesthesia, a urinary output of less than 20 mL/h in adults generally requires evaluation.

What issues should be addressed?
The following questions should be answered:

1. Is there a problem with the urinary catheter and drainage system?
2. Are hemodynamic parameters compatible with adequate renal function?
3. Could the decrease in urinary output be directly related to surgical manipulations?

_How can the urinary catheter and drainage system be evaluated intraoperatively?_

Incorrect catheter placement is not uncommon and should be suspected if there has been a total absence of urine flow since the time of catheter insertion. The catheter may be inadvertently placed and inflated in the urethra in men or the vagina in women. Catheter displacement, kinking, obstruction, or disconnection from the reservoir tubing can all present with features similar to this case, with complete or near-complete cessation of urinary flow. The diagnosis of such mechanical problems requires retracing and inspecting the path of urine (often under the surgical drapes) from the catheter to the collection reservoir. Obstruction of the catheter can be confirmed by an inability to irrigate the bladder with saline through the catheter.

_What hemodynamic parameters should be evaluated?_

Decreased urinary output during surgery is most commonly the result of hormonal and hemodynamic changes. In many instances, a decrease in intravascular volume (hypovolemia), cardiac output, or mean arterial blood pressure is responsible. Redistribution of renal blood flow from the renal cortex to the medulla may also play a role.

Intravascular volume depletion can rapidly develop when intravenous fluid replacement does not match intraoperative blood loss and insensible fluid loss. Oliguria requires careful assessment of intravascular volume to exclude hypovolemia. An increase in urinary output following an intravenous fluid bolus is highly suggestive of hypovolemia. In contrast, oliguria in patients with a history of congestive heart failure may require inotropes, vasodilators, or diuretics. Intravascular volume status is often difficult to optimize, and goal-directed hemodynamic and fluid therapy utilizing arterial pulse contour analysis (eg, LIDCO Rapid, Vigileo FloTrak), esophageal Doppler, or transesophageal echocardiography should be considered when accurate determination of hemodynamic and fluid...
volume status is critically important, particularly in patients with underlying heart, kidney, or advanced liver disease (see Chapter 5). In addition to providing more accurate assessment of the patient’s volume and hemodynamic status than that obtained with central venous pressure monitoring, these modalities avoid the risks associated with central venous access procedures and with pulmonary artery catheter placement and use.

When mean arterial blood pressure drops below the lower limit of renal autoregulation (80 mm Hg), urinary flow may become blood pressure dependent. The latter may be particularly true in patients with chronic systemic hypertension, in whom renal autoregulation has shifted to a higher range of mean arterial blood pressure. Reductions in anesthetic depth, intravenous fluid boluses, or the administration of a vasopressor or inotrope will usually increase blood pressure and urinary output in such instances.

Otherwise normal patients may exhibit decreased urinary output in spite of normal intravascular volume, cardiac output, and mean arterial blood pressure. A small dose of a loop diuretic (eg, furosemide, 5–10 mg) usually restores urinary flow in such instances but is not necessary since such therapy does not convey protection against acute kidney injury.

**How can surgical manipulations influence urinary output?**

In addition to the neuroendocrine response to surgery, mechanical factors related to the surgery itself can alter urinary output. This is particularly true during pelvic surgery, when compression of the bladder by retractors, unintentional cystotomy, and ligation or severing of one or both ureters can dramatically affect urinary output. Retractor compression combined with a head-down (Trendelenburg) position commonly impedes emptying of the bladder. Excessive pressure on the bladder will often produce hematuria. Excessive insufflation pressure during laparoscopy may result in abdominal compartment syndrome, with decreased or absent urine output, as previously described.

When mechanical problems with the urinary catheter drainage system and hemodynamic factors are excluded, a surgical explanation should be sought. The surgeon should be notified so that the position of the retractors can be checked, the ureters identified, and their path retraced in the operative area. Intravenous methylene blue or indigo carmine dyes (excreted in urine) are useful in identifying the site of an unintentional cystotomy or the end of a severed ureter. Note that the appearance of dye in the urinary drainage reservoir does not exclude unilateral ligation of one
ureter. Methylene blue and, to a much lesser extent, indigo carmine, can transiently give falsely low pulse oximeter readings (see Chapter 6). In the case of laparoscopic surgery, the surgeon should be asked to verify and to minimize insufflation pressure.

What was the outcome?
